3.8. Clustering and visualization of powder-diffraction data

C. J. Gilmore, G. Barr and W. Dong

3.8.1. Introduction

In high-throughput crystallography, crystallization experiments using robotics coupled with automatic sample changers and two-dimensional (2D) detectors can generate and measure over 1000 powder-diffraction patterns on a series of related compounds, often polymorphs or salts, in a day (Storey *et al.*, 2004). It is also possible to simultaneously measure spectroscopic data, especially Raman (Alvarez *et al.*, 2009). The analysis of these patterns poses a difficult statistical problem: a need to classify the data by putting the samples into clusters based on diffraction-pattern similarity so that unusual samples can be readily identified. At the same time, suitable visualization tools to help in the data-classification process are required; the techniques of classification and visualization go hand-in-hand. Interestingly, the techniques developed for large data sets with poor-quality data also have great value when looking at smaller data sets, and the visualization tools developed for high-throughput studies are especially useful when looking at phase transitions, mixtures *etc.*

In this chapter the methods for comparing whole patterns will be described. The mathematics of cluster analysis will then be explained, followed by a discussion of the associated visualization tools. Examples using small data sets from pharmaceuticals, inorganics and phase transitions will be given; the techniques used can be readily scaled up for handling large, high-throughput data sets. The same methods also work for spectroscopic data and the use of such information with and without powder X-ray diffraction (PXRD) data will be discussed. Finally, the use of visualization tools in quality control is demonstrated.

3.8.2. Comparing 1D diffraction patterns

Comparing 1D diffraction patterns or spectra cannot be done by simply using the peaks and their relative intensities for a number of reasons:

(1) The accurate determinations of the peak positions may be difficult, especially in cases where peak overlap occurs or there is significant peak asymmetry.
(2) The hardware and the way in which the sample is prepared can also affect the *d*-spacing (or 2θ value) that is recorded for the peak. Shoulders to main peaks and broad peaks can also be problematic.
(3) There is a subjective element to deciding how many peaks there are in the pattern, especially for weak peaks and noisy data.
(4) Weak peaks may be discarded. This can affect the quantitative analysis of mixtures if one component diffracts weakly or is present only in small amounts.
(5) Differences in sample preparation and instrumentation can lead to significant differences in the powder-diffraction patterns of near-identical samples.
(6) Preferred orientation may be present: this is a very difficult and common problem.
(7) The reduction of the pattern to point functions can also make it difficult to design effective algorithms.

In order to use the information contained within the full profile, algorithms are required that utilize each measured data point in the analysis. We use two correlation coefficients for the purpose of comparing PXRD patterns: the Pearson and the Spearman coefficients.

3.8.2.1. *Spearman's rank order coefficient*

Consider two diffraction patterns, *i* and *j*, each with *n* measured points $n((x_1, y_1), \ldots, (x_n, y_n))$. These are transformed to ranks $R(x_k)$ and $R(y_k)$. The Spearman test (Spearman, 1904) then gives a correlation coefficient (Press *et al.*, 2007),

$$R_{ij} = \frac{\sum\limits_{k=1}^{n} R(x_k)R(y_k) - n\left(\frac{n+1}{2}\right)^2}{\left(\sum\limits_{k=1}^{n} R(x_k)^2 - n\left(\frac{n+1}{2}\right)^2\right)^{1/2} \left(\sum\limits_{k=1}^{n} R(y_k)^2 - n\left(\frac{n+1}{2}\right)^2\right)^{1/2}}, \tag{3.8.1}$$

where $-1 \le R_{ij} \le 1$.

3.8.2.2. *Pearson's r coefficient*

Pearson's *r* is a parametric linear correlation coefficient widely used in crystallography. It has a similar form to Spearman's test, except that the data values themselves, and not their ranks, are used:

$$r_{ij} = \frac{\sum\limits_{k=1}^{n} (x_k - \overline{x})(y_k - \overline{y})}{\left[\sum\limits_{k=1}^{n} (x_k - \overline{x})^2 \sum\limits_{k=1}^{n} (y_k - \overline{y})^2\right]^{1/2}}, \tag{3.8.2}$$

where $\overline{x}$ and $\overline{y}$ are the means of intensities taken over the full diffraction pattern. Again, *r* can lie between −1.0 and +1.0.

Fig. 3.8.1 shows the use of the Pearson and Spearman correlation coefficients (Barr *et al.*, 2004*a*). In Fig. 3.8.1(*a*) $r = 0.93$ and $R = 0.68$. The high parametric coefficient arises from the perfect match of the two biggest peaks, but the much lower Spearman coefficient acts as a warning that there are unmatched regions in the two patterns. In Fig. 3.8.1(*b*) the situation is reversed: $r = 0.79$, whereas $R = 0.90$, and it can be seen that there is a strong measure of association with the two patterns, although there are some discrepancies in the region 15–35°. In Fig. 3.8.1(*c*) $r = 0.66$ and $R = 0.22$; in this case the Spearman test is again warning of missing match regions. Thus, the use of the two coefficients acts as a valuable balance of their respective properties when processing complete patterns. The Spearman coefficient is also robust in the statistical sense and useful in the case of preferred orientation.

3.8.2.3. *Combining the correlation coefficients*

Correlation coefficients are not additive, so it is invalid to average them directly; they need to be transformed into the Fisher *Z* value to give

Copyright © 2019 International Union of Crystallography

$$\rho_{ij} = \tanh\left[\left(\tanh^{-1} R_{ij} + \tanh^{-1} r_{ij}\right)/2\right]. \qquad (3.8.3)$$

3.8.2.4. *Full-profile qualitative pattern matching*

Before performing pattern matching, some data pre-processing may be necessary. In order not to produce artefacts, this should be minimized. Typical pre-processing activities are:

(1) The data are normalized such that the maximum peak intensity is 1.0.

(2) The patterns need to be interpolated if necessary to have common increments in 2θ. High-order polynomials using Neville's algorithm can be used for this (Press *et al.*, 2007).

(3) If backgrounds are large they should be removed. High-throughput data are often very noisy because of low counting times and the sample itself. If this is the case, smoothing of the data can be carried out. The SURE (Stein's Unbiased Risk Estimate) thresholding procedure (Donoho & Johnstone, 1995; Ogden, 1997) employing wavelets is ideal for this task since it does not introduce potentially damaging artefacts, for example ringing around peaks (Barr *et al.,* 2004*a*; Smrčok *et al.*, 1999).

After pre-processing, which needs to be carried out in an identical way for each sample, the following steps are carried out:

(1) The intersecting 2θ range of the two data sets is calculated, and each of the pattern correlation coefficients is calculated using only this region.

(2) A minimum intensity is set, below which profile data are set to zero. This reduces the contribution of background noise to the matching process without reducing the discriminating power of the method. We usually set this to $0.1I_{\max}$ as a default, where $I_{\max}$ is the maximum measured intensity.

(3) The Pearson correlation coefficient is calculated.

(4) The Spearman R is computed in the same way.

(5) An overall ρ value is calculated using (3.8.3).

(6) A shift in 2θ values between patterns is often observed, arising from equipment settings and data-collection protocols. Three possible simple corrections are

$$\Delta(2\theta) = a_0 + a_1 \cos\theta, \qquad (3.8.4)$$

which corrects for the zero-point error *via* the a_0 term and, *via* the $a_1 \cos\theta$ term, for varying sample heights in reflection mode, or

$$\Delta(2\theta) = a_0 + a_1 \sin\theta, \qquad (3.8.5)$$

which corrects for transparency errors, for example, and

$$\Delta(2\theta) = a_0 + a_1 \sin 2\theta, \qquad (3.8.6)$$

which provides transparency coupled with thick specimen error corrections, where a_0 and a_1 are constants that can be determined by shifting patterns to maximize their overlap as measured by ρ. It is difficult to obtain suitable expressions for the derivatives $\partial a_0/\partial\rho_{ij}$ and $\partial a_1/\partial\rho_{ij}$ for use in the optimization, so we use the downhill simplex method (Nelder & Mead, 1965), which does not require their calculation.

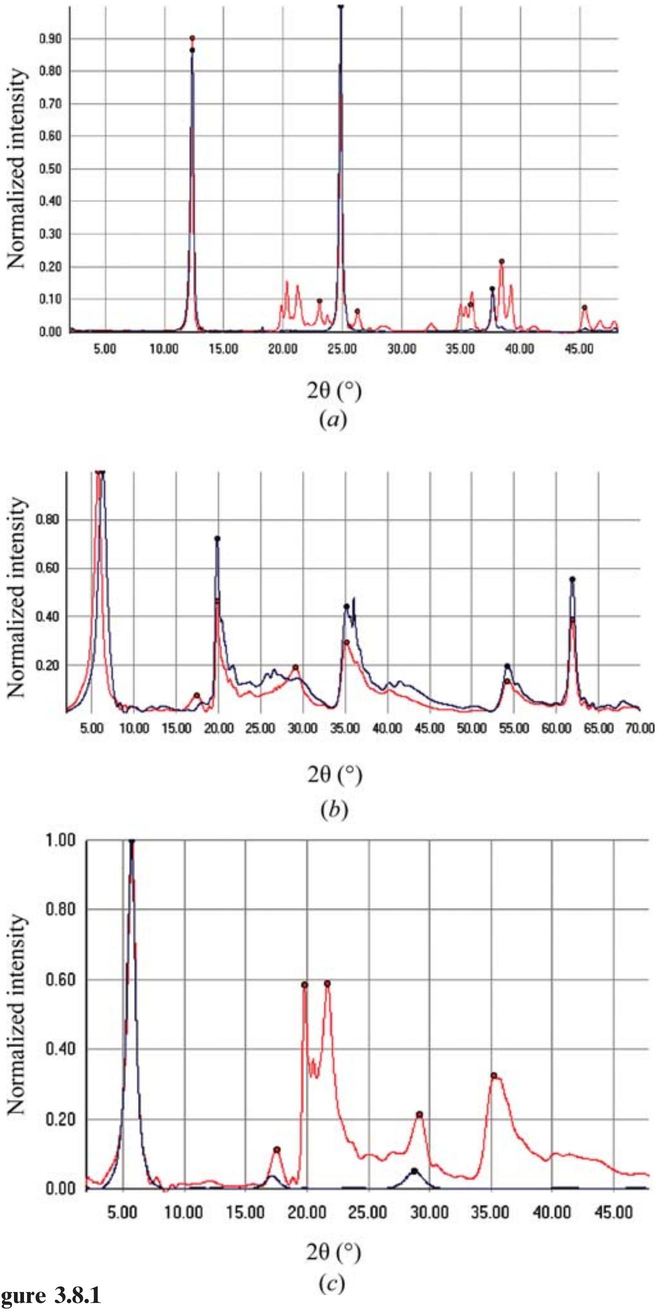

Figure 3.8.1
The use of the Pearson (r) and Spearman (R) correlation coefficients to quantitatively match powder patterns: (*a*) $r = 0.93$, $R = 0.68$; (*b*) $r = 0.79$, $R = 0.90$; (*c*) $r = 0.66$, $R = 0.22$.

3.8.2.5. *Generation of the correlation and distance matrices*

Using equation (3.8.3), a correlation matrix is generated in which a set of n patterns is matched with every other to give a symmetric ($n \times n$) correlation matrix $\boldsymbol{\rho}$ with unit diagonal. The matrix $\boldsymbol{\rho}$ can be converted to a Euclidean distance matrix, $\mathbf{d}$, of the same dimensions *via*

$$\mathbf{d} = 0.5(1.0 - \boldsymbol{\rho}) \qquad (3.8.7)$$

or a distance-squared matrix,

$$\mathbf{D} = 0.25(1 - \boldsymbol{\rho})^2 \qquad (3.8.8)$$

for each entry i, j in $\mathbf{d}$, $0.0 \le d_{ij} \le 1.0$. A correlation coefficient of 1.0 translates to a distance of 0.0, a coefficient of −1.0 to 1.0, and zero to 0.5. There are other methods of generating a distance matrix from $\boldsymbol{\rho}$ (see, for example, Gordon, 1981, 1999), but we have found this to be both simple and as effective as any other.

For other purposes a dissimilarity matrix $\mathbf{s}$ is also needed, whose elements are defined *via*

$$s_{ij} = 1 - d_{ij}/d^{\max}, \qquad (3.8.9)$$

where $d^{\max}$ is the maximum distance in matrix $\mathbf{d}$. A dissimilarity matrix, $\boldsymbol{\delta}$, is also generated with elements

$$\delta_{ij} = d_{ij}/d_{ij}^{\max}. \qquad (3.8.10)$$

Table 3.8.1
Six commonly used clustering methods

For each method, the coefficients α_i, β and γ in equation (3.8.11) are given.

Method	α_i	β	γ
Single link	$\frac{1}{2}$	0	$-\frac{1}{2}$
Complete link	$\frac{1}{2}$	0	$\frac{1}{2}$
Average link	$n_i/(n_i + n_j)$	0	0
Weighted-average link	$\frac{1}{2}$	0	0
Centroid	$n_i/(n_i + n_j)$	$-n_in_j/(n_i + n_j)^2$	0
Sum of squares	$(n_i + n_k)/(n_i + n_j + n_k)$	$-n_k/(n_i + n_j + n_k)$	0

In some cases it can be advantageous to use $I^{1/2}$ in the distance-matrix generation; this can enhance the sensitivity of the clustering to weak peaks (Butler *et al.*, 2019).

3.8.3. Cluster analysis

Cluster analysis uses **d** (or **s**, or $\boldsymbol{\delta}$) to partition the patterns into groups based on the similarity of their diffraction profiles. Associated with cluster are a number of important ancillary techniques all of which will be discussed here. A flowchart of these methods is shown in Fig. 3.8.4.

3.8.3.1. *Dendrograms*

Using **d** and **s**, agglomerative, hierarchical cluster analysis is now carried out, in which the patterns are put into clusters as defined by their distances from each other. [Gordon (1981, 1999) and Everitt *et al.* (2001) provide excellent and detailed introductions to the subject. Note that the two editions of Gordon's monograph are quite distinct and complementary.] The method begins with a situation in which each pattern is considered to be in a separate cluster. It then searches for the two patterns with the shortest distance between then, and joins them into a single cluster. This continues in a stepwise fashion until all the patterns form a single cluster. When two clusters (C_i and C_j) are merged, there is the problem of defining the distance between the newly formed cluster $C_i \cup C_j$ and any other cluster C_k. There are a number of different ways of doing this, and each one gives rise to a different clustering of the patterns, although often the difference can be quite small. A general algorithm has been proposed by Lance & Williams (1967), and is summarized in a simplified form by Gordon (1981). The distance from the new cluster formed by merging C_i and C_j to any other cluster C_k is given by

$$\begin{aligned} d(C_i \cup C_j,\ C_k) &= \alpha_i d(C_i,\ C_k) + \alpha_j d(C_j,\ C_k) + \beta d(C_i,\ C_j) \\ &\quad + \gamma\left|d(C_i,\ C_k) - d(C_j,\ C_k)\right|. \end{aligned} \tag{3.8.11}$$

There are many possible clustering methods. Table 3.8.1 defines six commonly used clustering methods, defined in terms of the parameters α, β and γ. All these methods can be used with powder data; in general, the group-average-link or single-link formalism is the most effective, although differences between the methods are often slight.

The results of cluster analysis are usually displayed as a dendrogram, a typical example of which is shown in Fig. 3.8.6(a), where a set of 13 powder patterns is analysed using the centroid method. Each pattern begins at the bottom of the plot as a separate cluster, and these amalgamate in stepwise fashion linked by horizontal tie bars. The height of the tie bar represents a similarity measure as measured by the relevant distance. As an indication of the differences that can be expected in the various algorithms used for dendrogram generation, Fig. 3.8.6(e) shows the same data analysed using the single-link method: the resulting clustering is slightly different: the similarity measures are larger, and, in consequence, the tie bars are higher on the graph. [For further examples see Barr *et al.* (2004b,c) and Barr, Dong, Gilmore & Faber (2004).]

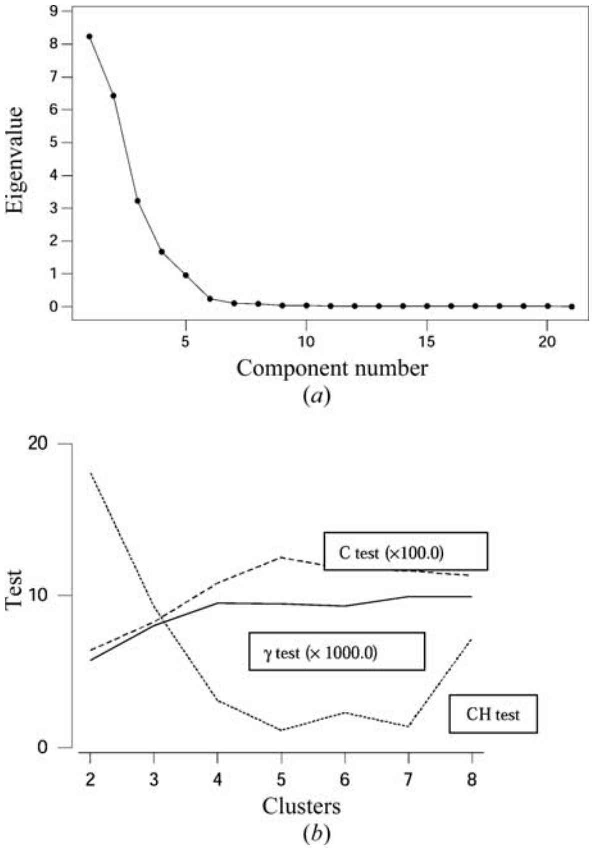

Figure 3.8.2
Four different methods of estimating the number of clusters present in a set of 23 powder patterns for the drug doxazosin. A total of five polymorphs are present, as well as two mixtures of these polymorphs. (a) A scree plot from the eigenvalue analysis of the correlation matrix; (b) the use of the C test (the coefficients have been multiplied by 100.0), which gives an estimate of five clusters using its local maximum. The γ test estimates that there are seven clusters and the CH test has a local maximum at seven clusters. Numerical details are given in Table 3.8.2.

3.8.3.2. *Estimating the number of clusters*

An estimate of the number of clusters present in the data set is needed. In terms of the dendrogram, this is equivalent to 'cutting the dendrogram' *i.e.* the placement of a horizontal line across it such that all the clusters as defined by tie lines above this line remain independent and unlinked. The estimation of the number of clusters is an unsolved problem in classification methods. It is easy to see why: the problem depends on how similar the patterns need to be in order to be classed as the same, and how much variability is allowed within a cluster. We use two approaches: (a) eigenvalue analysis of matrices $\boldsymbol{\rho}$ and **A**, and (b) those based on cluster analysis.

Eigenvalue analysis is a well used technique: the eigenvalues of the relevant matrix are sorted in descending order and when a fixed percentage (typically 95%) of the data variability has been accounted for, the number of eigenvalues is selected. This is shown graphically *via* a scree plot, an example of which is shown in Fig. 3.8.2.

We carry out eigenvalue analysis on the following:

(1) Matrix $\boldsymbol{\rho}$.

(2) Matrix **A**, as described in Section 3.8.3.3.

(3) A transformed form of $\boldsymbol{\rho}$ in which $\boldsymbol{\rho}$ is standardized to give $\boldsymbol{\rho}_s$ in which the rows and columns have zero mean and unit variance. The matrix $\boldsymbol{\rho}_s\boldsymbol{\rho}_s^T$ is then computed and subjected to eigenanalysis. It tends to give a lower estimate of cluster numbers than (1).

The most detailed study on cluster counting is that of Milligan & Cooper (1985), and is summarized by Gordon (1999). From this we have selected three tests that seem to operate effectively with powder data:

(4) The Calinški & Harabasz (1974) (CH) test:

$$\mathrm{CH}(c) = \left[B/(c-1)\right]/\left[W/(n-c)\right]. \tag{3.8.12}$$

A centroid is defined for each cluster. W denotes the total within-cluster sum of squared distances about the cluster centroids, and B is the total between-cluster sum of squared distances. Parameter c is the number of clusters chosen to maximize CH.

(5) A variant of Goodman & Kruskal's (1954) γ test, as described by Gordon (1999). The dissimilarity matrix is used. A comparison is made between all the within-cluster dissimilarities and all the between-cluster dissimilarities. Such a comparison is marked as concordant if the within-cluster dissimilarity is less than the between-cluster dissimilarity, and discrepant otherwise. Equalities, which are unusual, are disregarded. If S_+ is the number of concordant and S_- the number of discrepant comparisons, then

$$\gamma(c) = \left(S_+ - S_-\right)/\left(S_+ + S_-\right). \tag{3.8.13}$$

A maximum in γ is sought by an appropriate choice of cluster numbers.

(6) The C test (Milligan & Cooper, 1985). This chooses the value of c that minimizes

$$\mathrm{C}(c) = \left[W(c) - W_{\min}\right]/(W_{\max} - W_{\min}). \tag{3.8.14}$$

$W(c)$ is the sum of all the within-cluster dissimilarities. If the partition has a total of r such dissimilarities, then $W_{\min}$ is the sum of the r smallest dissimilarities and $W_{\max}$ is the sum of the r largest.

The results of tests (4)–(6) depend on the clustering method being used. To reduce the bias towards a given dendrogram method, these tests are carried out on four different clustering methods: the single-link, the group-average, the sum-of-squares and the complete-link methods. Thus there are 12 semi-independent estimates of the number of clusters from clustering methods, and three from eigenanalysis, making 15 in all.

A composite algorithm is used to combine these estimates. The maximum and minimum values of the number of clusters ($c_{\max}$ and $c_{\min}$, respectively) given by the eigenanalysis results [(1)–(3) above] define the primary search range; tests (4)–(6) are then used in the range $\min(c_{\max} + 3, n) \leq c \leq \max(c_{\min} - 3, 0)$ to find local maxima or minima as appropriate. The results are averaged, any outliers are removed, and a weighted mean value is taken of the remaining indicators, then this is used as the final estimate of the number of clusters. Confidence levels for c are also defined by the estimates of the maximum and minimum cluster numbers after any outliers have been removed.

A typical set of results for the PXRD data from 23 powder patterns for doxazosin (an anti-hypertension drug) in which five polymorphs are present, as well as two mixtures of polymorphs, is shown in Fig. 3.8.2(a) and (b) (see also Table 3.8.2). The scree plot arising from the eigenanalysis of the correlation matrix indicates that 95% of the variability can be accounted for by five components, and this is shown in Fig. 3.8.2(a). Eigenvalues from other matrices indicate that four clusters are appropriate. A search for local optima in the CH, γ and C tests is then initiated in the range 2–8 possible clusters. Four different clustering methods are tried, and the results indicate a range of 4–7 clusters. There are no outliers, and the final weighted mean value of 5 is calculated. As Fig. 3.8.2(b) shows, the optimum points for the C and γ tests are often quite weakly defined (Barr *et al.*, 2004*b*).

Table 3.8.2

Estimate of the number of clusters for the 23 sample data set for doxazosin

There are five polymorphs present, plus two mixtures of these polymorphs. The maximum estimate is 7; the minimum estimate is 4; the combined weighted estimate of the number of clusters is 6, and the median value is 5. The dendrogram cut level is set to give 5 clusters, and the lower and upper confidence limits are 4 and 7, respectively.

Method	No. of clusters

C statistic using complete linkage	—

3.8.3.3. *Metric multidimensional scaling*

This is, in its essentials, the particle-in-a-box problem. Each powder pattern is represented as a single sphere, and these spheres are placed in a cubic box of unit dimensions such that the positions of the spheres reproduce as closely as possible the distance matrix, **d**, generated from correlating the patterns. The spheres have an arbitrary orientation in the box.

To do this, the $(n \times n)$ distance matrix **d** is used in conjunction with metric multidimensional scaling (MMDS) to define a set of p underlying dimensions that yield a Euclidean distance matrix, $\mathbf{d}^{\mathrm{calc}}$, whose elements are equivalent to or closely approximate the elements of **d**.

The method works as follows (Cox & Cox, 2000; Gower, 1966; Gower & Dijksterhuis, 2004).

The matrix **d** has zero diagonal elements, and so is not positive semidefinite. A positive definite matrix, $\mathbf{A}(n \times n)$ can be constructed, however, by computing

$$\mathbf{A} = -\frac{1}{2}\left[\mathbf{I}_n - \frac{1}{n}\mathbf{i}_n\mathbf{i}_n'\right]\mathbf{D}\left[\mathbf{I}_n - \frac{1}{n}\mathbf{i}_n\mathbf{i}_n'\right], \tag{3.8.15}$$

where $\mathbf{I}_n$ is an $(n \times n)$ identity matrix, $\mathbf{i}_n$ is an $(n \times 1)$ vector of unities and **D** is defined in equation (3.8.8). The matrix $[\mathbf{I}_n - (1/n)\mathbf{i}_n\mathbf{i}_n']$ is called a centring matrix, since **A** has been derived from **D** by centring the rows and columns.

The eigenvectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$ and the corresponding eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_n$ are then obtained. A total of p eigenvalues of **A** are positive and the remaining $(n - p)$ will be zero. For the p

non-zero eigenvalues a set of coordinates can be defined *via* the matrix $\mathbf{X}(n \times p)$,

$$\mathbf{X} = \mathbf{V}\Lambda^{1/2}, \tag{3.8.16}$$

where $\boldsymbol{\Lambda}$ is the vector of eigenvalues.

If $p = 3$, then we are working in three dimensions, and the $\mathbf{X}(n \times 3)$ matrix can be used to plot each pattern as a single point in a 3D graph. This assumes that the dimensionality of the problem can be reduced in this way while still retaining the essential features of the data. As a check, a distance matrix $\mathbf{d}^{\rm calc}$ can be calculated from $\mathbf{X}(n \times 3)$ and correlated with the observed matrix $\mathbf{d}$ using both the Pearson and Spearman correlation coefficients. In general the MMDS method works well, and correlation coefficients greater than 0.95 are common. For large data sets this can reduce to ~0.7, which is still sufficiently high to suggest the viability of the procedure. Parallel coordinates based on the MMDS analysis can also be used, and this is discussed in Sections 3.8.4.2.1 and 3.8.4.2.2.

There are occasions in which the underlying dimensionality of the data is 1 or 2, and in these circumstances the data project onto a plane or a line in an obvious way without any problems.

An example of an MMDS plot is shown in Fig. 3.8.6(*b*), which is linked to the dendrogram in Fig. 3.8.6(*a*).

3.8.3.4. *Principal-component analysis*

It is also possible to carry out principal-component analysis (PCA) on the correlation matrix. The eigenvalues of the correlation matrix can be used to estimate the number of clusters present *via* a scree plot, as shown in Fig. 3.8.2(*a*), and the eigenvectors can be used to generate a score plot, which is an $\mathbf{X}(n \times 3)$ matrix and can be used as a visualization tool in exactly the same way as the MMDS method to indicate which patterns belong to which class. Score plots traditionally use two components with the data thus projected on to a plane; we use 3D plots in which three components are represented. In general, we find that the MMDS representation of the data is nearly always superior to the PCA analysis for powder and spectroscopic data.

3.8.3.5. *Choice of clustering method*

It is possible to use the MMDS plot (or, alternatively, PCA score plots) to assist in the choice of clustering method, since the two methods operate semi-independently. The philosophy here is to choose a technique that results in the tightest, most isolated clusters as follows:

1. The MMDS formalism is used to derive a set of three-dimensional coordinates stored in matrix $\mathbf{X}(n \times 3)$.
2. The number of clusters, c, is estimated as described in Section 3.8.3.2.
3. Each of six dendrogram methods (see Table 3.8.1) is employed in turn, stopping when c clusters have been generated. Each entry in $\mathbf{X}$ can now be assigned to a cluster.
4. A sphere is drawn around each point in $\mathbf{X}$ and the average between-cluster overlap of the spheres is calculated for each of the N clusters C_1 to C_N. If the total number of overlaps is m, this can be written as

$$S = \sum_{i=1}^{n} \sum_{\substack{j=1,n \\ j\neq i}}^{n} \left(\int_V s_{i\in C_i} s_{j\in C_j} \,{\rm d}s \right) \Big/ m. \tag{3.8.17}$$

If the clusters are well defined then S should be a minimum. Conversely, poorly defined clusters will tend to have large values of S. In the algorithm used in *PolySNAP* (Barr, Dong & Gilmore, 2009) and *DIFFRAC.EVA* (Bruker, 2018), the sphere size depends on the number of diffraction patterns.

5. The tightness of each cluster is also estimated by computing the mean within-cluster distance. This should also be a minimum for well defined, tight clusters.
6. The mean within-cluster distance from the centroid of the cluster can also be computed, which should also be a minimum.
7. Steps (4)–(6) are repeated using coordinates derived from PCA 3D score plots.
8. Tests (4)–(7) are combined in a weighted, suitably scaled mean to give an overall figure of merit (FOM); the minimum is used to select which dendrogram method to use (Barr *et al.*, 2004*b*).

3.8.3.6. *The most representative sample*

Similar techniques can be used to identify the most representative sample in a cluster. This is defined as the sample that has the minimum mean distance from every other sample in the clusters, *i.e.* for cluster J containing m patterns, the most representative sample, i, is defined as that which gives

$$\min\left(\sum_{\substack{j=1 \\ i,j\in J}}^{m} d(i,j)/m \right). \tag{3.8.18}$$

The most representative sample is useful in visualization and can, with care, be used to create a database of known phases (Barr *et al.*, 2004*b*).

3.8.3.7. *Amorphous samples*

Amorphous samples are an inevitable consequence of high-throughput experiments, and need to be handled correctly if they are not to lead to erroneous indications of clustering. To identify amorphous samples the total background for each pattern is estimated and its intensity integrated; the integrated intensity of the non-background signal is then calculated. If the ratio falls below a preset limit (usually 5%, but this may vary with the type of samples under study) the sample is treated as amorphous. The distance matrix is then modified so that each amorphous sample is given a distance and dissimilarity of 1.0 from every other sample, and a correlation coefficient of zero. This automatically excludes the samples from the clustering until the last amalgamation steps, and also limits their effect on the estimation of the number of clusters (Barr *et al.*, 2004*b*). Of course, the question of amorphous samples is not a binary (yes/no) one: there are usually varying degrees of amorphous content, which further complicates matters.

3.8.4. Data visualization

3.8.4.1. *Primary data visualization*

It is important when dealing with large data sets to have suitable visualization tools. These tools are also a valuable resource for exploring smaller data sets. This methodology provides four primary aids:

1. A pie chart is produced for each sample, corresponding to the sample wells used in the data-collection process, in which each well is given a colour as defined by the dendrogram. If mixtures of known phases are detected, the pie charts give the relative proportions of the pure samples as estimated by quantitative analysis (see Section 3.8.7).

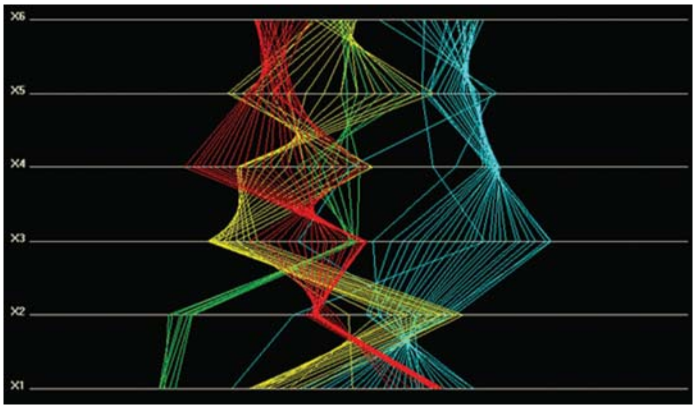

Figure 3.8.3
Example of a parallel-coordinates plot in six dimensions, with axes labeled X1, X2, . . . , X6, for a set of 80 organic PXRD samples partitioned into four clusters. The plot shows that the clustering looks realistic and that it is maintained when the data are examined in six dimensions.

(2) The dendrogram gives the clusters, the degree of association within the clusters and the differential between a given cluster and its neighbours. Different colours are used to distinguish each cluster. The cut line is also drawn along with the associated confidence levels. The dendrogram is the primary visualization tool.

(3) The MMDS method reproduces the data as a 3D plot in which each point represents a single powder pattern. The colour for each point is taken from the dendrogram. The most representative sample for each cluster is marked with a cross.

(4) Similarly, the eigenvalues from principal-component analysis can be used to generate a 3D score plot in which each point also represents a powder pattern. Just as in the MMDS formalism, the colour for each point is taken from the dendrogram, and the most representative sample is marked with a cross.

These aids give graphical views of the data that are semi-independent and thus can be used to check for consistency and discrepancies in the clustering. They are also interactive. No one method is optimal, and a combination of mathematical and visualization techniques is required, techniques that often need tuning for each individual application (Barr, Cunningham *et al.*, 2009; Barr, Dong & Gilmore, 2009).

3.8.4.2. *Secondary visualization using parallel coordinates, the grand tour and minimum spanning trees*

In the MMDS and PCA methods $p = 3$ [equation (3.8.16)] to work in three dimensions; the **X** matrix can then be used to plot each pattern as a single point in a 3D graph. However, this has reduced the dimensionality of the data to three, and the question arises as to the validity of this: are three dimensions sufficient? The use of parallel-coordinates plots coupled with the grand tour can assist here as well as giving us an alternative view of the data.

3.8.4.2.1. *Parallel-coordinates plots*

A parallel-coordinates plot is a graphical data-analysis technique for plotting multivariate data. Usually orthogonal axes are used when doing this, but in parallel-coordinates plots orthogonality is abandoned and replaced with a set of N equidistant parallel axes, one for each variable and labelled X1, X2, X3, . . . , XN (Inselberg, 1985, 2009; Wegman, 1990). Each data point is plotted on each axis and the points are joined *via* a line connecting each data point. The data now become a set of lines. The lines are given the colours of the cluster to which they belong as defined by the current dendrogram. A parallel-coordinates display can be interpreted as a generalization of a two-dimensional scatterplot, and it allows the display of an arbitrary number of dimensions. The method can also be used to validate the clustering itself without using dendrograms. Using this technique it is possible to determine whether the clustering shown by the MMDS (or PCA) plot in three dimensions continues in higher dimensions.

Fig. 3.8.3 shows a typical example for a set of 80 organic samples partitioned into four clusters (Barr, Dong & Gilmore, 2009). The plot shows that the clustering looks realistic when

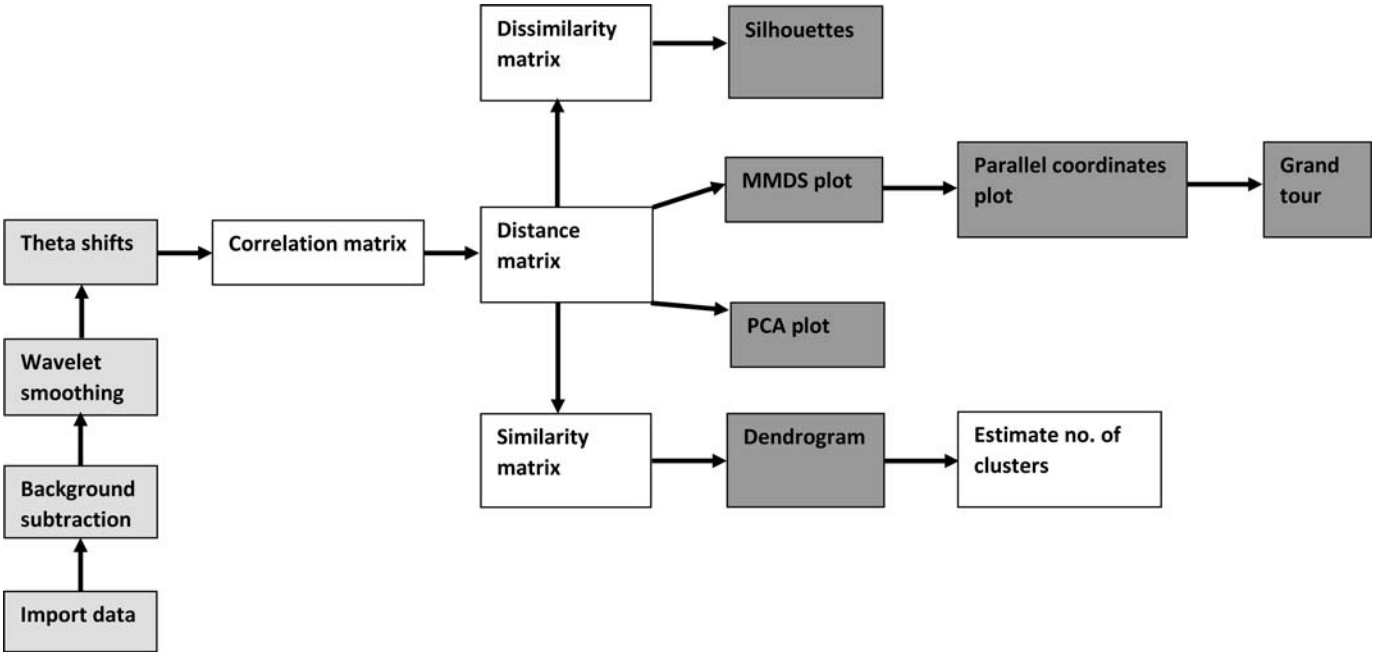

Figure 3.8.4
Flowchart for the cluster-analysis and data-visualization procedure described in this chapter. The light grey boxes denote data-visualization elements and the dark grey objects are optional data pre-processing operations.

viewed in this way and that it is maintained when the data are examined in six dimensions.

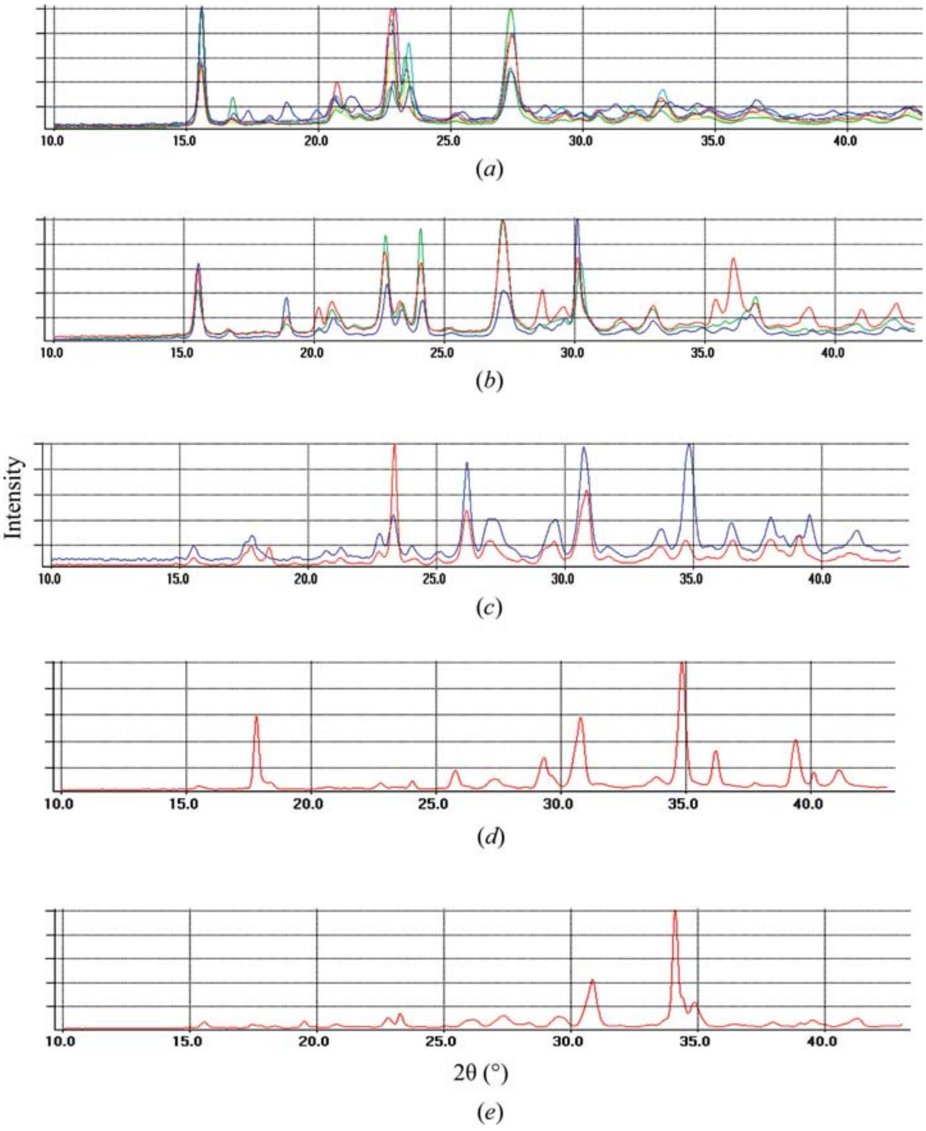

Figure 3.8.5

Powder patterns for 13 commercial aspirin samples partitioned into five sets. The patterns are in highly correlated sets: (*a*) comprises patterns 1, 3, 5, 6, 9 and 12; (*b*) comprises patterns 10, 11 and 13; (*c*) contains patterns 2 and 4; (*d*) contains pattern 7 and (*e*) contains pattern 8.

3.8.4.2.2. *The grand tour*

The grand tour is a method of animating the parallel-coordinates plot to examine it from all possible viewpoints. Consider a 3D data plot using orthogonal axes: a grand tour takes 2D sections through these data and displays them in parallel-coordinates plots in a way that explores the entire space in a continuous way. The former is important, because the data can be seen from all points of view, and the latter allows the user the follow the data without abrupt discontinuities. This concept was devised by Asimov (1985) and further developed by Wegman (1990). In more than three dimensions it becomes a generalized rotation of all the coordinate axes. A *d*-dimensional tour is a continuous geometric transformation of a *d*-dimensional coordinate system such that all possible orientations of the coordinate axes are eventually achieved. The algorithm for generating a smooth and complete view of the data is described by Asimov (1985).

To do this, the restriction of $p = 3$ in the MMDS calculation is relaxed to 6, so that there is now a 6D data set with six orthogonal axes. The choice of six is somewhat arbitrary – more can be used, but six is sufficient to see whether the clustering is maintained without generating unduly complex plots and requiring extensive computing resources. The data are plotted as a parallel-coordinates plot. The grand-tour method is then applied by a continuous geometric transformation of the 6D coordinate system such that all possible orientations of the axes are achieved. Each orientation is reproduced as a parallel-coordinates plot using six axes.

Figs. 3.8.9(*j*) and (*k*) show an example from the clustering of the 13 aspirin samples using PXRD data. Fig. 3.8.9(*j*) shows the default parallel-coordinates plot. Fig. 3.8.9(*k*) shows alternative views of the data taken from the grand tour. In Fig. 3.8.9(*j*) there appears to be considerable overlap between clusters in the 4th, 5th and 6th dimensions (X4, X5 and X6), but the alternative view given in Fig. 3.8.9(*k*) show that the clustering is actually well defined in all six dimensions (Barr, Dong & Gilmore, 2009).

3.8.4.2.3. *Powder data as a tree: the minimum spanning trees*

The minimum spanning tree (MST) displays the MMDS plot as a tree whose points are the data from the MMDS calculation (in three dimensions) and whose weights are the distances between these points. The minimum-spanning-tree problem is that of joining the points with a minimum total edge weight. (As an example, airlines use minimum spanning trees to work out their basic route systems: the best set of routes taking into account airport hubs, passenger numbers, fuel costs *etc.* is the minimum spanning tree.) Because a tree is used, each point is only allowed a maximum of three connections to other points.

To do this Kruskal's (1956) algorithm can be used, in which the lowest weight edge is always added to see if it builds a spanning tree; if so, it is added or otherwise discarded. This process continues until the tree is constructed. An example is shown in Figs. 3.8.7 for the 13-sample aspirin data. A complete tree for this data set using three dimensions and the MMDS-derived coordinates is shown in Fig. 3.8.7(*a*). This has 12 links between the 13 data points. Reducing the number of links to 10 gives Fig. 3.8.7(*b*).

3.8.5. Further validating and visualizing clusters: silhouettes and fuzzy clustering

Other techniques exist to validate the clusters, and these are discussed here.

3.8.5.1. *Silhouettes*

Silhouettes (Rousseeuw, 1987; Kaufman & Rousseeuw, 1990) are a property of every member of a cluster and define a coef-

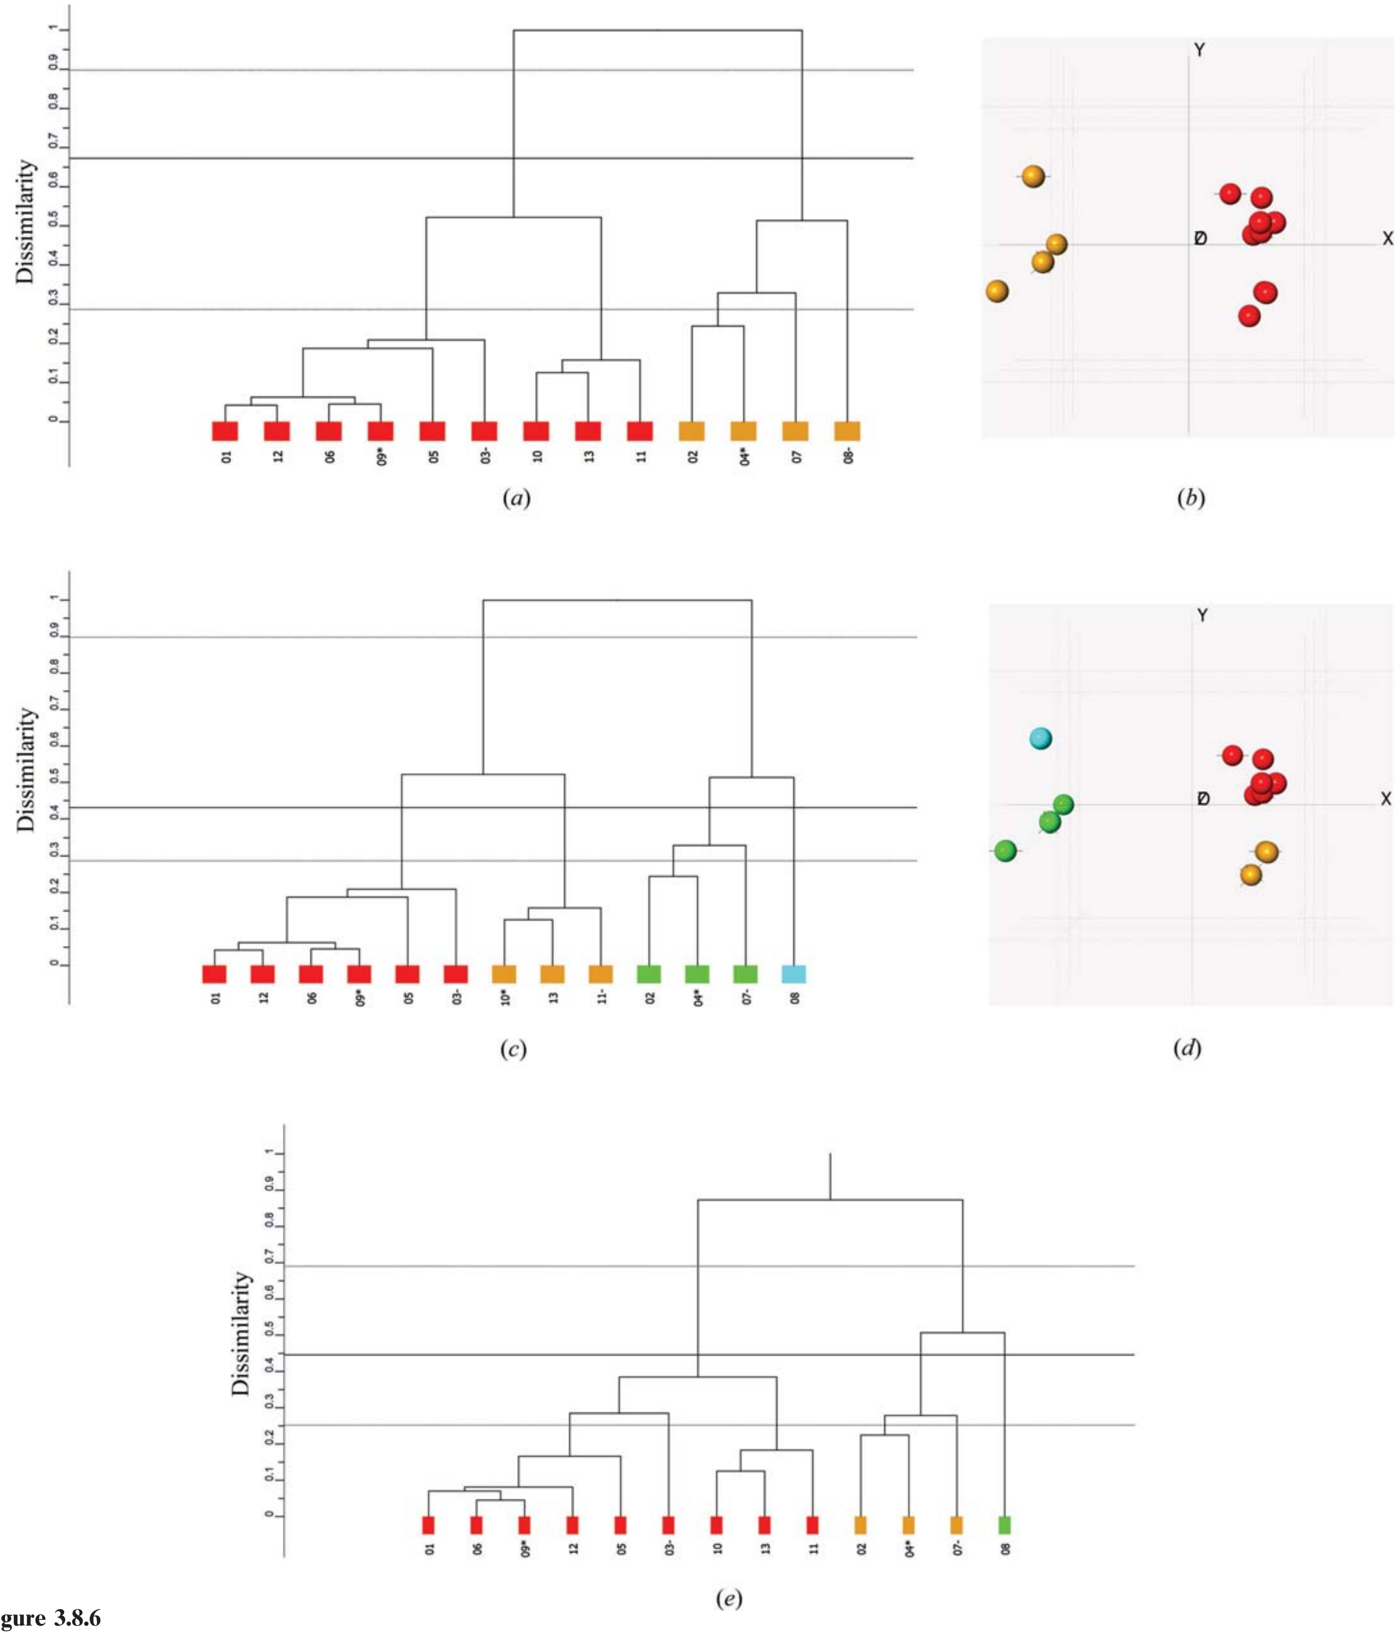

Figure 3.8.6
(*a*) The initial default dendrogram using the centroid clustering method on 13 PXRD patterns from 13 commercial aspirin samples. (*b*) The corresponding MMDS plot. It can be seen that both clusters have a natural break in them and should be partitioned into two clusters. (*c*) The dendrogram cut line is reduced. (*d*) The corresponding MMDS plot. The red cluster is now partitioned into two; the remaining patterns are a light-blue singleton and a green triplet cluster. (*e*) The default dendrogram using the single-link method.

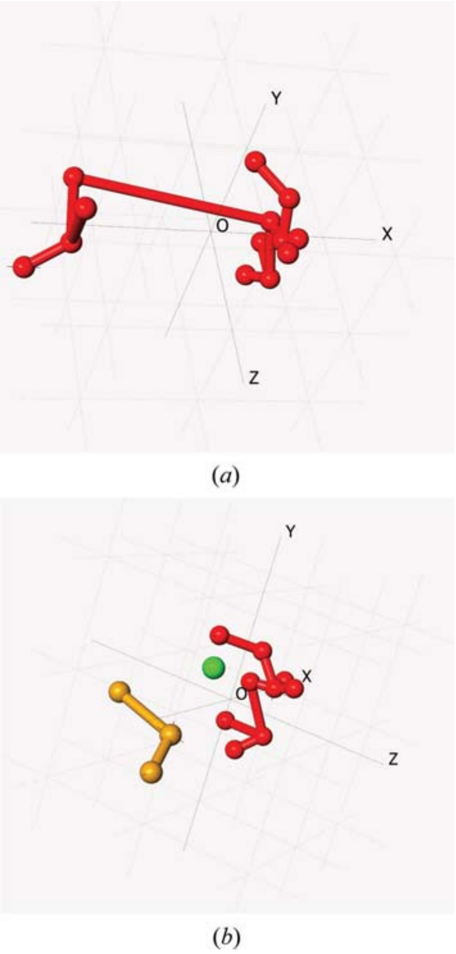
ficient of cluster membership. To compute them, the dissimilarity matrix, $\boldsymbol{\delta}$, is used. If the pattern i belongs to cluster C_r which contains n_r patterns, we define

$$a_i = \sum_{\substack{j\in C_r\\ j\neq i}} \delta_{ij}/(n_r - 1). \tag{3.8.19}$$

This defines the average dissimilarity of pattern i to all the other patterns in cluster C_r. Further define

$$b_i = \min_{s\neq r}\left\{\sum_{j\in C_s} \delta_{ij}/n_s\right\}. \tag{3.8.20}$$

The silhouette for pattern i is then



(*a*)

(*b*)

Figure 3.8.7
The use of minimum spanning trees (MSTs). (*a*) The MST with 12 links. (*b*) The MST with 10 links; three clusters are now present.

$$h_i = \frac{b_i - a_i}{\max(a_i,\ b_i)}. \qquad (3.8.21)$$

Clearly $-1 \le h_i \le 1.0$. It is not possible to define silhouettes for clusters with only one member (singleton clusters). Silhouettes are displayed such that each cluster is represented as a histogram of frequency plotted against silhouette values so that one can look for outliers or poorly connected plots.

From our experience with powder data collected in reflection mode on both organic and inorganic samples (Barr *et al.*, 2004*b*), we conclude that for any given pattern

(1) $h_i > 0.5$ implies that pattern i is probably correctly classified;
(2) $0.2 < h_i < 0.5$ implies that pattern i should be inspected, since it may belong to a different or new cluster;
(3) $h_i < 0.2$ implies that pattern i belongs to a different or new cluster.

The use of silhouettes in defining the details of the clustering is shown for the aspirin data in Fig. 3.8.8. The silhouettes for the red cluster corresponding to the dendrogram in Fig. 3.8.6(*a*) are shown in Fig. 3.8.8(*a*) and those for the corresponding orange cluster are shown in Fig. 3.8.8(*b*). Both sets of silhouettes have values < 0.5, which indicates that the clustering is not optimally defined. When the cut line is moved to give the dendrogram in Fig. 3.8.6(*c*), the silhouettes for the red cluster are shown in Fig. 3.8.8(*c*). The entry centred on a silhouette value of 0.15 is pattern 3. This implies that pattern 3 is only loosely connected to the cluster and this is demonstrated in Fig. 3.8.8(*d*) where pattern 3 and the most representative pattern for the cluster (No. 9) are superimposed. Although there is a general sense of similarity there are significant differences and the combined correlation coefficient is only 0.62. In Fig. 3.8.8(*e*), the silhouettes for the orange cluster are shown. They imply that this is a single cluster without outliers. The silhouettes for the green cluster corresponding to the dendrogram in Fig. 3.8.6(*c*) are shown in Fig. 3.8.8(*f*). The clustering is poorly defined here.

3.8.5.2. *Fuzzy clustering*

In standard clustering methods a set of n diffraction patterns are partitioned into c disjoint clusters. Cluster membership is defined *via* a membership matrix $\mathbf{U}(n \times c)$, where individual coefficients, u_{ik}, represent the membership of pattern i of cluster k. The coefficients are equal to unity if i belongs to c and zero otherwise, *i.e.*

$$u_{ik} \in [0, 1] \quad (i = 1, \ldots, n;\ k = 1, \ldots, c). \qquad (3.8.22)$$

If these constraints are relaxed, such that

$$0 \le u_{ik} \le 1 \quad (i = 1, \ldots, n;\ k = 1, \ldots, c), \qquad (3.8.23)$$

$$0 < \sum_{i=1}^{n} u_{ik} < n \quad (k = 1, \ldots, c) \qquad (3.8.24)$$

and

$$\sum_{k=1}^{c} u_{ik} = 1, \qquad (3.8.25)$$

then fuzzy clusters are generated, in which there is the possibility that a pattern can belong to more than one cluster (see, for example, Everitt *et al.*, 2001; Sato *et al.*, 1966). Such a situation is quite feasible in the case of powder diffraction, for example, when mixtures can be involved. It is described in detail by Barr *et al.* (2004*b*).

3.8.5.3. *The PolySNAP program and DIFFRAC.EVA*

All these techniques have been incorporated into the *PolySNAP* computer program (Barr *et al.*, 2004*a*,*b*,*c*; Barr, Dong, Gilmore & Faber, 2004; Barr, Dong & Gilmore, 2009), which was developed from the *SNAP-D* software (Barr, Gilmore & Paisley, 2004). *PolySNAP* has subsequently been incorporated into the Bruker *DIFFRAC.EVA* program (Bruker, 2018), and the following sections are based on its use.

3.8.6. Examples

All the elements for clustering and visualization are now in place. Fig. 3.8.4 shows this as a flowchart. Hitherto we have looked at elements of the aspirin data to demonstrate how methods work; we now examine the aspirin data in detail as a single analysis.

3.8.6.1. *Aspirin data*

In this example we use 13 powder patterns from commercial aspirin samples collected in reflection mode on a Bruker D8 diffractometer. Since these samples include fillers, the active pharmaceutical ingredient (API) and other formulations, it is not surprising that peak widths are high: ~0.5° full width at half maximum (FWHM). The data-collection range was 10–43° in 2θ using Cu $K\alpha$ radiation. The 13 powder data sets are shown in Fig. 3.8.5 arranged into groups based on similarity. We have already described the methods of analysis and have shown typical results in Figs. 3.8.6 to 3.8.8, and now present detailed examples. The correlation matrix derived from equation (3.8.3) is shown in Fig.

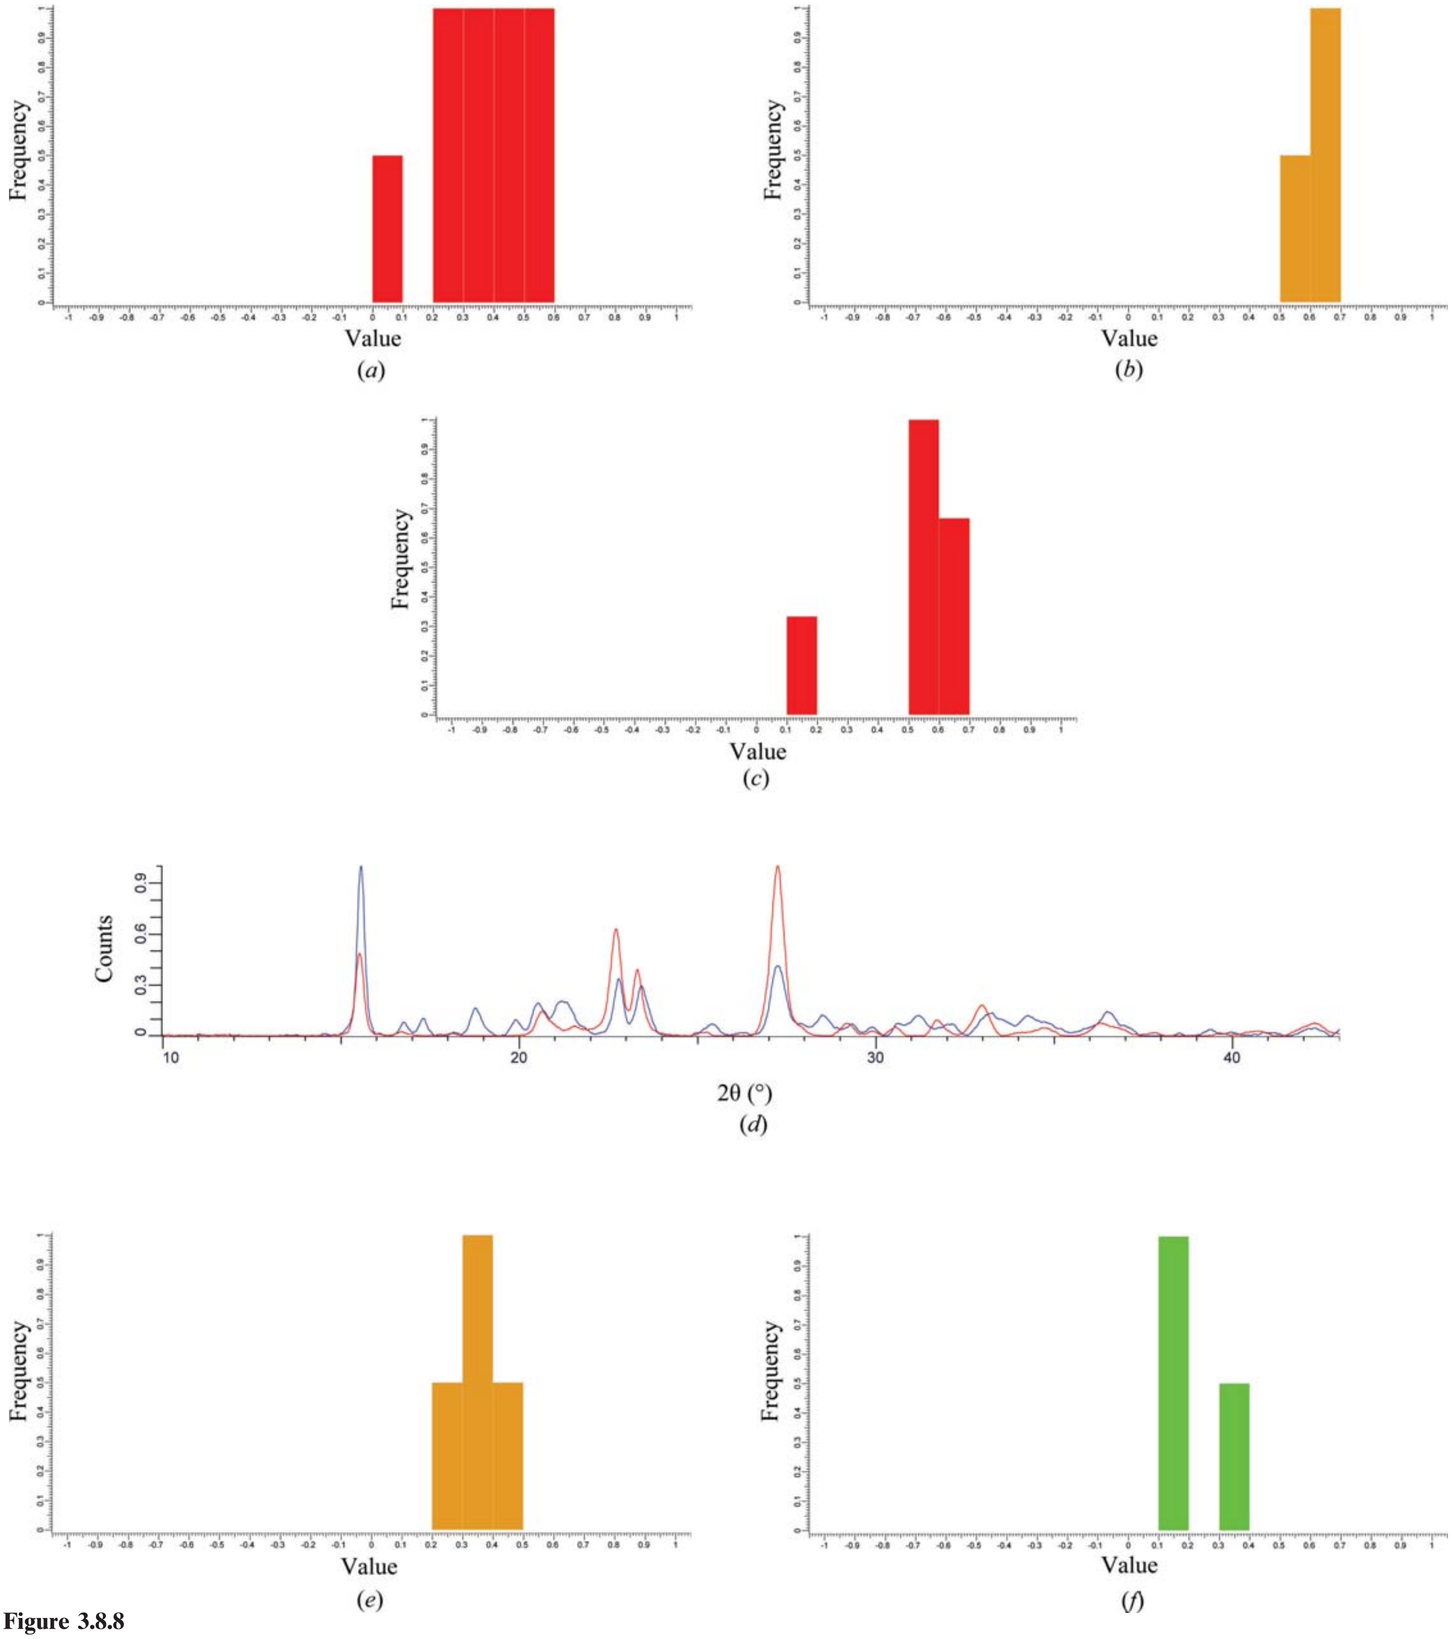


Figure 3.8.8
The use of silhouettes in defining the details of the clustering. (*a*) The silhouettes for the red cluster in the dendrogram from Fig. 3.8.6(*a*). (*b*) The corresponding orange cluster. Both sets of silhouettes have values that are less than 0.5, which indicates that the clustering is not well defined. (*c*) The silhouettes for the red cluster corresponding to the dendrogram in Fig. 3.8.6(*c*). The entry centred on a silhouette value of 0.15 is pattern 3. This implies that pattern 3 is only loosely connected to the cluster and this is demonstrated in part (*d*), where pattern 3 and the most representative pattern for the cluster (No. 9) are superimposed. Although there is a general sense of similarity there are significant differences and the combined correlation coefficient is only 0.62. (*e*) The silhouettes for the orange cluster corresponding to the dendrogram in Fig. 3.8.6(*c*). The silhouettes imply that this is a single cluster without outliers. (*f*) The silhouettes for the green cluster corresponding to the dendrogram in Fig. 3.8.6(*c*). The clustering is poorly defined here.

3.8.9(*a*), colour coded to reflect the values of the coefficients; the darker the shade, the higher the correlation. The resulting dendrogram and MMDS plot are shown in Figs. 3.8.9(*b*) and (*c*), respectively. Four clusters are identified in the dendrogram and these have been appropriately coloured. Other visualization tools are now shown. In Fig. 3.8.9(*d*) the pie chart is displayed; the number of rows can be adjusted to reflect the arrangement of the samples in a multiple sample holder. Fig. 3.8.9(*e*) shows the default minimum spanning tree with 12 links. In Fig. 3.8.9(*f*) the scree plot indicates that three clusters will account for more than 95% of the data variability. The steep initial slope is a clear indication of good cluster estimation. The silhouettes are shown in Fig. 3.8.9(*g*–*i*). These were discussed in Section 3.8.5.1. In Fig. 3.8.9(*j*) the default parallel-coordinates plot for the same data is shown, and in Fig. 3.8.9(*k*) there is another view taken from the grand tour. These two plots validate the clustering and also indicate that there is no significant error introduced into the MMDS plot by truncating it into three dimensions.

3.8.6.1.1. *Aspirin data with amorphous samples included*

As a demonstration of the handling of data from amorphous samples, five patterns for amorphous samples were included in the aspirin data and the clustering calculation was repeated. The results are shown in Fig. 3.8.10. Fig. 3.8.10(*a*) shows the dendrogram. It can be seen that the amorphous samples are positioned as isolated clusters on the right-hand end. They also appear as an isolated cluster in the MMDS plot and the parallel-coordinates plots, as shown in Figs. 3.8.10(*b*) and (*c*). It could be argued that these samples should be treated as a single, five-membered cluster rather than five individuals, but we have found that this confuses the clustering algorithms, and it is clearer to the user if the data from amorphous samples are presented as separate classes.

3.8.6.2. *Phase transitions in ammonium nitrate*

Ammonium nitrate exhibits temperature-induced phase transformations. Between 256 and 305 K it crystallizes in the orthorhombic space group *Pmmm* with $a = 5.745$, $b = 5.438$, $c = 4.942$ Å and $Z = 2$; from 305 to 357 K it crystallizes in *Pbnm* with

(*g–i*) The silhouettes for the red, the orange and the green clusters, respectively. These are discussed in detail in the caption to Fig. 3.8.8. (*j*) The default parallel-coordinates plot. The clusters are well maintained into the 4th, 5th and 6th dimensions. (*k*) Another view of the parallel coordinates using the grand tour. The clustering remains well maintained in higher dimensions.

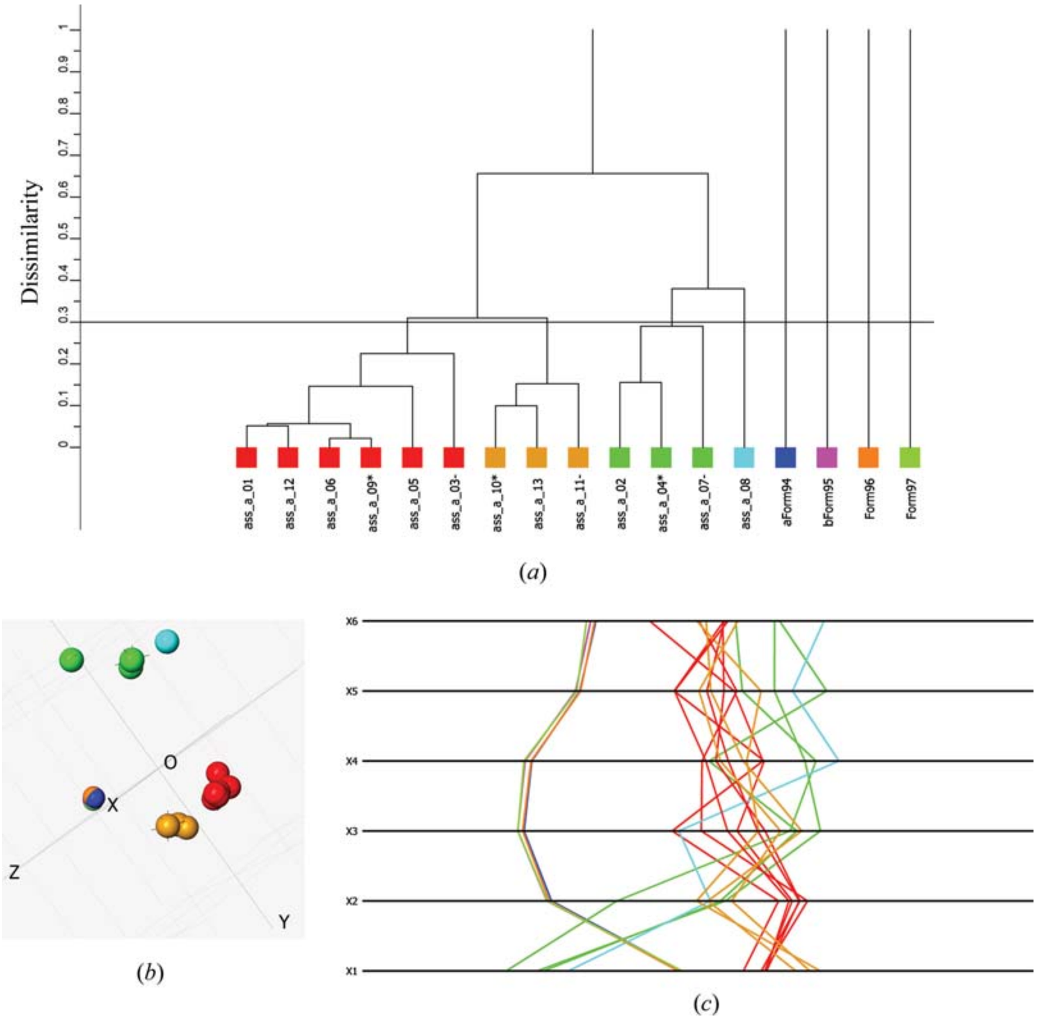

Figure 3.8.10
The aspirin data including data from five amorphous samples. (*a*) The resulting dendrogram and (*b*) the corresponding MMDS plot. (*c*) The parallel-coordinates plot.

$a = 7.14$, $b = 7.65$, $c = 5.83$ Å with $Z = 4$; between 357 and 398 K it crystallizes in the tetragonal space group $P\overline{4}2_1m$ with $a = 5.719$, $c = 4.932$ Å, $Z = 2$, and above 398 K it transforms to the cubic space group $Pm\overline{3}m$ with $a = 4.40$ Å and $Z = 1$. PXRD data containing 75 powder patterns taken at intervals of 3 K starting at 203 K using a D5000 Siemens diffractometer and Cu $K\alpha$ radiation with a 2θ range of 10–100° were used (Herrmann & Engel, 1997). Fig. 3.8.11(*a*) shows the data in the 2θ range 17–45°.

The visualization of these data following cluster analysis is shown in Fig. 3.8.11(*b*) using an MMDS plot on which has been superimposed a line showing the route followed by the temperature increments. The purple line follows the transition from a mixture of forms IV and V at low temperature (red) through form IV (yellow), form II (blue) and finally form I at high temperature (green). This is an elegant and concise representation of the data in a single diagram.

3.8.7. Quantitative analysis with high-throughput PXRD data without Rietveld refinement

Since mixtures are so common in high-throughput experiments, and indeed in many situations with multiple data sets, it is useful to have a method of automatic quantitative analysis. The quality of data that results from high-throughput crystallography makes it unlikely that an accuracy better than 5–10% can be achieved but, nonetheless, the identification of mixtures can be carried out by whole-profile matching. First a database of N pure phases is created, or, if that is not possible, then the most representative patterns with appropriate safeguards can be used. Assume that there is a sample pattern, S, which is considered to be a mixture of up to N components. S comprises m data points, $S_1, S_2, \ldots, S_m$. The N patterns can be considered to make up fractions $p_1, p_2, p_3, \ldots, p_N$ of the sample pattern. The best possible combination of the database patterns to fit the sample pattern is required. A system of linear equations can be constructed in which x_{11} is measurement point 1 of pattern 1 *etc.*:

$$\begin{aligned} x_{11}p_1 + x_{12}p_2 + x_{13}p_3 + \ldots + x_{1N}p_N &= S_1, \\ x_{21}p_1 + x_{22}p_2 + x_{23}p_3 + \ldots + x_{2N}p_N &= S_2, \\ &\vdots \\ x_{m1}p_1 + x_{m2}p_2 + x_{m3}p_3 + \ldots + x_{mN}p_N &= S_m. \end{aligned} \tag{3.8.26}$$

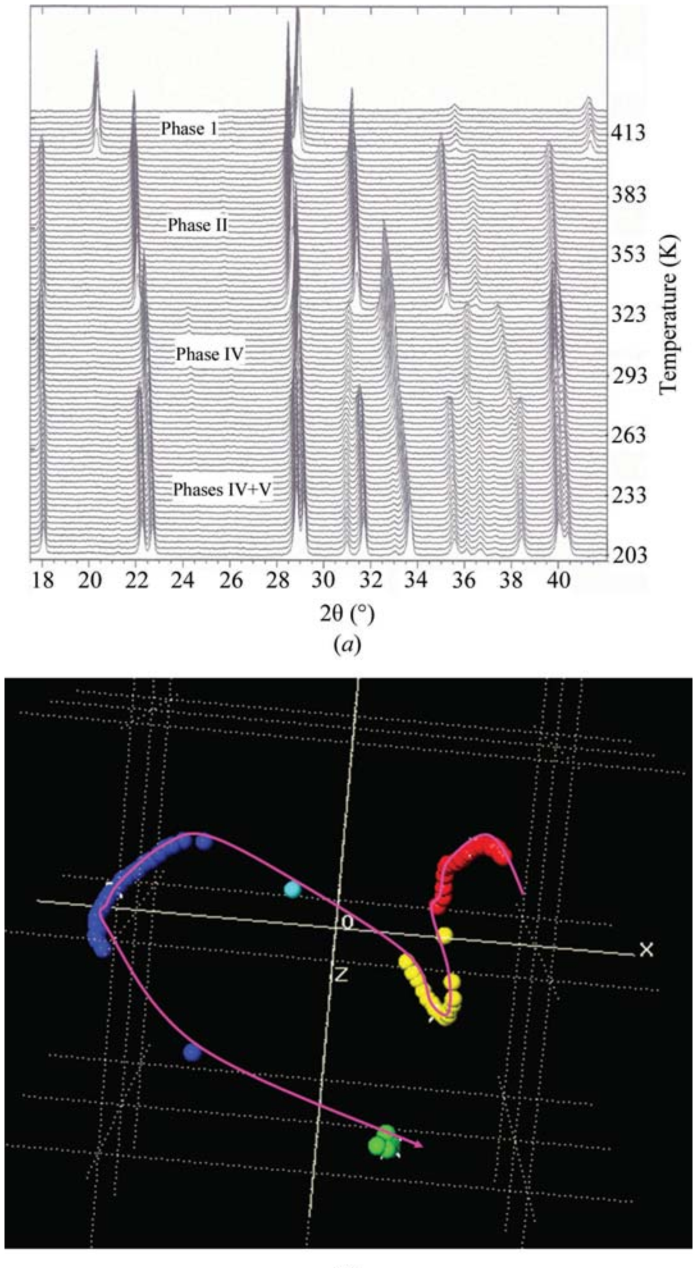
Writing these in matrix form, we get

$$\begin{bmatrix} x_{11} & x_{12} & x_{13} & \ldots & x_{1N} \\ x_{21} & x_{22} & x_{23} & \ldots & x_{2N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ x_{m1} & x_{m2} & x_{m3} & \ldots & x_{mN} \end{bmatrix} \begin{bmatrix} p_1 \\ p_2 \\ \vdots \\ p_N \end{bmatrix} = \begin{bmatrix} S_1 \\ S_2 \\ \vdots \\ S_N \end{bmatrix} \tag{3.8.27}$$

or

$$\mathbf{xp} = \mathbf{S}. \tag{3.8.28}$$

A solution for S that minimizes



(*a*)

(*b*)

Figure 3.8.11
Ammonium nitrate phase transitions. (*a*) The raw powder data measured between 203 and 425 K. Reproduced with permission from Herrmann & Engel (1997). Copyright (1997) John Wiley and Sons. (*b*) The MMDS plot. The purple line follows the temperature change from 203 to 425 K.

$$\chi^2 = \left|\mathbf{xp} - \mathbf{S}\right|^2. \tag{3.8.29}$$

is required. Since $N \ll m$, the system is heavily overdetermined, and least-squares or singular value decomposition can be used to solve (3.8.29) for the fractional percentages arising from the scattering power of the component mixtures, $s_1, s_2, \ldots, s_N$. The values of s can be used to calculate a weight fraction for that particular phase provided that the atomic absorption coefficients are known, and this in turn requires the unit-cell dimensions and cell contents, but not the atomic coordinates (Smith *et al.*, 1988; Cressey & Schofield, 1996). The general formula for the weight fraction of component n in a mixture comprising N components is (Leroux *et al.*, 1953)

$$c_n = p_n \frac{\mu^*}{\mu_n^*}, \tag{3.8.30}$$

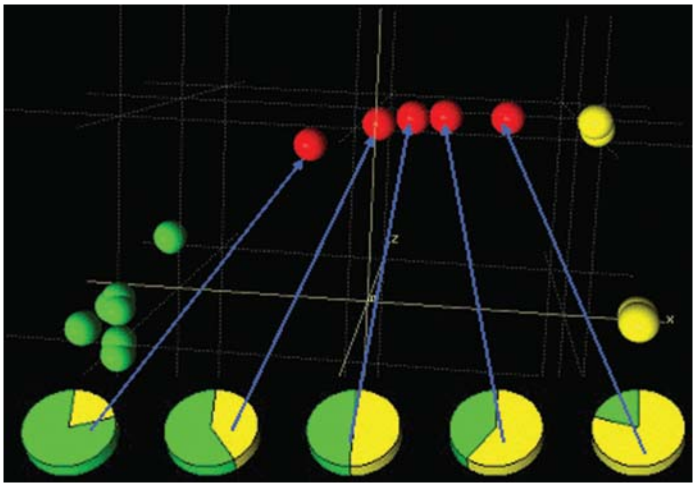


Figure 3.8.12
Identifying mixtures using lanthanum strontium copper oxide and caesium thiocyanate diffraction data taken from the ICDD Clay Minerals database. The green spheres represent pure phases of lanthanum strontium copper oxide and the yellow pure caesium thiocyanate. The red spheres represent mixtures of the two in the relative proportions of lanthanum strontium copper oxide/caesium thiocyanate 80/20, 60/40, 50/50, 40/60 and 20/80 in an arc commencing on the left-hand side of the diagram. The pie charts give the results of an independent quantitative calculation in which lanthanum strontium copper oxide and caesium thiocyanate have been included as pure phases in a reference database.

where

$$\mu^* = \sum_{j=1}^{N} c_j \mu_j^* \tag{3.8.31}$$

and

$$\mu_j^* = \mu_j / \rho_j, \tag{3.8.32}$$

where μ_j is the atomic X-ray absorption coefficient and ρ_j is the density of component j. For polymorphs, the absorption coefficients are sufficiently close and the method sufficiently approximate that the effects of absorption can be ignored.

3.8.7.1. *Example: inorganic mixtures*

As an example, a set of 19 patterns from set 78 of the ICDD database for inorganic compounds (ICDD, 2018) was imported into *DIFFRAC.EVA*. To this was added some simulated mixture data generated by adding the patterns for lanthanum strontium copper oxide and caesium thiocyanate in the proportions 80/20, 60/40, 50/50, 40/60 and 20/80. Two calculations were performed: an analysis without the pure-phase database and a second where the pure phases of lanthanum strontium copper oxide and caesium thiocyanate were present.

The results are shown in Fig. 3.8.12. In the MMDS plot the green spheres represent pure lanthanum strontium copper oxide while the yellow are pure caesium thiocyanate. The red spheres represent mixtures of the two. The latter form an arc between the green and yellow clusters. The distance of the spheres representing mixtures from the lanthanum strontium copper oxide and caesium thiocyanate spheres gives a semi-quantitative representation of the mixture contents. Running the analysis in quantitative mode gives the pie charts also shown in Fig. 3.8.12; they reproduce exactly the relative proportions of the three components.

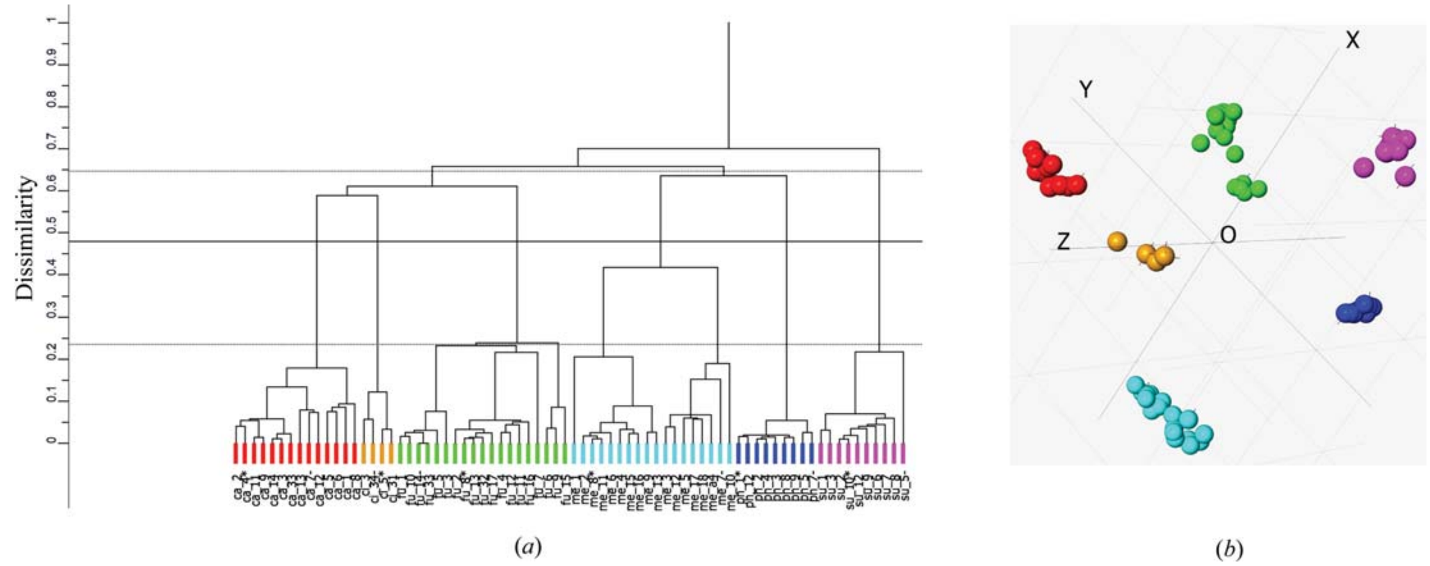

Figure 3.8.13
(*a*) The dendrogram generated from 74 Raman spectra without background corrections applied. Labelling from the left-hand side, the red samples are carbamazepine, the orange are cimetidene, the green are two forms of furosemide, the light blue is mefenamic acid, the dark blue is phenilbutazone and the purple at the right-hand side is sulfamerazine. (*b*) The MMDS plot. The sphere colours are taken from the dendrogram. This representation shows clearly discrete clusters in correspondence with those generated by the dendrogram.

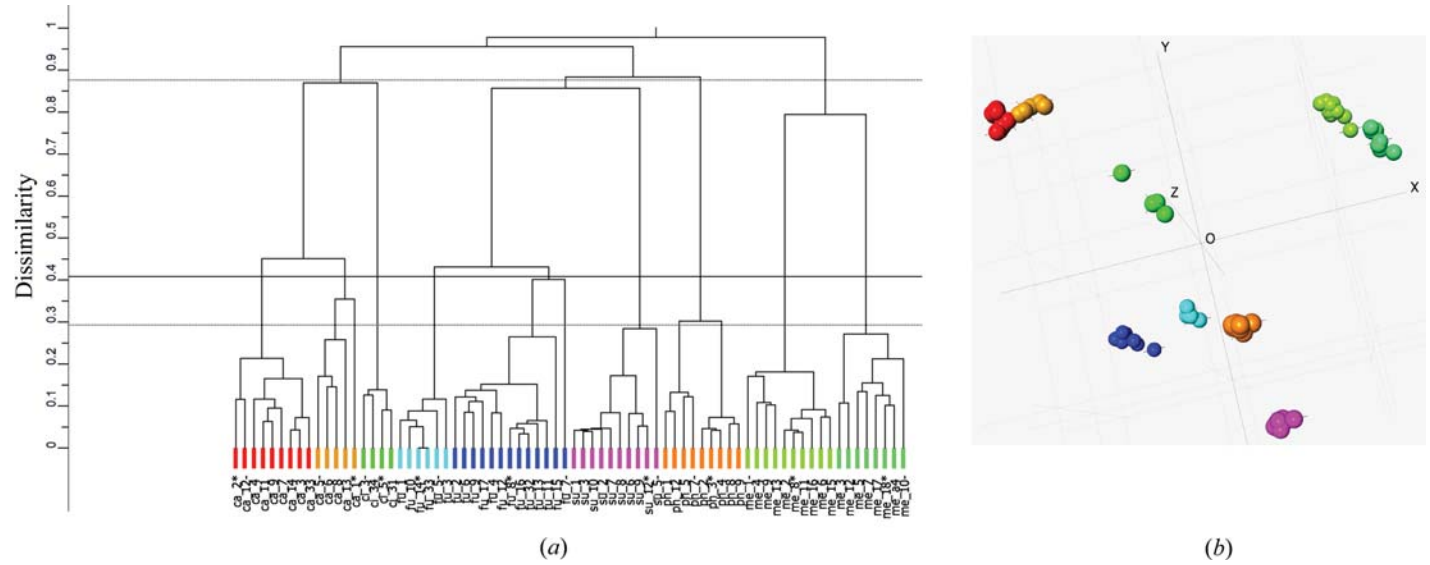

Figure 3.8.14
Clustering the 74 Raman spectra without background corrections applied using first-derivative data. (*a*) The dendrogram. Labelling from the left-hand side, the red and orange entries are carbamazepine; the green are cimetidene; the light blue and dark blue are two forms of furosemide; the purple are sulfamerazine; the brown are phenilbutazone and the right-hand light and dark green are two forms of mefenamic acid. (*b*) The MMDS plot. The clusters are well defined but the orange and red (both carbamazepine) are very close to each other.

For further details of this method with organic samples, see Dong *et al.* (2008).

3.8.8. Using spectroscopic data

There is no reason why the methodology described in this chapter cannot be used for other 1D data sets, *e.g.* Raman, IR, NMR and near-IR spectroscopies, although different data pre-processing is usually required. Raman spectroscopy is well suited to high-throughput screening: good-quality spectra can be collected in a few minutes, and sample preparation is straightforward and flexible, although the resulting spectra are not always as distinct as the PXRD equivalents (Mehrens *et al.*, 2005; Boccaleri *et al.*, 2007).

As an example we show the results of cluster analysis carried out on samples of carbamazepine, cimetidene, furosemide, mefenamic acid, phenilbutazone and sulfamerazine using Raman spectroscopy. A total of 74 samples were measured on a LabRam HR-800/HTS-Multiwell spectrometer at room temperature, equipped with a backscattering light path system of a light-emitting diode laser (785 nm, 300 mW) as an excitation source and an air-cooled charge-coupled device detector. A 20-fold superlong working distance objective lens was used to collect the backscattered light. The spectra were acquired with 5.84 cm^{-1} spectral width and at least 30 s exposure (Kojima *et al.*, 2006). The spectra had backgrounds subtracted but no other corrections were carried out.

The initial clustering is shown in Fig. 3.8.13(*a*) with the default cut level in the dendrogram. There are six clusters: labelling from the left-hand side, the red are three polymorphs of carbamazepine; the orange are cimetidene; the green cluster contains three polymorphs of furosemide; the light blue contains three poly-

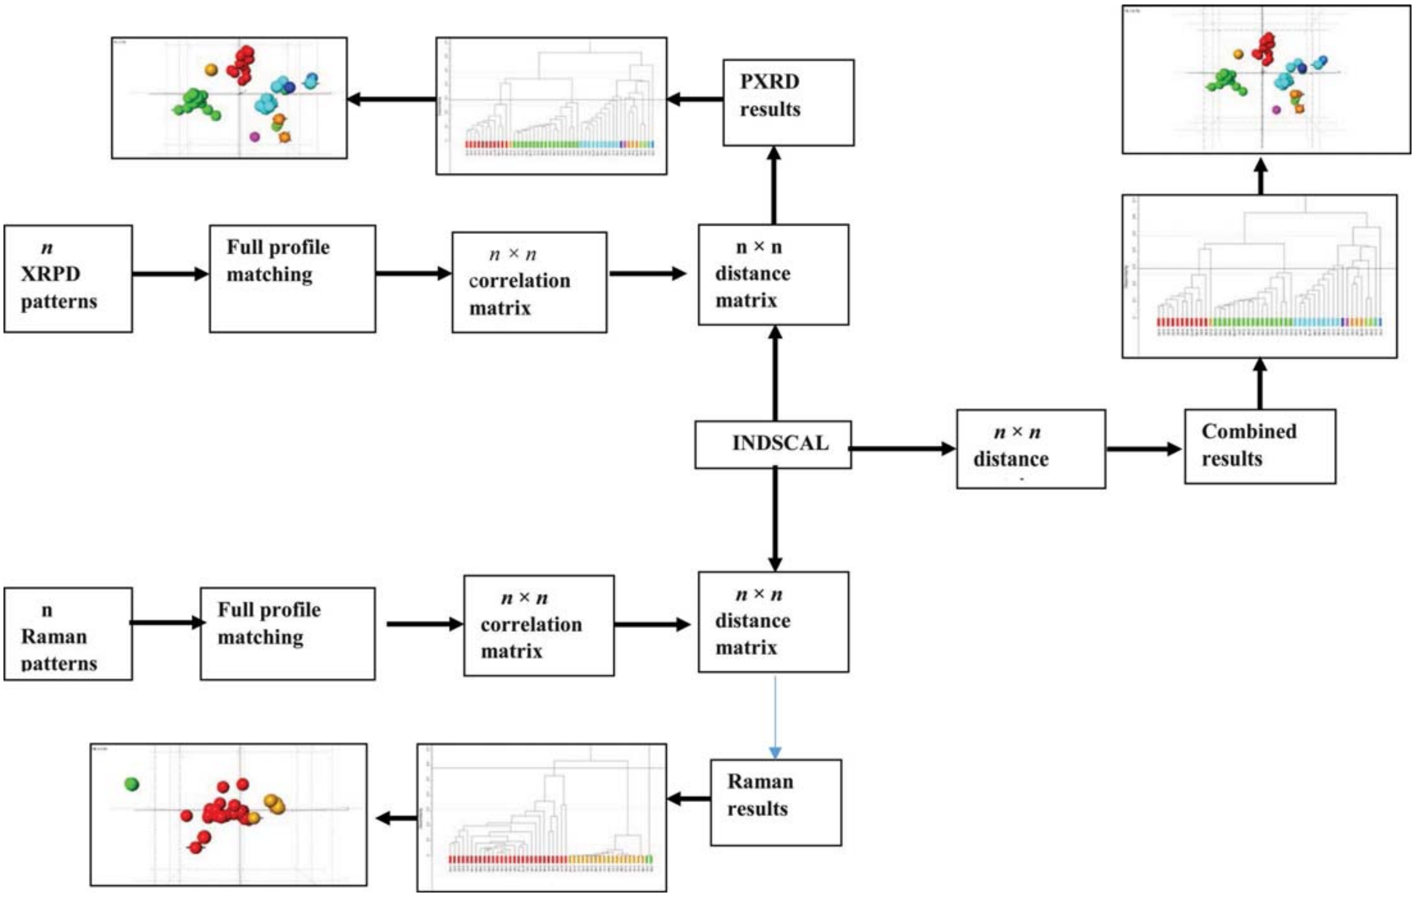

Figure 3.8.15
A flowchart for the INDSCAL method using Raman and PXRD data. Note that any combination of any 1D data can be used here.

morphs of mefenamic acid; the dark blue contains phenilbutazone; and finally the purple cluster contains sulfamerazine. The MMDS plot gives a complementary visualization of the data that supports the clustering.

It is also possible to use derivative data in place of the original spectra for clustering. The results of this for the 74 Raman spectra without initial background subtraction followed by the generation of first-derivative data are shown in Fig. 3.8.14. The clusters are well defined but now the carbamazepine data have split into two clusters. These correspond to forms I and III of carbamazepine, although the differences in the Raman spectra for these three species are small (O'Brien *et al.*, 2004). At the same time, both furosemide and mefenamic acid are each split into two groups. This is probably the best description of the data in terms of clustering and cluster membership corresponding to the chemical differences in the samples. The dendrogram also has the feature that the tie bars between samples are higher, *i.e.* the similarities are lower, reflecting the fact that the use of first derivatives accentuates small differences in the data.

It is interesting to note that, in general, PXRD works less well with derivative data. The reason for this is not clear, but possibly the presence of partial overlapping peaks and the associated issues of peak shape are partly responsible.

3.8.9. Combining data types: the INDSCAL method

It is now common to collect more than one data type, and some instruments now exist for collecting spectroscopic and PXRD data on the same samples, for example the Bruker D8 Screenlab, which combines PXRD and Raman measurement for high-throughput screening (Boccaleri *et al.*, 2007).

A technique for combining the results of more than one data type is needed. One method would be to take individual distance matrices from each data type and generate an average distance matrix using equation (3.8.3), but this leaves open the question of how best to define the associated weights in an optimal, objective way. Should, for example, PXRD be given a higher weight than Raman data? The individual differences scaling method (INDSCAL) of Carroll & Chang (1970) provides an unbiased solution to this problem by, as the name suggests, scaling the differences between individual distance matrices.

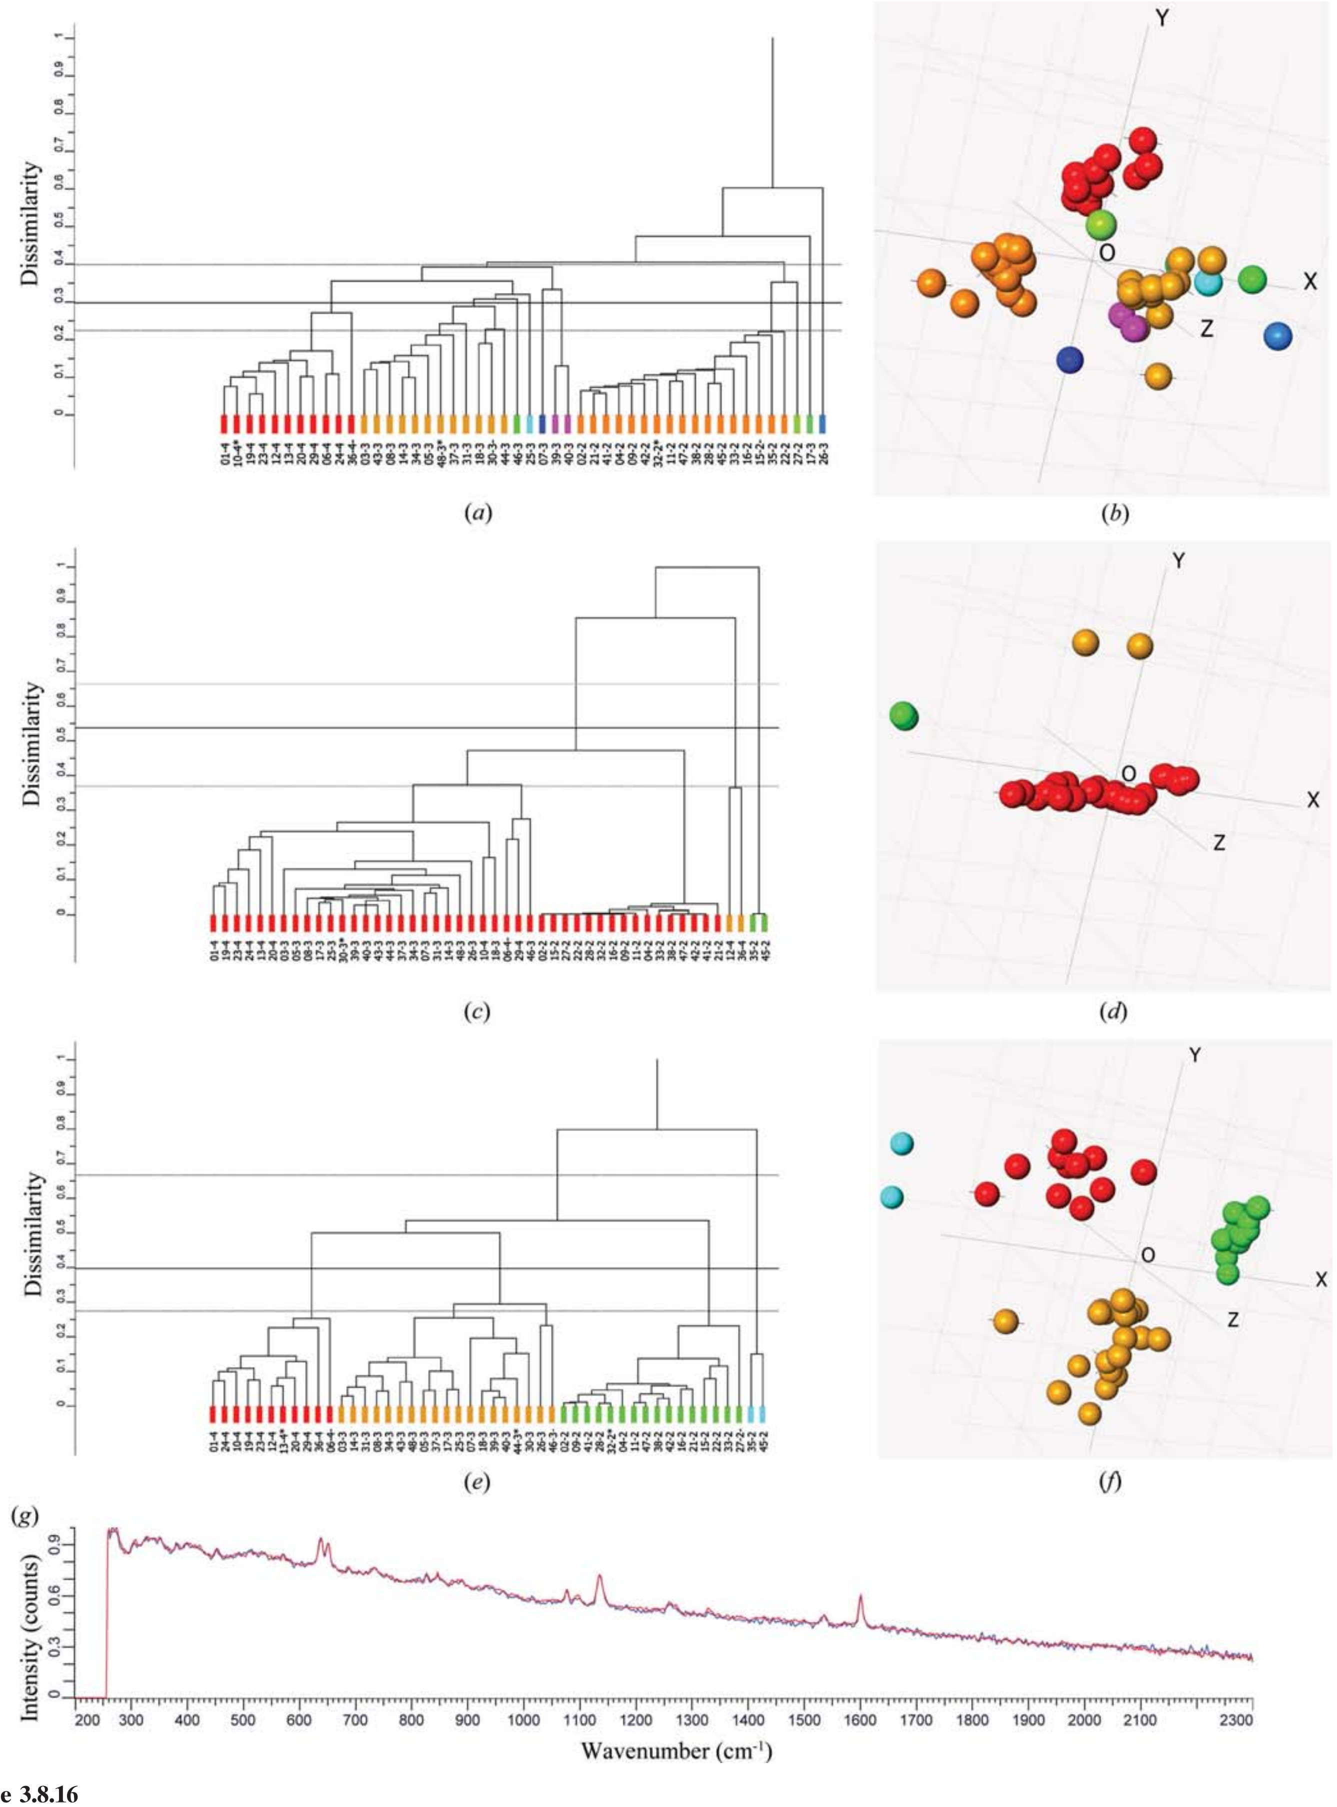
In this method, let $\mathbf{D}_k$ be the squared distance matrix of dimension $(n \times n)$ for data type k with a total of K data types. For example, if we have PXRD, Raman and differential scanning calorimetry (DSC) data for each of n samples, then $K = 3$. A group-average matrix $\mathbf{G}$ (which we will specify in two dimensions) is required that best represents the combination of the K data types. To do this, the $\mathbf{D}$ matrices are first put into inner-product form by the double-centring operation to give

$$\mathbf{B}_k = -\tfrac{1}{2}(\mathbf{I} - \mathbf{N})\mathbf{D}_k(\mathbf{I} - \mathbf{N}), \qquad (3.8.33)$$

where $\mathbf{I}$ is the identity matrix and $\mathbf{N}$ is the centring matrix $I - \mathbf{11}'/N$; $\mathbf{1}$ is a column vector of ones. The inner-product matrices thus generated are matched to the weighted form of the group average, $\mathbf{G}$, which is unknown. To do this the function

$$S = \sum_{1}^{K} \left\| \mathbf{B}_k - \mathbf{G}\mathbf{W}_k^2\mathbf{G}' \right\| \qquad (3.8.34)$$

is minimized. The weight matrices, $\mathbf{W}_k$, are scaled such that



(*a*) (*b*)

(*c*) (*d*)

(*e*) (*f*)

Figure 3.8.16

Clustering 48 PXRD spectra with background corrections applied for three polymorphs of sulfathiazole. (*a*) The dendrogram. Each sample is identified by a four-digit code. The first two digits are the well number, and the last digit defines whether the sample is form 2, 3 or 4 of sulfathiazole. (*b*) The MMDS plot: the red cluster is well defined but the rest of the spheres are diffuse and intermingled. (*c*) The dendrogram derived from clustering 48 Raman spectra of sulfathiazole with background corrections applied. (*d*) The corresponding MMDS plot. The clusters are poorly defined. (*e*) The results of the INDSCAL method. The dendrogram is shown with the default cut level. The clustering is correct; all the samples are placed in the correct group except for patterns 35-2 and 45-2. (*f*) The MMDS plot validates the dendrogram. (*g*) The Raman patterns for 35-2 and 45-2 superimposed. They are primarily background noise.

$$\sum_{k=1}^{K} \mathbf{W}_k^2 = K\mathbf{I}. \qquad (3.8.35)$$

The INDSCAL method employs an iterative technique to solve equation (3.8.7) in which one parameter is kept fixed whilst the other is determined by least-squares refinement. An initial estimate for **G** is taken either from the average of the **D** matrices for each sample or as a random matrix. This is then used to estimate the weight matrices, and the whole process repeated until a minimum value of S is obtained. The algorithm derived by Carroll and Chang was used in the example below. When random matrices are used to generate the initial **G** matrix, the INDSCAL procedure is repeated 100 times and the solution with the minimum value of S is kept. In practice, there is very little difference in the results of these two procedures. The resulting **G** matrix is used as a standard-distance matrix, and used in the standard way to generate dendrograms, MMDS plots *etc*. The method has the property that where data types show samples to be very similar this is reinforced, whereas where there are considerable variations the differences are accentuated in the final **G** matrix. For a fuller description of the INDSCAL method with examples see Gower & Dijksterhuis (2004), Section 13.2, and for a useful geometric interpretation see Husson & Pagès (2006).

3.8.9.1. *An example combining PXRD and Raman data*

We now present an example of the INDSCAL method applied to data collected on sulfathiazole using PXRD and Raman spectroscopy (Barr, Cunningham *et al.*, 2009). A flowchart is shown in Fig. 3.8.15. Three polymorphs of sulfathiazole were prepared and PXRD data were collected on a Bruker C2 GADDS system. Each sample was run for 2 min over a 3–30° range in 2θ using Cu $K\alpha$ radiation. Raman data were collected on a Bruker SENTINEL. The Raman probe was integrated into the PXRD instrument.

The only data pre-processing performed was background removal. Fig. 3.8.16(*a*) shows the resulting dendrogram (with the default cut level) and Fig. 3.8.16(*b*) shows the corresponding MMDS plot. To identify each sample they are numbered *via* a four-digit code: the first two digits are the well number, and the last digit defines whether the sample is form 2, 3 or 4 of sulfathiazole. It can be seen that the clustering is only partly successful: form 4 (red) is correctly clustered; form 3 (orange) gives five clusters and form 2 gives three clusters.

Fig. 3.8.16(*c*) shows the clustering from the Raman spectra. The results are poor: most of form 2 is correctly clustered, but forms 4 and 3 are intermixed, and the MMDS plot in Fig. 3.8.16(*d*) is diffuse with little structure.

The INDSCAL method is now applied starting from random **G** matrices and the results are shown in Fig. 3.8.16(*e*) and (*f*) with the dendrogram cut level at its default value. The clustering is almost correct; all the samples are placed in the correct groups except that there are two outliers coloured in blue. Fig. 3.8.16(*g*) shows the Raman patterns for these samples: they are primarily background with very little usable signal.

3.8.10. Quality control

Quality control (Gilmore, Barr & Paisley, 2009) is designed for situations where the stability of a material is being monitored over time, for example as part of a production-line system, or for periodic equipment alignment. A set of reference patterns is collected that represents acceptable measurements – any measurement sufficiently close to these references represents a good measurement. Various sample patterns are then imported and compared with those reference patterns, and any that vary significantly from the ideal are noted and highlighted.

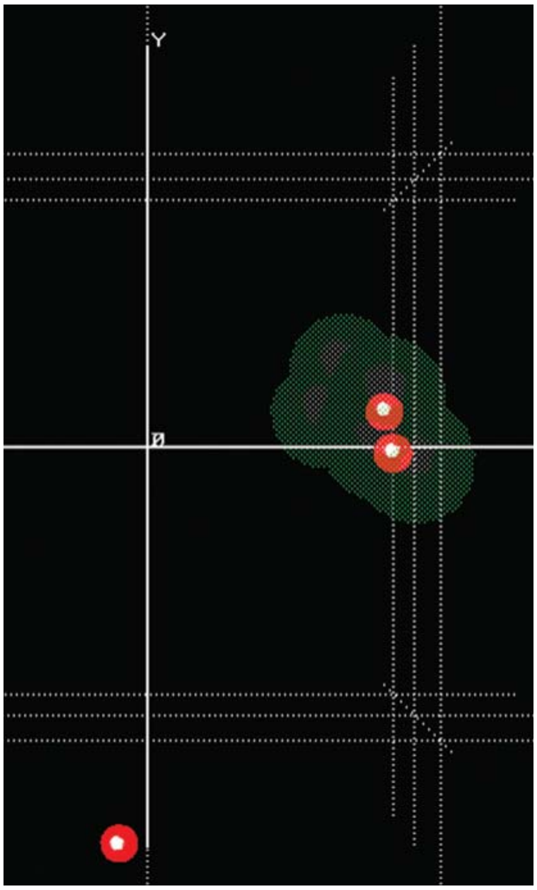


Figure 3.8.17
Visualization tools for quality-control procedures using a modified MMDS plot. The red outlier is a sample unacceptably far from the cluster of reference measurements.

The results are best displayed graphically using a variant of the MMDS method, of which an example is shown in Fig. 3.8.17. The reference patterns define a green shaded surface with acceptable sample patterns, coloured red, shown within it, and potentially problematic sample patterns appearing outside it. The volume of the green shape is defined by intersecting spheres around each reference sample and these can be altered to allow more- or less-stringent quality control.

3.8.11. Computer software

These calculations can be carried out using MATLAB (http://www.mathworks.co.uk/products/matlab/) or the open-source R software (http://www.r-project.org/; Crawley, 2007) with graphics using the *GGobi* software (Cook & Swayne, 2007). There are four commercial packages for handling powder data: *DIFFRAC.EVA* and *PolySNAP 3*, both from Bruker (http://www.bruker.com/; Gilmore, Barr & Paisley, 2004; Barr, Dong & Gilmore, 2009), *Jade* from Materials Data Inc. (http://www.materialsdata.com) and *HighScore* from Malvern PANalytical (http://www.panalytical.com/).

Data were kindly provided by Gordon Cunningham at Glasgow University, Arnt Kern of Bruker AXS in Karlsruhe and Michael Herrman at the Fraunhofer Institute, Germany.

3.9. Quantitative phase analysis

I. C. Madsen, N. V. Y. Scarlett, R. Kleeberg and K. Knorr

3.9.1. Introduction

The field of quantitative phase analysis (QPA) from powder diffraction data is almost as old powder diffraction itself. Debye and Scherrer first developed the method around 1916 (Debye & Scherrer, 1916, 1917) and between 1917 and 1925 Hull (1917, 1919) and Navias (1925) were reporting studies of QPA related to the new technique. However, further developments in QPA were relatively slow, as much of the activity in X-ray diffraction (XRD) at the time was dedicated to the solution of crystal structures rather than the extraction of other information present in a powder diffraction pattern. While a small number of QPA applications continued to be published in the intervening years, it was not until the advent of scanning diffractometers around 1947 (Langford, 2004, Parrish, 1965) and the work of Alexander and Klug in 1948 (Alexander & Klug, 1948), which provided the formal methodology and a practical approach, that the field began to expand.

Since those original developments, which utilized the intensity of individual peaks or a small group of peaks in the diffraction pattern, there have been extensions to the methodology that use whole-pattern approaches. These methods operate *via* the summation of either (i) patterns collected from pure components or (ii) component contributions calculated from their crystal structures. There are a number of benefits accruing from the whole-pattern approaches since all reflections in the pattern, which may number in the hundreds or thousands, now contribute to the final analysis.

The mathematical basis of QPA is well established and, ideally, QPA should be a relatively straightforward science. However, there are a significant number of factors, many of them experimental, that serve to decrease the accuracy that can be obtained (Chung & Smith, 2000). Some of these, such as accuracy and precision in measurement of peak position and intensity, resolution of overlapping peaks and counting statistics, relate to instrument geometry and data-collection conditions. Other sources of error derive from sample-related issues and include effects such as (i) preferred orientation (which distorts the observed relative intensities from those expected for a randomly oriented powder); (ii) crystallite size and strain broadening (leading to increased peak width and hence overlap); (iii) the grain-size effect (where there may be too few crystallites contributing to the diffraction process to ensure that a representative powder pattern can be measured);[1] and (iv) microabsorption (where phases that strongly absorb the incident and diffracted beams are underestimated with respect to weakly absorbing phases). Of these, microabsorption remains the largest impediment to accurate QPA and is more pronounced in X-ray diffraction than in neutron-based studies.

While there is a very broad scope for the application of diffraction-based estimation of phase abundance, the perceived difficulty involved in developing and using these methods often deters non-specialist users. Consequently, they may resort to other, non-diffraction, material characterization techniques that are more readily implemented.

Analytical techniques for most of the 92 naturally occurring elements are generally well established and, in many cases, the subject of internationally accepted standards. However, the physical properties of minerals and materials formed by these elements, and the manner in which they react, is not solely dependent on their chemical composition but also on how the constituent elements are arranged; that is, their crystal structures. This finite number of known elements combines in an almost infinite array within the 230 crystallographic space groups. Further variability is induced by factors such as solid solution, degree of crystallinity and morphology, thus making QPA by diffraction methods considerably more difficult to implement.

In industry, many manufacturing or processing lines are controlled by measurement of elemental composition alone, simply because these values can be readily obtained to a high degree of accuracy and precision. For example, a plant extracting Cu from an ore body might measure the Cu content of the feed ore and the concentrate, and the plant conditions are optimized based on efficiency of extraction. However, if the mineralogical form of the Cu changes in the feed, then it may not behave in the same manner during grinding, flotation and density separation, and this will affect the recovery. Frequently, where knowledge of the mineralogy or phase abundance is actually used in plant optimization and control, it is derived from bulk or micro-compositional analysis rather than being measured directly. This is often achieved by normative calculation, where the results of element composition analysis are assigned to specific phases based on an assumed knowledge of individual phase composition. Further details of this approach can be found in Chapter 7.7.

In materials science, new compounds are being synthesized at a rapidly increasing rate with techniques such as high-throughput synthesis capable of generating hundreds of new variants in a single experiment. Such techniques are being used in fields ranging from drug discovery, catalyst synthesis and new metal alloy design. The properties of these materials, and their suitability for their designed purpose, are not only dependent on their structural form but, for multiphase materials, on the amount of each component present. In this case, accurate, or at the very least reproducible, QPA is crucial to the screening process.

This chapter focuses on the application of QPA techniques for the extraction of phase abundance from diffraction data. While there is extensive coverage of the QPA methodology in other texts (Klug & Alexander, 1974; Smith *et al.*, 1987; Snyder & Bish, 1989; Zevin & Kimmel, 1995), some of the more commonly used approaches will be described here along with examples of their use in practical applications.

3.9.2. Phase analysis

There are a number of traditional methods for the estimation of phase abundance in multiphase materials (Zevin & Kimmel, 1995). In summary, these can be divided into two groups:

---

[1] It is worth noting that the grain-size effect becomes even more of an issue as the divergence of the instrument is decreased with, for example, high-resolution laboratory or synchrotron-based instruments, since fewer crystallites are likely to meet the diffraction condition.

Copyright © 2019 International Union of Crystallography

(1) *Indirect methods* – these are usually based on the measurement of total chemical composition, which is then apportioned according to an assumed composition for each phase. A very widely used form of this normative calculation approach is the Bogue method (Bogue, 1929) for the quantitative estimation of Portland cement phases. The limitations in this approach arise when the actual compositions of individual phases vary from those assumed in the calculation. This frequently occurs in the cement industry, where variance in local materials and production conditions can affect detailed phase compositions. Normative calculation has the potential to be unstable when a number of phases in the mixture have similar chemical composition and it cannot be used at all for the limiting case of polymorphs that have identical chemical composition.

(2) *Direct methods* – these are based on a property that is specific to phases of interest in the sample. These methods are often not generally applicable to the entire sample, but are useful in estimating abundances of selected components. Examples include:

   (*a*) Magnetic susceptibility – this is applicable to samples in which component phases have different magnetic properties. The magnetic component can be separated and weighed to determine its weight fraction in the starting material. This approach assumes that the magnetic phase is well separated from non-magnetic phases and accuracy will be reduced when there is a fine inseparable intergrowth of magnetic and non-magnetic components.

   (*b*) Selective dissolution – where the rate and extent of dissolution can be phase dependent, and the weight fraction of the residue is used to determine the fractions of soluble and insoluble components.

   (*c*) Density – involves the physical separation of phases with different densities. As with magnetic separation, this approach assumes that the phase of interest is well separated from other phases.

   (*d*) Image analysis – optical microscopy using thin sections is still frequently used for the analysis of mineralogical samples. Thin sections can be time consuming to prepare and analyse, and the observations can be highly subjective depending on the analyst's experience. While automated image analysis of optical and electron-beam images brings more consistency to the estimation of phase abundance, issues in stereology may still affect the determined phase abundances.

   (*e*) Thermal analysis – where the magnitude of endo- and exothermic features during phase transitions are proportional to the amount of the phases present. This can be effective for well known and characterized phases, but is less useful for new phases or complex multiphase samples where there may be significant overlap in the features in the observed patterns. There may also be difficulty in distinguishing features related to individual minerals, for example H_2O evolution from co-existing hydrated minerals.

   (*f*) Infrared (IR) techniques – these are gaining in popularity, especially in mineral exploration environments because of their portability, speed and ability to measure directly from a cleaned drill core or section. However, because the IR beam only penetrates 1–2 µm into the sample, it is a surface-analysis technique providing a semi-quantitative analysis at best. To work effectively, the method needs to be calibrated using other techniques such as diffraction-based phase analysis.

   (*g*) Powder diffraction may be included in the direct-methods category, as it distinguishes and quantifies phases on the basis of their unique crystal structures, giving the technique broad applicability for crystalline materials.

Quantification from powder diffraction data is reliant on determination of the contribution to the final pattern of each component phase in a mixture. Commonly used methods can be divided into two distinct groups:

(1) The traditional 'single-peak' methods, which rely on the measurement of the intensity of a peak, or group of peaks, for each phase of interest and assumes that the intensity of these peaks is representative of the abundance of the individual phases. This is often not the case because of peak overlap and phase-dependent factors, such as preferred orientation and microabsorption, which affect the relative observed intensities.

(2) Whole-pattern methods, which rely on the comparison of observed diffraction data over a wide range of 2θ with a calculated pattern formed from the summation of individual phase components which have either been (i) measured from pure phase samples, or (ii) calculated from crystal-structure information.

3.9.3. QPA methodology

The integrated intensity $I_{(hkl)\alpha}$ of reflection *hkl* for phase α in a multiphase mixture, measured on a flat-plate sample of infinite thickness using a diffractometer with Bragg–Brentano geometry, is given by (Snyder & Bish, 1989; Zevin & Kimmel, 1995; Madsen *et al.*, 2013)

$$\begin{aligned} I_{(hkl)\alpha} = {} & \left[\frac{I_0\lambda^3}{32\pi r}\frac{e^4}{m_e^2c^4}\right] \\ & \times \left[\frac{M_{hkl}}{2V_\alpha^2}\left|F_{(hkl)\alpha}\right|^2\left(\frac{1+\cos^2 2\theta\cos^2 2\theta_m}{\sin^2\theta\cos\theta}\right)\exp\left(-2B(\sin\theta/\lambda)^2\right)\right] \\ & \times \left[\frac{W_\alpha}{\rho_\alpha\mu_m^*}\right], \qquad (3.9.1) \end{aligned}$$

where I_0 is the incident-beam intensity, λ is the wavelength, e is the charge on an electron, m_e is the mass of an electron, r is the distance from the scattering electron to the detector and c is the speed of light. M_{hkl} and F_{hkl} are the multiplicity and structure factor of the *hkl* reflection, respectively, V_α is the unit-cell volume of phase α, and θ and θ_m are the diffraction angles for the *hkl* reflection and the monochromator (if present), respectively. B is the mean atomic displacement parameter (ADP). W_α and ρ_α are the weight fraction and density of phase α respectively, while μ_m^* is the mass absorption coefficient of the entire sample.

3.9.3.1. *Absorption–diffraction method*

The various terms in equation (3.9.1) are related to the (i) instrument configuration (first set of square brackets), (ii) crystal-structure-related parameters for reflection *hkl* of phase α (second set of square brackets), and (iii) phase-specific and whole-sample parameters including the weight fraction W_α for phase α (last set of square brackets).

The instrument-related and phase-dependent parameters, including phase density, can be grouped together and defined as a constant $C_{i\alpha}$ for the ith reflection of phase α for a specific set of measurement conditions. This greatly simplifies the relationship between reflection intensity and weight fraction to

$$I_{i\alpha} = C_{i\alpha}\frac{W_\alpha}{\mu_m^*}. \quad (3.9.2)$$

On rearrangement, the weight fraction can be derived from

$$W_\alpha = \frac{I_{i\alpha}\mu_m^*}{C_{i\alpha}}. \quad (3.9.3)$$

Application of equation (3.9.3) (Klug & Alexander, 1974), referred to as the absorption–diffraction method, requires:

(1) the determination of $C_{i\alpha}$ using a rearranged equation (3.9.3) by (i) the preparation of standards with known additions W of phase α_α, (ii) measurement of peak intensity $I_{i\alpha}$ for the standards, and (iii) estimation of the standard sample mass absorption coefficient μ_m^*;

(2) measurement of $I_{i\alpha}$ and estimation of μ_m^* for the unknown samples; and

(3) calculation of W_α *via* equation (3.9.3).

The value of μ_m^* can be estimated by direct measurement of the beam intensity through a sample of known thickness t in a beam of the same wavelength as that used in the XRD data collection. Following measurement of the beam intensity with the sample in (I) and removed from (I_0) the beam, μ_m^* can be calculated using

$$\frac{I}{I_0} = \exp(-\mu_m^*\rho_m t). \quad (3.9.4)$$

However, this usually involves (i) the preparation of an additional, thinner, sample for presentation to the X-ray beam, (ii) in some cases, the addition of a diluent with a low mass absorption coefficient to produce I/I_0 ratios in a range where reasonable accuracy can be achieved, and (iii) knowledge of the 'mass thickness' $\rho_m t$. It should also be noted that there are few commercially available instruments that would be suitable for such measurements due to safety-related issues in accessing the X-ray beam path.

An alternative approach is to calculate μ_m^* from the sum of the products of the theoretical mass absorption coefficient (μ_j^*) of each element (or phase) and the weight fractions (W_j) of all n elements (or phases) in the sample. The elemental composition may be determined, for example, by X-ray fluorescence (XRF) measurement and its use is more accurate than the use of phase composition as it takes into account any amorphous material not represented by peaks in the diffraction pattern but which still contributes to μ_m^*,

$$\mu_m^* = \sum_{j=1}^{n}\mu_j^* W_j. \quad (3.9.5)$$

3.9.3.2. *Internal standard method*

A more general, and experimentally simpler, approach is to eliminate μ_m^* from the analysis altogether *via* the inclusion of an internal standard s in known weight fraction W_s. Substitution of the measured intensity of the jth peak (or group of peaks) of the standard phase, I_{js}, into equation (3.9.2) yields

$$I_{js} = C_{js}\frac{W_s}{\mu_m^*}. \quad (3.9.6)$$

The ratio of equations (3.9.2) and (3.9.6) gives

$$\frac{I_{i\alpha}}{I_{js}} = \frac{C_{i\alpha}}{C_{js}}\frac{W_\alpha}{W_s}. \quad (3.9.7)$$

Since μ_m^* now appears both in the numerator and denominator, its effect on the analysis, and hence the need to measure or calculate it, is removed from the calculation. Rearrangement of equation (3.9.7) yields

$$\frac{I_{i\alpha}}{I_{js}}\frac{W_s}{W_\alpha} = \frac{C_{i\alpha}}{C_{js}} = C_{js}^{i\alpha}, \quad (3.9.8)$$

where $C_{js}^{i\alpha}$ is a calibration constant specific to the phase and internal standard used. Once $C_{js}^{i\alpha}$ has been determined, the weight fraction of the unknown, W_α, can then be determined from

$$W_\alpha = \frac{W_s}{C_{\alpha s}^{ij}}\frac{I_{i\alpha}}{I_{js}}. \quad (3.9.9)$$

This approach, referred to as the *internal standard method*, relies on the determination of $C_{\alpha s}^{ij}$ using known mixtures of standard and analyte phases. The value of $C_{\alpha s}^{ij}$ will be specific to the diffraction peaks used in its determination; if other lines are used in subsequent analysis, then an appropriate value of C will have to be redetermined.

It should be noted that the presence of systematic errors (such as preferred orientation and microabsorption) that influence the measurement of intensity and vary as a function of W_α will not be detected through application of equation (3.9.9). The use of consistent sample-preparation and presentation techniques is required to minimize the effect of these aberrations on the analysis (Zevin & Kimmel, 1995).

3.9.3.2.1. *Selection of an internal standard*

The selection of an appropriate material for use as an internal standard for QPA is not always straightforward. Ideally, the material selected should:

(1) Have a simple diffraction pattern resulting in minimal overlap with peaks of interest in the sample.

(2) Have a mass absorption coefficient similar to that of the sample to avoid introducing microabsorption effects and thus reducing accuracy.

(3) Have minimal sample-related aberrations that may affect observed intensities. For example, it should be fine-grained to ensure minimal grain-size effects on the observed intensities and not be subject to preferred orientation. Importantly, it should have 100% (or known) crystallinity.

(4) Be stable over an extended time and be unreactive, especially for *in situ* studies where it may be subjected to extreme conditions.

Some possibilities for use as internal standard include α-Al_2O_3 (corundum), TiO_2 (rutile), ZnO (zincite), Cr_2O_3 (eskolaite), α-Fe_2O_3 (haematite), CeO_2 (cerianite), CaF_2 (fluorite) and C (diamond). Cline *et al.* (2011) have described the certification of the standard reference material SRM 676a with accurately known amorphous content for use as an internal standard for QPA (see Chapter 3.1). Alternatively, it is possible to use an independent measure (*e.g.* chemical analysis) to derive the concentration of a phase already present in the sample and then to designate it as the internal standard.

Selection of the amount of internal standard to add is often based on folklore or local practices with reported additions ranging from 5 to 50 wt%. Westphal *et al.* (2009) have described the mathematical basis for selecting the optimal internal standard addition in the context of amorphous phase determination. The amount of internal standard added has a strong influence on the precision of the determination of amorphous content and ‘a poor choice can make determination impossible, while a clever choice can enhance the precision’.

With the exception of diamond, all of the phases listed above tend to have absorption coefficients that are too high for use with organic materials. The development and verification of a suitable low-absorption-coefficient standard material that meets the criteria given above remains an important area of research.

3.9.3.3. *Reference intensity ratio methods*

The reference intensity ratio (RIR) (Hubbard *et al.*, 1976; Hubbard & Snyder, 1988) is an instrument-independent phase constant developed specifically for use in quantitative phase analysis and is defined as the ratio of strongest peak of phase α to the strongest peak of standard s. The RIR can be derived directly from equation (3.9.8):

$$\mathrm{RIR}_{\alpha s} = C_{js}^{i\alpha} = \frac{I_{i\alpha}}{I_{js}} \frac{W_s}{W_\alpha}. \tag{3.9.10}$$

In some cases, the strongest lines of either the standard or phase of interest may not be accessible for measurement if, for example, they strongly overlap with peaks from another phase or if they are out of the 2θ range considered. Equation (3.9.10) can be generalized (Hubbard & Snyder, 1988) to use less intense peaks while keeping the same value of RIR:

$$\frac{I_{i\alpha}}{I_{js}} \frac{I_{js}^{\mathrm{rel}}}{I_{i\alpha}^{\mathrm{rel}}} \frac{W_s}{W_\alpha} = \mathrm{RIR}_{\alpha s}, \tag{3.9.11}$$

where I^{rel} is the ratio of the intensity of the peak used for analysis to the most intense peak for the phase. $\mathrm{RIR}_{\alpha,s}$ is now the generalized reference intensity ratio for phase α with respect to standard s.

Quantification of the unknown phase in the presence of a known standard addition can be achieved by the rearrangement of equation (3.9.11):

$$W_\alpha = \frac{I_{i\alpha}}{I_{js}} \frac{I_{js}^{\mathrm{rel}}}{I_{i\alpha}^{\mathrm{rel}}} \frac{W_s}{\mathrm{RIR}_{\alpha s}}. \tag{3.9.12}$$

The generally accepted reference material for QPA *via* the RIR method is corundum because of its relatively simple diffraction pattern, stability and availability as a highly crystalline and pure single phase. If corundum is used, the RIR equates to I/I_c (or ‘I over I corundum’) for the phase; these are the most commonly reported values in the literature.

RIRs can be determined either by (i) calculation using published crystal-structure information with Rietveld analysis software set to pattern-calculation mode, or (ii) direct measurement by taking the ratio of the strongest peak of the pattern to the intensity of the strongest peak of corundum in a 50/50 weight mixture [or through use of equation (3.9.11) for non-equal proportions]. However, for some phases, there can be ambiguity about which peak is the most intense. For example, the 104 (2.551 Å) and 113 (2.085 Å) peaks of corundum have very similar observed intensities, as do the 111 (3.154 Å) and 022 (1.932 Å) peaks of fluorite. This may lead the analyst to select a peak different from that chosen for reported RIR values.

Collated lists of RIR values for frequently encountered phases can be found in the ICDD database (Fawcett *et al.*, 2017) and Smith *et al.* (1987). It is important to note, however, that the user must be very careful when selecting an appropriate RIR value for their particular experiment. The values of RIR will depend upon the data-collection and measurement strategy employed (for example, peak height, integrated peak area, whole pattern, X-ray wavelength employed and so on) in their derivation. This must match the conditions used in the experiment to which the value is to be applied. In general, RIR values should be determined for the material currently being studied using the methodologies employed rather than relying on published values. Greater accuracy will be achieved if the relative intensities are determined as part of the calibration process using pure samples of the phase and standard or, preferably, samples in which the phases of interest have high and known concentration. If published values of RIR are used, then the determined phase abundances must be referred to as being only semi-quantitative.

3.9.3.4. *Matrix-flushing method*

An important feature of RIR-based techniques is that, once the RIRs are determined for the analyte phases of interest, the standard phase does not need to be present in the sample. The effect of the sample mass absorption coefficient is also removed by taking the ratio of the intensity of phase α to another unknown phase β. Hence the ratio of the weight fractions of the two phases can be derived from

$$\frac{W_\alpha}{W_\beta} = \frac{I_{i\alpha}}{I_{j\beta}} \frac{I_{j\beta}^{\mathrm{rel}}}{I_{i\alpha}^{\mathrm{rel}}} \frac{\mathrm{RIR}_{\beta s}}{\mathrm{RIR}_{\alpha s}}. \tag{3.9.13}$$

For a system comprising n phases, equation (3.9.13) allows the derivation of $n-1$ weight fraction ratios. Chung (1974*a*,*b*) has demonstrated that, if all components are crystalline and included in the analysis, an additional constraint of the following form can be included:

$$\sum_{k=1}^{n} W_k = 1.0. \tag{3.9.14}$$

This forms a system of n linear equations which can be solved to give the weight fractions of all components in the analysis according to (Chung, 1974*a*,*b*; Snyder & Bish, 1989)

$$W_\alpha = \frac{I_\alpha}{\mathrm{RIR}_{\alpha s} I_\alpha^{\mathrm{rel}}} \left(\sum_{k=1}^{n} \frac{I_k}{\mathrm{RIR}_{ks} I_k^{\mathrm{rel}}} \right)^{-1}. \tag{3.9.15}$$

The weight fractions analysed *via* this method are correct relative to each other but may not be correct in an absolute sense if unidentified or amorphous materials are present in the sample. In this case, the reported phase abundances will be overestimated. The addition of an internal standard to the system, or knowledge of the amount of a component phase determined by another technique, allows calculation of the absolute amount $W_{\alpha(\mathrm{abs})}$ of each phase [equation (3.9.16)] and thus the derivation of the amount W_{unk} of unknown (amorphous and/or unidentified) components [equation (3.9.17)].

$$W_{\alpha(\mathrm{abs})} = W_\alpha \times \frac{W_{\mathrm{std(known)}}}{W_{\mathrm{std(meas)}}}, \tag{3.9.16}$$

$$W_{\mathrm{unk}} = 1.0 - \sum_{k=1}^{n} W_{k(\mathrm{abs})}, \tag{3.9.17}$$

where $W_{\alpha(\mathrm{abs})}$ is the absolute weight fraction of phase α, $W_{\mathrm{std(known)}}$ is the known weight fraction of the standard added to the sample, $W_{\mathrm{std(meas)}}$ is the weight fraction of the standard reported by equation (3.9.15) and $W_{\rm unk}$ is the weight fraction of the unidentified and/or amorphous component in the mixture.

If an internal standard has been used, then initial calculation of its concentration *via* equation (3.9.15) may be:

(i) the same as the weighed amount, indicating that there are unlikely to be amorphous or unidentified phases present;

(ii) greater than the weighed amount, indicating that amorphous or unidentified phases may be present; or

(iii) less than the weighed amount, indicating operator error or the use of invalid RIR or $I^{\rm rel}$ values.

3.9.3.5. *Full-pattern fitting methods*

The quantitative XRD techniques described above have traditionally been applied using phase intensity estimates derived from either single peaks or a small group of peaks. This approach can be effective when there is minimal peak overlap but becomes less useful in complex phase systems where it may be difficult to identify freestanding peaks in the pattern. In addition, the presence of sample-related effects such as preferred orientation skew the measured intensities from what would be expected from an ideal powder diffraction pattern, thus reducing the expected accuracy.

Some of these effects can be partially overcome by using full-pattern fitting methods (Smith *et al.*, 1987; Batchelder & Cressey, 1998; Chipera & Bish, 2002, 2013; Eberl, 2003; Toraya & Tsusaka, 1995; Cressey & Schofield, 1996), where wide-range diffraction patterns of phases of interest are scaled, summed and compared with the observed diffraction data in a least-squares minimization process. The method relies on the generation of a library of standard patterns for each phase expected in the analysis collected under the same instrumental conditions as those used in subsequent analyses. The selection of standards that are a good match for the phases in the unknown sample is a critically important step. While the library will normally contain patterns of well ordered phases, it can also include patterns for less well ordered material such as glasses, polymers, clay minerals and gels, thus allowing their direct quantification. Where it is not possible to obtain a measured pattern, calculated patterns may also be included in the library.

Weight fractions are obtained by the solution of simultaneous equations that take into account the scale factors of the individual components and the mass absorption coefficients derived from knowledge of the elemental composition of each phase.

Alternatively, the contribution of library patterns to observed data can be normalized by scaling phases to an internal standard, typically corundum, using an RIR approach. Given the compositional and structural variability of some phases, especially in mineralogical applications, RIRs measured using the same minerals as those to be analysed are preferred to reported RIRs. Toraya (Toraya 2016*a*,*b*) has devised a QPA method which uses observed integrated peaks intensities measured of a wide 2θ range. Phase calibration constants are calculated using only their chemical formula weight and the sum of the square of the number of electrons in the formula unit. While the method is effective for wide-range data, it cannot be applied to single-peak data or data that cover only a limited 2θ range.

The full-pattern fitting method is relatively easy to use and can be applied to difficult samples containing highly disordered materials. For some disordered phases where no crystal structure is available and where peak overlap means that individual peak intensities cannot be measured, full-pattern fitting may be the most appropriate approach to QPA. The major limitations of the method include the need (i) to define and subtract the pattern background, with a subsequent impact on QPA, and (ii) to obtain or generate a library of standard patterns of the phases of interest. The use of an internal standard is recommended and the method is best applied when all standard patterns have first been normalized to an internal standard intensity (Chipera & Bish, 2002, 2013).

3.9.3.6. *Rietveld-based QPA*

The advent of the Rietveld method (Rietveld, 1969) and its extension into the field of QPA (Bish & Howard, 1988; Hill, 1983; Hill & Howard, 1987; O'Connor & Raven, 1988; Taylor, 1991) has brought some significant benefits when compared with the conventional single-peak and pattern-addition methods. Recent surveys (Madsen *et al.*, 2001; Scarlett *et al.*, 2002) show that the majority of participants, greater than 75%, use a Rietveld-based approach for QPA. The benefits derive from (Hill, 1991; Kaduk, 2000):

(i) The use of the entire diffraction pattern. Depending on the 2θ range of the data and the crystallography of the component phases, this may involve hundreds or thousands of reflections rather than the few peaks in conventional methods. This helps to minimize the impact of some systematic sample-related effects such as preferred orientation and extinction.

(ii) The ability to accurately deconvolute overlapping peaks to extract the component intensities, thus allowing more complex patterns to be analysed. The development of fundamental-parameters models (Bergmann *et al.*, 1998, 2000; Cheary & Coelho, 1992; Cheary *et al.*, 2004), which aim to distinguish instrument from sample contributions to the diffraction pattern, minimizes the number of profile parameters that need to be refined, further enhancing this profile-fitting step.

(iii) Refinement of the crystal structure, when supported by the data, to minimize differences between the intensities in the calculated and observed patterns. This brings additional information such as systematic changes in structure parameters from published data.

(iv) The ability to model some remaining systematic effects such as preferred orientation or anisotropic crystallite size/strain peak broadening.

The Rietveld method uses a least-squares procedure to minimize the difference between a calculated pattern and the measured data. The calculated pattern is derived from a model containing crystal-structure information for each phase included in the analysis, convoluted with expressions describing peak shape and width, along with functions to correct systematic variances such as preferred orientation. The calculated pattern is multiplied by an overall scaling factor which may be equated to the peak intensities ($I_{i\alpha}$) considered by the single-peak methods. The Rietveld scale factor for phase α, S_α, can be defined as (Bish & Howard, 1988; Hill, 1991; Hill & Howard, 1987; O'Connor & Raven, 1988)

$$S_\alpha = \left[\frac{K}{V_\alpha^2}\right]\left[\frac{W_\alpha}{\rho_\alpha}\right]\frac{1}{2\mu_m^*}, \qquad (3.9.18)$$

where K is an 'experiment constant' used to put W_α on an absolute basis, and V_α, W_α and ρ_α are the volume of the unit cell, the weight fraction and the density for phase α, respectively.

Since equation (3.9.18) inherently contains the weight-fraction information, it can be rearranged to derive W_α:

$$W_\alpha = \frac{S_\alpha \rho_\alpha V_\alpha^2 \mu_m^*}{K}. \qquad (3.9.19)$$

O'Connor & Raven (1988) and Bish & Howard (1988) have shown that K is dependent only on the instrumental conditions and is independent of individual phase and overall sample-related parameters. Therefore a single measurement is sufficient to determine K for a given instrument configuration and set of data-collection conditions. Determination of K may be carried out by (i) a measurement of either a pure phase, or a phase of known proportion in a mixture, separately from the measurement of the actual unknown mixture, or (ii) using a phase that is present in the sample in a known amount. The value of K calculated in this way will be appropriate for the calibration of subsequent measurements as long as all instrumental and data-collection conditions remain the same as those used in its determination.

For each phase, the density ρ_α can be calculated from the published (or refined) crystal-structure information using

$$\rho_\alpha = \frac{ZM_\alpha}{V_\alpha}, \qquad (3.9.20)$$

where ZM is the mass of the unit-cell contents (Z is the number of formula units in the unit cell and M is the molecular mass of the formula unit) and V is the unit-cell volume.[2]

Substitution of equation (3.9.20) in equation (3.9.19) shows that

$$W_\alpha = \frac{S_\alpha (ZMV)_\alpha \mu_m^*}{K}. \qquad (3.9.21)$$

In this context, $(ZMV)_\alpha$ is the 'phase constant' and can be calculated from published or refined crystal-structure information alone. It is worth noting that, if the crystal structure is refined as part of the analysis, ZMV is updated and hence becomes a dynamic phase constant.

The methodology embodied in equation (3.9.21) is important in many applications in that it produces, within the limits of experimental error, *absolute phase abundances* and is referred to hereafter as the *external standard* approach. While the use of a phase that already exists within the sample to determine K may be considered as an internal standard approach, in some applications, including *in situ* studies, that phase may be removed from the system through, for example, decomposition or dissolution. However, the value of K remains valid for subsequent determination of phase abundances provided that the instrumental and data-collection conditions do not change.

Equation (3.9.21) is directly applicable to the analysis of those phases for which detailed crystal-structure information is available. For phases where only a partial structure (for example, an indexed unit cell but no atom coordinates or site-occupation factors) is available, an empirical ZMV can be derived using mixtures of the phase of interest with known amounts of a well characterized standard (Scarlett & Madsen, 2006). QPA of phases with partial structure is also possible through the use of equation (3.9.19), but an estimate of the phase density, obtained through direct measurement, is required.

The limitations of the approach embodied in equations (3.9.19) and (3.9.21) derive from the need to (i) conduct a measurement of K and (ii) estimate the value of the mass absorption coefficient μ_m^* for the sample(s) used to determine K, as well as for each sample of interest. However, similar to the earlier discussion about the single-peak methods, μ_m^* can be determined by direct measurement or calculation using equations (3.9.4) or (3.9.5), respectively. The benefits that can be derived from the extraction of the absolute, rather than relative, phase abundances, make it worth pursuing in many analytical situations. For example, in time-resolved studies where phases transform and material is lost in the course of reaction, the calculation of relative abundances summed to 100% may give a misleading impression of increased amounts of the remaining phases.

In some diffraction instruments, there may be decay in the incident-beam intensity during the course of measurement. This may happen on the timescale of months for a laboratory-based instrument owing to X-ray tube ageing, or on the scale of minutes at a synchrotron instrument where the storage-ring current is only refreshed once or twice per day. In this case, the change in incident intensity can be taken into account by incorporating an additional term into equation (3.9.21):

$$W_{\alpha i} = \frac{S_{\alpha i} (ZMV)_\alpha \mu_m^*}{K} \frac{I_0}{I_i}, \qquad (3.9.22)$$

where I_0 and I_i are the incident beam intensities present during the determination of K and the collection of data set i, respectively.

The need to measure K, and measure or calculate μ_m^*, serves to increase the overall experimental difficulty and can be eliminated in ways analogous to those used in the single-peak methodology described earlier. For a simple two-phase mixture where both phases, α and β, are 100% crystalline, the sum of their weight fractions W_α and W_β equals unity and can be expressed as (Bish & Howard, 1988)

$$W_\alpha = \frac{W_\alpha}{W_\alpha + W_\beta}. \qquad (3.9.23)$$

Substitution of equation (3.9.21) for phases α and β in equation (3.9.23) results in

$$W_\alpha = \frac{S_\alpha (ZMV)_\alpha}{S_\alpha (ZMV)_\alpha + S_\beta (ZMV)_\beta}. \qquad (3.9.24)$$

Alternatively, in a multiphase sample, the addition of an internal standard s in known amount W_s and taking the ratio of equation (3.9.21) for analyte and standard phases provides the relationship

$$W_\alpha = W_s \frac{S_\alpha (ZMV)_\alpha}{S_s (ZMV)_s}. \qquad (3.9.25)$$

The method embodied in equation (3.9.25) is analogous to the *internal standard* approach in equation (3.9.9) and also serves to produce *absolute phase abundances* $W_{\alpha(\text{abs})}$. Once again, the benefit accruing from the use of absolute phase abundances is the ability to estimate the presence and amount of any amorphous and/or unidentified phases $W_{(\text{unk})}$ through application of equations (3.9.16) and (3.9.17).

Hill & Howard (1987) and Bish & Howard (1988) have adapted the matrix-flushing method of Chung (1974*a*,*b*) to the Rietveld analysis context. By constraining the sum of the analysed weight fractions to the assumed concentration of the crystalline components (usually unity), the weight fraction of phase α in an n-phase mixture is given by the relationship[3]

---

[2] When calculating phase density from crystallographic parameters, a factor of $1.6604 = 10^{24}/6.022 \times 10^{23}$ is needed to convert ρ in a.m.u. Å^{-3} to g cm^{-3}.

[3] It should be noted that the implementation of the matrix-flushing method by Bish and Howard retains the use of phase density, but their approach is essentially the same as that of Hill and Howard.

$$W_\alpha = \frac{S_\alpha(ZMV)_\alpha}{\sum_{k=1}^{n} S_k(ZMV)_k}. \qquad (3.9.26)$$

The use of equation (3.9.26) in QPA again eliminates the need to measure the instrument calibration constant and estimate the sample mass absorption coefficient. However, the necessity of normalizing the sum of the analysed weight fractions to unity only produces the correct *relative phase abundances*. This approach is the most widely used in Rietveld-based QPA and is almost universally coded into Rietveld analysis programs. If the sample contains amorphous phases and/or minor amounts of unidentified crystalline phases, the analysed weight fractions will be overestimated. Where absolute phase abundances are required in, for example, the derivation of reaction mechanisms in *in situ* studies, then one of the methods that produces absolute phase abundances must be used.

3.9.4. Demonstration of methods

The sample 1 suite from the IUCr Commission on Powder Diffraction (CPD) round robin on QPA (Madsen *et al.*, 2001) provides a useful basis for demonstrating the applicability some of the methods described above. Sample 1 was designed to provide a relatively simple analytical system in order to determine the levels of accuracy and precision that could be expected under ideal conditions. The key design criteria required that the phases exhibit little peak overlap in the low-angle region of the diffraction pattern and the samples have at least one freestanding peak for each phase in the *d*-spacing range 3.7 to 1.9 Å.

The three components (corundum, α-Al_2O_3; fluorite, CaF_2; and zincite, ZnO) were prepared in a ternary design to provide a total of eight different mixtures in order to cover as wide a range of composition as possible for each phase. The result is that each phase is present in the suite with concentrations of approximately 1, 4, 15, 33, 55 and 95 wt%. The exact compositions (Madsen *et al.*, 2001) can be found in Table 3.9.1. The unique chemical composition of the component phases also allowed the weighed compositions to be confirmed by measurement of total elemental composition using X-ray fluorescence (XRF) methods.

Data sets were collected from three replicates of the eight mixtures using a Philips X'Pert diffractometer equipped with a Cu long fine focus tube operated at 40 kV and 40 mA. The beam path was defined with 1° divergence, 0.3 mm receiving and 1° scatter slits. A curved graphite post-diffraction monochromator was fitted to eliminate $K\beta$ radiation. Data were collected from 15 to 145° 2θ in increments of 0.02° using a counting time of 1.5 s per step. These data sets are available as supporting information from http://it.iucr.org/ for any reader wishing to develop and test their skills in various methods.

For the single-peak methods, the net intensity for all peaks in the range 22 to 65° 2θ was extracted using a fundamental-parameters approach to peak fitting coded in the *TOPAS* software package (Bruker AXS, 2013). The choice of peak profile type is important, since any misfit will be reflected in the estimation of peak area and hence in the QPA. Unless otherwise stated, QPA was undertaken using the strongest peak in the pattern for each phase (corundum 113, d = 2.085 Å; fluorite 022, d = 1.932 Å; zincite 011, d = 2.476 Å). The average values for these peaks can be found in Table 3.9.2. For those methods requiring knowledge of the mass absorption coefficient, μ_m^* for each sample was calculated from the XRF chemical analysis results.

Table 3.9.1
Weighed composition (weight fraction) of the eight mixtures comprising sample 1 in the IUCr CPD round robin on QPA (Madsen *et al.*, 2001)

Sample	Corundum	Fluorite	Zincite
1A	0.0115	0.9481	0.0404
1B	0.9431	0.0433	0.0136
1C	0.0504	0.0136	0.9359
1D	0.1353	0.5358	0.3289
1E	0.5512	0.2962	0.1525
1F	0.2706	0.1772	0.5522
1G	0.3137	0.3442	0.3421
1H	0.3512	0.3469	0.3019

Table 3.9.2
Average values (n = 3) of net peak intensity derived using profile fitting for the strongest peaks of corundum (113), fluorite (022) and zincite (011)

The figures in parentheses are the standard deviations of the means. The sample mass absorption coefficient μ_m^* was calculated from the XRF-L determined composition.

Sample	Corundum	Fluorite	Zincite	μ_m^* (cm^2 g^{-1})
1A	34.8 (0.6)	8958.7 (33.0)	509.9 (6.0)	93.02
1B	6561.3 (28.6)	1095.5 (7.1)	474.3 (3.8)	34.45
1C	244.4 (0.9)	250.9 (10.1)	22898.0 (37.0)	49.03
1D	474.5 (3.5)	6559.6 (2.8)	5468.5 (9.5)	71.71
1E	2525.3 (27.9)	4835.5 (27.0)	3370.7 (16.3)	53.17
1F	1251.3 (7.8)	2935.8 (9.0)	12494.9 (22.4)	52.67
1G	1295.0 (8.7)	5041.7 (17.0)	6787.9 (26.6)	59.64
1H	1436.5 (7.3)	5132.0 (13.6)	5996.8 (59.5)	59.10

3.9.4.1. *Absorption–diffraction method*

In this method, the QPA of each phase is conducted independently of the others. For each phase, the determination of a specific calibration constant, C, was achieved using a rearranged equation (3.9.3). The sample where the relevant phase was present at about 55 wt% (sample 1E for corundum, 1D for fluorite and 1F for zincite) was taken to be the calibration sample.

For fluorite the determination of C proceeded using

$$C_{i,\alpha} = I_{i,\alpha}\frac{\mu_m^*}{W_\alpha} = 6559.6 \times \frac{71.71}{0.5358} = 877\,919. \qquad (3.9.27)$$

All data sets were then analysed using equation (3.9.3), as demonstrated here using sample 1H.

$$W_\alpha = I_{i,\alpha}\frac{\mu_m^*}{C_{i,\alpha}} = 5132.0 \times \frac{59.1}{877919} = 0.3455, \qquad (3.9.28)$$

compared with a value of 0.3469 added to the sample by weight. Fig. 3.9.1 shows the analysed concentration for all 24 fluorite measurements along with the bias from the known values. The bias (analysed − known) all fall within the range −0.3 to 0.5 wt% with no systematic bias as a function of concentration. The similar results achieved for corundum and zincite demonstrate the validity of the approach where there is minimal peak overlap.

3.9.4.2. *Internal standard method*

Application of the internal standard method normally requires the addition of an appropriate phase in known amount to each sample to be analysed. In order to use this data for demonstration of the internal standard method, it is necessary to designate one of the existing phases as the internal standard. Sample 1H has been used to derive the calibration constant, with fluorite considered to be the phase of interest while zincite is designated as the internal standard. The intensities (Table 3.9.2) and known concentrations (Table 3.9.1) of these phases can then be used to derive $C^{ij}_{\alpha s}$ from equation (3.9.8) to eliminate the need to know or measure μ^*_m for the sample.

$$\frac{I_{\text{fluorite}}}{I_{\text{zincite}}}\frac{W_{\text{zincite}}}{W_{\text{fluorite}}} = C^{ij}_{\alpha s} = \frac{5132.0}{5996.8}\times\frac{0.3019}{0.3469} = 0.7448. \qquad (3.9.29)$$

Analysis of the unknowns (Fig. 3.9.2) then proceeds *via* equation (3.9.9) and is demonstrated here using sample 1D:

$$W_{\text{fluorite}} = \frac{W_{\text{zincite}}}{C^{ij}_{\alpha s}}\frac{I_{\text{fluorite}}}{I_{\text{zincite}}} = \frac{0.3289}{0.7448}\frac{6559.6}{5468.5} = 0.5297, \qquad (3.9.30)$$

compared with a value of 0.5358 added to the sample by weight.

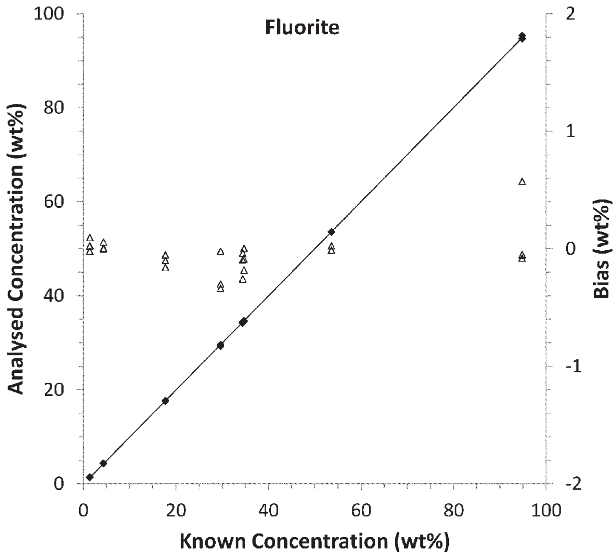

Figure 3.9.1
Plot of the analysed concentration (black diamonds – left axis) and the bias (open triangles – right axis) expressed as wt% for fluorite using the absorption–diffraction method. The analysis was calibrated using sample 1D, which has a fluorite concentration of 53.58 wt%.

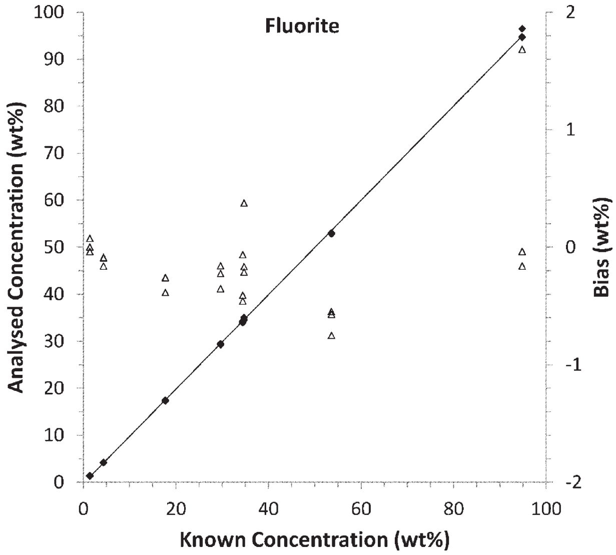

Figure 3.9.2
Plot of the analysed concentration (black diamonds – left axis) and the bias (open triangles – right axis) expressed as wt% for fluorite using the internal standard method with zincite designated as the internal standard. The analysis was calibrated using sample 1H where the fluorite and zincite concentrations are 34.69 and 30.19 wt%, respectively.

3.9.4.3. *Reference intensity ratio*

For this exercise, the peak intensities and phase concentrations in Tables 3.9.1 and 3.9.2 for sample 1H can be used to determine the RIRs for fluorite and zincite.

$$\text{RIR}_{\text{fluorite}} = \frac{5132.0}{1436.5}\times\frac{0.3512}{0.3469} = 3.617, \qquad (3.9.31)$$

$$\text{RIR}_{\text{zincite}} = \frac{5996.8}{1436.5}\times\frac{0.3512}{0.3019} = 4.856. \qquad (3.9.32)$$

These RIRs should be compared with reported values for fluorite in the ICDD database (ICDD, 2015) which have an average of 3.83 (n = 33) but range from 2.40 to 4.21. For zincite the reported RIR values have an average of 5.24 (n = 50) and range from 4.50 to 5.87. The discrepancies in the various reported values of the RIRs highlight the need to determine them under the same conditions as the samples being analysed if the highest accuracy is to be achieved.

Fig. 3.9.3 shows the RIR values calculated from all 24 (eight samples, three replicates each) measurements for fluorite and zincite plotted as a function of corundum concentration. At intermediate concentrations there is quite good agreement between the determined values. However, there are significant deviations at low corundum concentration, resulting in insufficient measured intensity in the corundum peak to ensure sufficient accuracy in the RIR. Hence, care should be taken to ensure that there are sufficient counts in the peaks used to determine the RIR. In addition, a low concentration automatically means that there are fewer grains contributing to the diffraction process; hence particle statistics may also present a significant problem.

The presence of other sample-related aberrations that affect the measured intensities also needs to be considered. For example, microabsorption may affect measured RIR values differently in different concentration ranges. The impact of such effects on the analysis is reduced by their inclusion in the measured RIR provided that variation induced by, for example, sample preparation can be kept to a minimum.

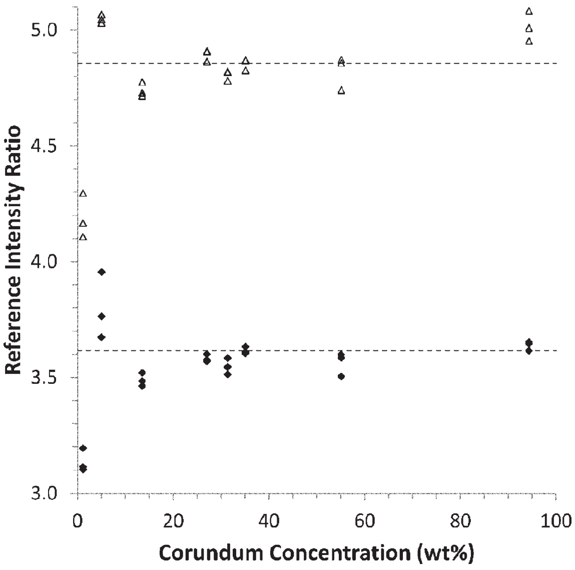

Figure 3.9.3
Plot of the 24 determined RIR values for fluorite (black diamonds) and zincite (open triangles) as a function of corundum concentration. The dashed lines represent the average RIR values for fluorite (lower) and zincite (upper) determined from the three replicates of sample 1H where all phases have approximately equal concentration.

3.9.4.4. *Matrix flushing*

Once the correct value of RIR is determined for each phase, the matrix-flushing method can be applied using equation (3.9.15). For fluorite in sample 1D, the calculation proceeds as follows:

$$\begin{aligned} W_{\rm fluorite} &= \frac{I_{\rm fluorite}/{\rm RIR}_{\rm fluorite}}{\sum_{k=1}^{n} I_k/{\rm RIR}_{ks}} \\ &= \frac{6559.6/3.617}{474.5/1.0 + 6559.6/3.617 + 5468.5/4.856} = 0.5312, \end{aligned} \tag{3.9.33}$$

compared with a value of 0.5358 added to the sample by weight. Fig. 3.9.4 shows the bias for fluorite in all samples analysed by the matrix-flushing method. Once again, there is good agreement between the weighed and analysed amounts. However, it is worth reiterating that this method normalizes the sum of all analysed weight fractions to unity. If amorphous or non-analysed phases are present in the sample, then the weight fractions will be overestimated relative to their absolute abundances.

3.9.4.5. *Rietveld-based methods*

The strengths and weaknesses of some of the methods described in Section 3.9.3 are highlighted through a study of the mechanism and kinetics of nucleation and crystal growth in the context of the Bayer process for the extraction of aluminium from bauxite ores (Webster *et al.*, 2010). Specifically, the experiments utilize synthetic Bayer liquors, consisting of Al-loaded caustic solutions to which a variety of seed material is added. Several polymorphs of $Al(OH)_3$ (gibbsite, bayerite and nordstrandite) crystallize from solution onto the seed material. The rate of crystallization and the ratio of the phases formed depend on the sample conditions used, including the Al and caustic concentrations in solution, as well as sample temperature.

The mechanism and rate of crystallization were followed by collecting XRD data at the powder-diffraction beamline of the Australian Synchrotron[4] over a period of about 3 h. The diffractometer incorporates a Mythen detector (Schmitt *et al.*, 2003) which allows for the simultaneous collection of 80° 2θ of the diffraction pattern. A wavelength of 0.826 Å was used to ensure adequate penetration of the beam in the sample. The sample environment (Madsen *et al.*, 2005; Norby *et al.*, 1998) consisted of a 1-mm quartz glass capillary containing a slurry of the seed and Bayer liquor heated to temperatures between 333 and 348 K using a hot-air blower.

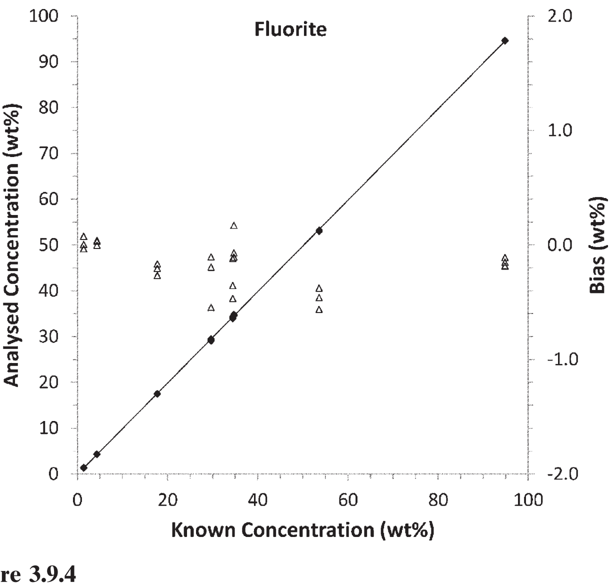

Figure 3.9.4
Plot of the analysed concentration (black diamonds – left axis) and the bias (open triangles – right axis) expressed as wt% for fluorite using the matrix-flushing method with RIRs of 1.0, 3.617 and 4.856 for corundum, fluorite and zincite, respectively. The RIRs were determined using sample 1H where the corundum, fluorite and zincite concentrations are 35.12, 34.69 and 30.19 wt%, respectively.

The data were analysed using *TOPAS* (Bruker AXS, 2013), where a learned-profile approach to peak modelling was used with an empirical instrument width and shape contribution determined using the NIST SRM660 LaB_6 profile standard. For the samples in the study, refined parameters included 2θ zero offset, a Chebychev polynomial pattern background and, for each phase, the Rietveld scale factor, crystallite size and strain, and unit-cell dimensions.

A number of different approaches were used to extract the phase abundances at each stage of the reaction. Initially, QPA was derived using equation (3.9.26); the value that many Rietveld analysis programs output as their first estimate of phase abundance. Fig. 3.9.5 shows the QPA output from an *in situ* experiment in which goethite (FeOOH) was added as the seed.

At the start of the experiment, prior to the crystallization of any of the $Al(OH)_3$ polymorphs, Fig. 3.9.5 shows that the reported concentration of the goethite seed is 100 wt% since it is the only phase represented in the analysis at that time. On formation of gibbsite, bayerite and nordstrandite, the goethite concentration appears to decrease progressively to about 65 wt% while the total $Al(OH)_3$ concentration reaches about 35 wt% at the end of the experiment. However, these figures are in disagreement with (i) the fact that goethite is unlikely to dissolve or otherwise be consumed in this system (Murray *et al.*, 2009), (ii) the known addition of goethite to the sample (14.13 wt%) and (iii) the total amount of $Al(OH)_3$ available from solution (15.92 wt%). The problem with the QPA in this case arises from the fact that only the crystalline components are considered in the analysis and that equation (3.9.26) normalizes the sum of their analysed weight fractions to unity. However, aluminium, which is in solution at the start of the run, forms crystalline phases continuously throughout the reaction after an initial induction period. In order to overcome the anomalies in the QPA results, it is necessary to consider the sample as a whole; that is, the concentration of both the solid and liquid components in the X-ray beam for the duration of the experiment.

In this sample, the concentration of the goethite seed was 14.13 wt% in the slurry injected into the sample capillary. If the assumption is made that, in this environment, goethite is unreactive and its concentration will not change during the reaction, it can be used as an internal standard to put the $Al(OH)_3$ concentrations on an absolute basis. The QPA results derived using the internal standard or 'spiked' approach in equation (3.9.25) are shown in Fig. 3.9.6.

The goethite concentration is fixed at the known addition (14.13 wt%) at the start of the experiment. However, the concentrations of the $Al(OH)_3$ polymorphs are now put on an absolute scale, thus allowing derivation of more meaningful reaction mechanisms.

If, however, there is residual doubt about the reactivity of the goethite, it may be necessary to use the external standard approach embodied in equation (3.9.21). In this case, the value for the instrument constant, K, can be derived using the Rietveld scale factor, ZMV and the known addition of goethite in a rearranged equation (3.9.21). For this determination, the goethite scale factor from the first few data sets, prior to the start of the reaction, was averaged to minimize any errors that may be introduced by counting statistics. The value of the sample mass absorption coefficient μ_m^* was set to an arbitrary value of unity for both the determination of K and all subsequent analyses, since the overall chemical content of the capillary, and hence the attenuation of the X-ray beam, does not change during the reaction.

---

[4] Australian Synchrotron beamtime award number AS091/PD1035.

This experimental work was conducted at the Australian Synchrotron where the storage-ring current was boosted every 12 h. Between these times the current, and hence the incident-beam intensity, decays, resulting in what amounts to a change in the 'instrument configuration'. This requires a modification of the K value and subsequent calculation of concentration to compensate for the changing incident intensity using equation (3.9.22).

Fig. 3.9.7 now shows the results of QPA derived from equation (3.9.22). In this case the concentrations of the $Al(OH)_3$ polymorphs are similar to those in Fig. 3.9.6. However, since the phase abundances are derived using an external standard approach, any changes in the apparent goethite concentration can now be monitored. Fig. 3.9.7 shows that the goethite concentration did not change significantly in the early stages of the experiment ($t < 10$ min) before $Al(OH)_3$ crystallization was observed but there is a small, systematic decrease in the apparent goethite concentration as the experiment progresses. At the end of the experiment, the goethite concentration appears to be lower by about 1% relative to the concentration at the start.

This apparent decrease could be due to a number of causes including (i) poor correction for beam-intensity changes or (ii) solid material moving about in the capillary with some movement out of the X-ray beam. Alternatively, the decrease could be attributed to the 'shielding' of the goethite from the X-ray beam by the $Al(OH)_3$ phases as they form and coat the goethite particles. This decrease could then be used to obtain an average thickness of the $Al(OH)_3$ phases on the seed particles. This layer was calculated to be about 5.5 µm (assuming a linear absorption coefficient of $9.5\ \text{cm}^{-1}$ for gibbsite at 0.826 Å) resulting in an overall particle size of about 11 µm at the end of the run (the goethite particles are about 0.2 × 2 µm and hence do not contribute significantly to the overall particle size). These values are in good agreement with independent studies (Webster *et al.*, 2010) where the gibbsite was examined using scanning electron microscopy (SEM) techniques (Fig. 3.9.8) following crystallization under similar conditions to those used here.

3.9.5. Alternative methods for determination of calibration constants

3.9.5.1. *Standardless determination of the phase constant C*

In order to determine the phase calibration constant C, it is common to obtain (i) a pure sample of the phase of interest that accurately reflects the form of the phase in the samples to be analysed, or (ii) a multiphase sample in which the phase concentration is known by other means (for example, chemical analysis or point counting). In some systems, there may be insufficient sample available to risk 'contaminating' it with an internal standard, especially if the material needs to be analysed using other techniques. The addition of an internal standard may also introduce microabsorption problems or increase the complexity of patterns that are already highly overlapped. For other situations, the time frame demanded for the analysis may prohibit the time-consuming procedures of standard addition, data collection and separate determination of the phase calibration constant.

Zevin & Kimmel (1995) have described an approach to the derivation of phase constants which relies on having a suite of samples to be analysed that (i) have the same phases present in all samples and (ii) exhibit a wide range of composition of these phases in various samples in order to stabilize the analysis. If we reconsider the relationship between the weight fraction W_α and the observed intensity [equation (3.9.3)],

$$W_\alpha = \frac{I_\alpha \mu_m^*}{C_\alpha}, \tag{3.9.34}$$

and assume that all phases in the system are known and included in the analysis, we can introduce the additional constraint that the sum of all W_α's is unity (or at least a known value):

$$\sum_{j=1}^{n} W_j = 1.0. \tag{3.9.35}$$

In a system of n samples containing m phases, we can explicitly write the relationships expressed in equations (3.9.34) and (3.9.35) as a set of simultaneous equations:

$$\begin{aligned}
1.0 &= \frac{1}{C_1} I_{11}\mu_1^* + \frac{1}{C_2} I_{12}\mu_1^* + \ldots + \frac{1}{C_m} I_{1m}\mu_1^*,\\
1.0 &= \frac{1}{C_1} I_{21}\mu_2^* + \frac{1}{C_2} I_{22}\mu_2^* + \ldots + \frac{1}{C_m} I_{2m}\mu_2^*,\\
1.0 &= \frac{1}{C_1} I_{n1}\mu_n^* + \frac{1}{C_2} I_{n2}\mu_n^* + \ldots + \frac{1}{C_m} I_{nm}\mu_n^*,
\end{aligned} \tag{3.9.36}$$

where μ_n^* is the mass absorption coefficient for the nth sample.

Knudsen (1981) has described a modification to this approach by including an internal standard in each of the samples to be analysed and using the ratio of intensities of the analyte and internal standard phases in place of the I_{nm} in equation (3.9.36). While this eliminates the need to determine and use the mass absorption coefficient, the tedious procedure of adding and mixing an internal standard is required for each sample and for reasons described above may not be appropriate.

The relationships embodied in equations (3.9.36) can be expressed more simply in matrix notation as

$$\mathbf{L}' = \mathbf{I}'\mathbf{C}', \tag{3.9.37}$$

where $\mathbf{L}'$ is a column vector (dimensions $1 \times n$) containing the known (or assumed) sum of weight fractions for each sample (unity in this case), $\mathbf{C}'$ is a column vector (dimensions $1 \times m$) containing the calibration constants for each phase and $\mathbf{I}'$ is a rectangular matrix (dimensions n rows × m columns) containing the measured peak intensities (or scale factors) for each phase multiplied by the sample mass absorption coefficient.

A least-squares solution of equation (3.9.37) to derive the value for C for each phase can be calculated using matrix-manipulation methods (Knudsen, 1981):

$$\mathbf{C}' = \left(\mathbf{I}'^T\mathbf{I}'\right)^{-1}\mathbf{I}'^T\mathbf{L}', \tag{3.9.38}$$

where the superscripts T and -1 represent the transpose and inverse matrix functions, respectively.

Accuracy in the calculation of the individual values of C is improved by having (i) phases of the same or similar composition in all samples and (ii) a wide range of concentrations of each phase across the sample suite. These conditions may be met in,

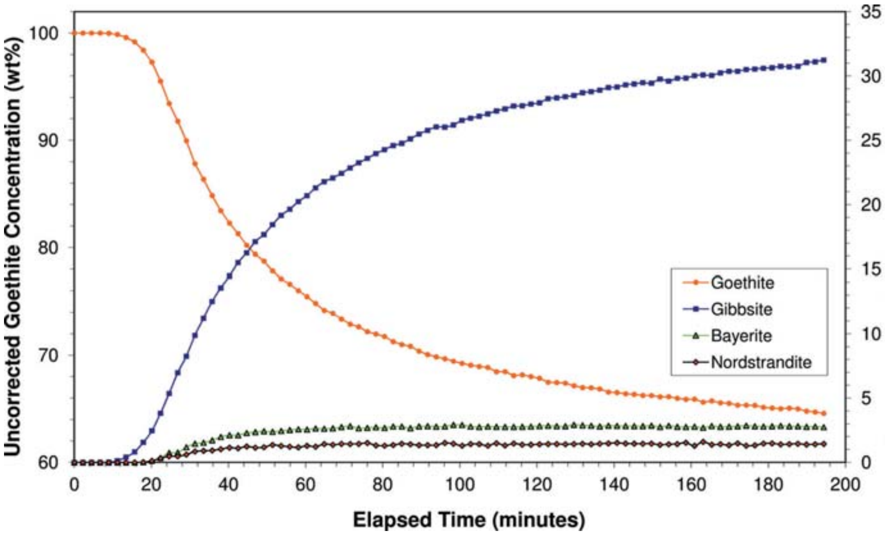

Figure 3.9.5
The results of QPA of the *in situ* XRD data collected during the seeding experiments of Webster *et al.* (2010). The values were derived using the Hill/Howard (Hill & Howard, 1987) relationship in equation (3.9.26). Note the decrease in apparent goethite concentration (left axis) as the polymorphs of Al(OH)$_3$ (right axis) crystallize from solution.

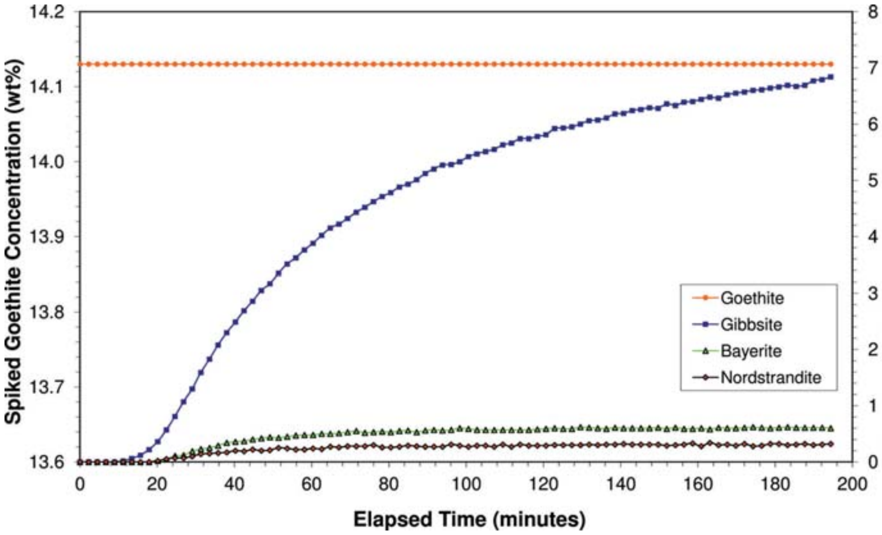

Figure 3.9.6
The results of QPA of the *in situ* XRD data collected during the seeding experiments of Webster *et al.* (2010).The values are absolute phase abundances derived using the internal standard relationship in equation (3.9.25).

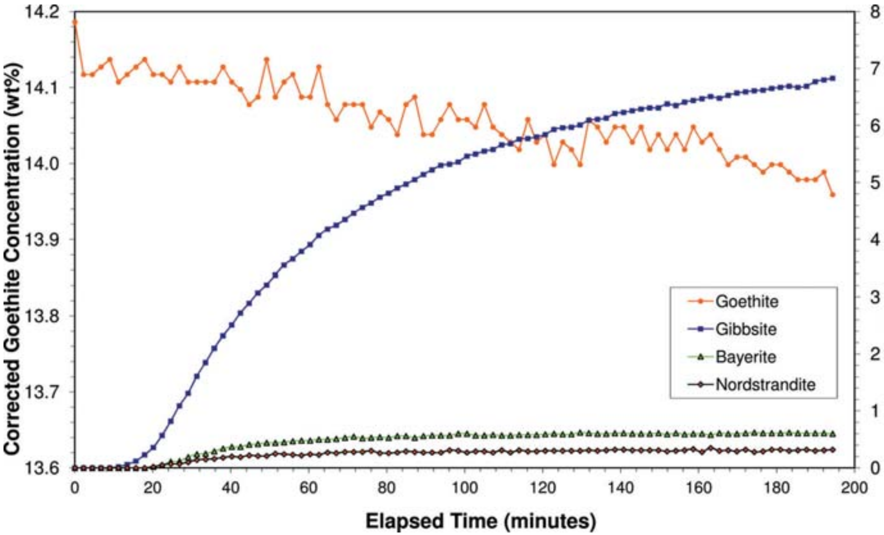

Figure 3.9.7
The results of QPA of the *in situ* XRD data collected during the seeding experiments of Webster *et al.* (2010). The values are absolute phase abundances derived using the external standard relationship in equation (3.9.22). Note the slight decrease in the goethite concentration (left axis) during the run.

for example, mineral exploration samples where a limited number of phases are present in a drill core but their abundance varies as a function of depth. In mineral processing or industrially based material manufacture, the goal is usually to control the system to minimize compositional variation in the product. The side effect of this is that the values of intensity in matrix **I** have too little variation, resulting in large errors in the derived values for C. In the limiting case, the system may become indeterminate with no unique solution available. To overcome this, forced or accidental changes to processing conditions may introduce sufficient compositional variation to stabilize the determination of the C values through equation (3.9.38). Alternatively, physical or chemical separation of selected components may be sufficient to provide the required compositional variation. Knudsen (1981) provides a detailed statistical analysis used in the determination of the errors in the phase constants.

While Zevin (Zevin & Kimmel, 1995) and Knudsen (1981) have demonstrated the application of this approach for single-peak methods, it is equally applicable if scale factors derived from whole-pattern fitting or Rietveld-based methods are used.

3.9.5.2. *Demonstration of the Zevin approach*

The sample 1 suite from the IUCr CPD round robin on QPA again provides an ideal platform for demonstrating the applicability of this method due to the wide variation of concentration of the constituent phases. A measure of intensity was derived using an hkl_phase (see Section 3.9.6) in which the peak positions were constrained to the space group and unit-cell parameters but the individual peak intensities were refined to empirical values using a pure sub-sample of each of the three phases. For the analysis of the samples, the relative peak intensities were fixed and an overall scale factor S for each phase in each sample (eight samples, three replicates, three phases), multiplied by the mass absorption coefficient calculated from the XRF-determined composition, was used as the measure of intensity. These $S\mu_m^*$ values then formed the intensity matrix **I** in equations (3.9.37) and (3.9.38) while all values in the vector **L** were assumed to be 1.0 (*i.e.* all samples were assumed to be fully crystalline). Microsoft Excel provides a useful platform for these calculations since it contains all of the matrix-manipulation functions required by equation (3.9.38). The determined values for C for the three phases are given in Table 3.9.3. The values in the C/C_{corundum} column should be compared with the values derived in Section 3.9.4.3 above.

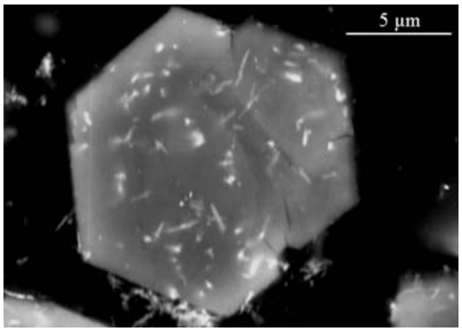

Figure 3.9.8
SEM image of $Al(OH)_3$ (grey hexagon) which has crystallized on goethite seed (light grey needles) (Webster *et al.*, 2010).

Application of these C values to the analysis of all samples *via* equation (3.9.34) yields the results given in Fig. 3.9.9. The results, displayed as bias from the known values, show that at all concentration ranges the analyses are within about ±1% of the weighed values. The important point to note here is that there has been *no prior calibration* conducted to obtain this result; the system is self-calibrating and has only relied on having a wide range of concentrations of the three phases in the sample suite. The only prior knowledge used in the analysis is (i) a measure of peak intensity embodied in the empirical phase scale factor and (ii) an estimate of μ_m^* for each sample calculated from the elemental composition.

3.9.5.3. *Experiment constant – a whole-sample approach*

Earlier discussion has noted that the experiment constant K used in equation (3.9.21) can be determined using (i) a standard pure phase or mixture measured separately from the measurement of the actual unknown mixture being analysed, or (ii) using a phase that is present in the sample in a known amount. However, in some cases, these approaches are not always effective in producing reliable values of K because the methodology assumes that the mass of sample contributing to the diffraction process is constant. While this condition is true for infinitely thick samples in Bragg–Brentano geometry, it is unlikely to be true for capillary or flat-plate samples in transmission geometry. In these cases, the sample thickness and packing density will have a significant influence on the amount of sample contributing to the diffraction process and hence on the observed intensity and the derived values of K. Therefore, a K value determined from one capillary sample is unlikely to be applicable to another capillary even though all other instrumental conditions remain the same. However, for *in situ* studies, a K value determined at the start of an experiment should remain valid as the analysis proceeds.

K can also be determined using the whole sample, rather than an individual phase. Since the determined value of K then applies equally to all phases in the sample, equation (3.9.21) can be summed over all analysed components thus:

$$\sum_{i=1}^{n} W_i = (\mu_m^*/K) \sum_{i=1}^{n} S_i(ZMV)_i. \tag{3.9.39}$$

If the crystallinity of the sample is known (or can safely be assumed), then individual phase abundances are not required and K can be calculated from

$$K = \frac{\mu_m^* \sum_{i=1}^{n} S_i(ZMV)_i}{\sum_{i=1}^{n} W_i}, \tag{3.9.40}$$

where $\sum W_i$ is the assumed crystallinity of the entire sample.

Table 3.9.3
Phase calibration constants for corundum, fluorite and zincite determined using the Zevin (Zevin & Kimmel, 1995) and Knudsen (Knudsen, 1981) method

The RIR values were derived earlier in this chapter.

Phase	C	$C/C_{\rm corundum}$	RIR
Corundum	240.91	1.0	1.0
Fluorite	874.27	3.629	3.617
Zincite	1190.81	4.943	4.856

For a sample that is 100% crystalline and all components included in the analysis, then the denominator is unity and K is simply the sum of the product of the scale factors and their respective ZMV's multiplied by the mass absorption coefficient of the entire sample.

For *in situ* studies where a reaction or process is examined dynamically, sealed capillary sample geometry is frequently used. In this environment, the *chemical* composition of the capillary contents will not change during the course of the reaction even though individual phases may be undergoing transformation. Equation (3.9.40) can be further simplified since the overall sample mass absorption coefficient remains constant throughout the reaction and can therefore be deleted and its effect incorporated into K.

This whole-sample approach to the determination of K is also useful in systems where there are residual errors that may not be evident when equation (3.9.21) is used with the concentration of a single phase. By way of demonstration, the sample 1 suite from the IUCr CPD round robin on QPA has been used to calculate K in two distinct ways:

(1) *Phase specific*: Three replicate measurements of the eight mixtures were analysed using a Rietveld-based surface-analysis approach (Stinton & Evans, 2007). This approach refines a single model to all data sets in the suite simultaneously allowing parameters that are common to all samples to be determined with a greater degree of certainty. Since the sample suite contains corundum, fluorite and zincite in a wide range of concentrations, application of a rearranged equation (3.9.21) using the refined scale factors results in 72 separate determinations of K. The value of μ_m^* for each sample was derived from XRF-determined compositions using equation (3.9.5), while the values for W_i were taken from the known weight additions.

(2) *Whole sample*: Equation (3.9.40) was applied to each of the 24 data sets (*i.e.* three replicates each of the eight samples) assuming (i) that all phases were known and fully crystalline, *i.e.* $\sum W_i = 1$; and (ii) μ_m^* for each sample was derived in the manner described above.

Fig. 3.9.10 shows the 72 individual determinations of K from the phase-specific method as a function of known phase concentration. At high concentrations, the values for K derived from each of the three phases are similar indicating that, for effectively pure phase samples, the approach embodied in equation (3.9.21) is valid. However, if K is determined using the known concentration of a single phase at a lower concentration in a multiphase sample, then residual errors in the measurement of pattern intensity serve to reduce its accuracy. At lower concentrations of corundum, there is a systematic increase in the determined value of K resulting from a small microabsorption effect present in these samples. Since corundum has the lowest mass absorption coefficient of the three phases in this system its intensity, and hence Rietveld scale factor, is slightly

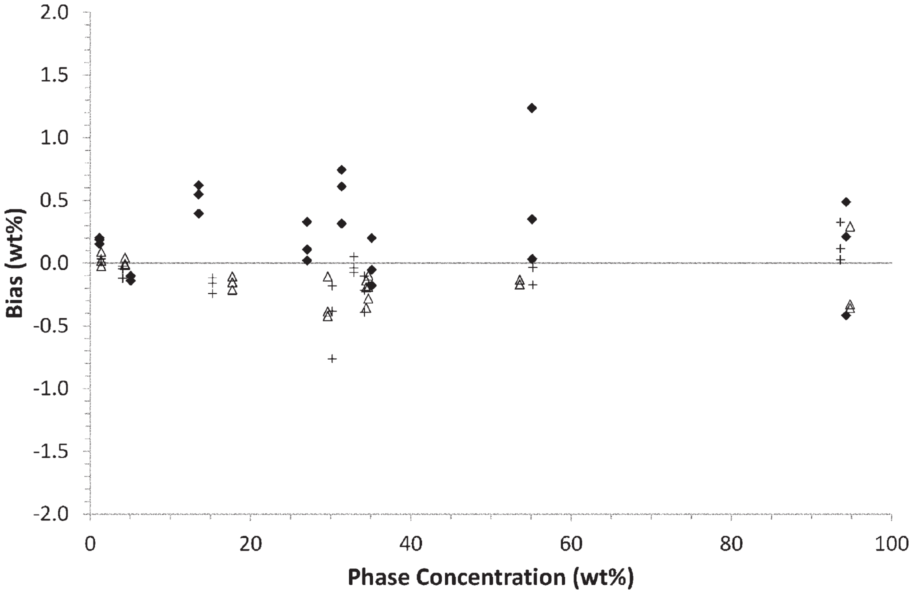

Figure 3.9.9
Plot of the bias (known − determined) in the analysed phase abundances using the Zevin & Kimmel (1995) approach for corundum (black diamonds), fluorite (open triangles) and zincite (crosses). The 72 determinations derive from three replicates of eight mixtures containing three phases each.

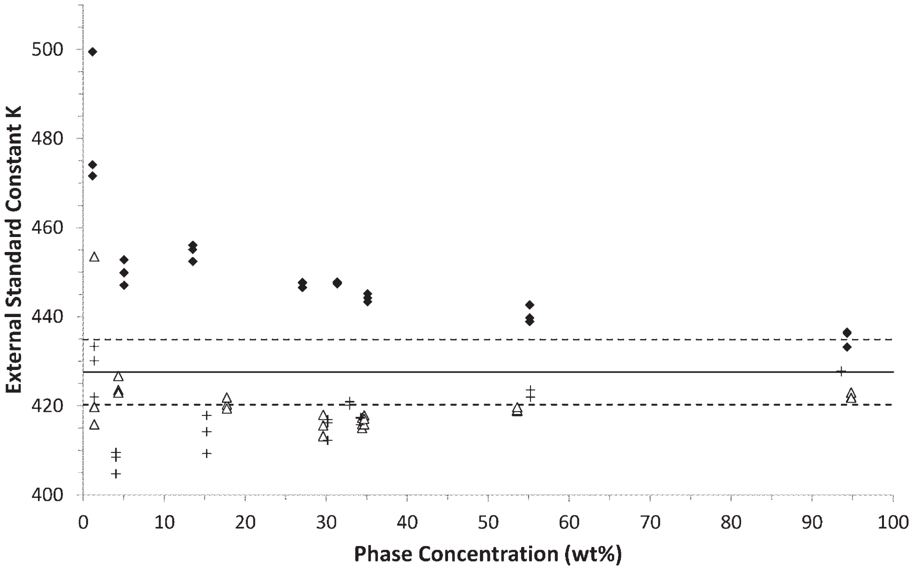

Figure 3.9.10
Plot of the experiment constant K as a function of known phase concentration for corundum (closed diamonds), fluorite (open triangles) and zincite (crosses) using the phase-specific method. The 72 determinations derive from three replicates of eight mixtures containing each of the three phases. The solid line is the mean of 24 values determined using the whole-sample approach. The dashed lines represent ±2 standard deviations about this mean.

overestimated relative to the fluorite and zincite. This results in an overestimation of the value of K relative to an ideal sample; the magnitude of this difference is about 5% relative. Use of these values for subsequent analysis will result in an underestimation of phase concentrations using equation (3.9.21). The converse is true if fluorite or zincite is used to determine K.

However, if the whole-sample approach embodied in equation (3.9.40) is used for the determination of K, these residual sample-related aberrations can be eliminated; the results of the determination of 24 values of K using this approach are also included in Fig. 3.9.10. The mean of all 24 determinations is 427.6 (3.7) representing a relative error of <0.8%. The important point to note here is that knowledge of the individual phase concentrations is not needed; the only assumption needed relates to the total crystallinity of each sample.

For *in situ* studies, using equation (3.9.40) to calculate K at each step i in the reaction (defined as K_i) can be useful in deriving details of the reaction mechanism. If K_i increases as the reaction progresses, this may be indicative of increasing crystallinity in the sample. Reductions in K_i during the reaction may point to the formation of intermediate amorphous material or unidentified crystalline components, the total concentration of which can be readily calculated using

$$\mathrm{wt\%}_{\mathrm{amorphous}} = 100\left(1 - \frac{K_i}{K}\right). \qquad (3.9.41)$$

Application of this can be demonstrated using sample 3 from the QPA round robin (Scarlett *et al.*, 2002), as it contains the same three crystalline phases as the sample 1 suite with the addition of 29.47 wt% amorphous silica flour. Calculation of K_i for sample 3, based only on the three crystalline phases, results in a value of 301.8. Substituting this into equation (3.9.41) along with the previously determined value of K (427.6) gives a measured amorphous content of 29.42 wt% – this is in good agreement with the known weighed amount. The important point to note here is that the data for sample 3 were collected at the same time, and under the same instrumental conditions, as for sample 1, which ensured that the true value of K was the same for all data.

3.9.6. Quantification of phases with partial or no known crystal structures

While the Rietveld-based methods described in Section 3.9.3.6 work for well ordered phases with known crystal structures, they are limited when published structure data do not accurately represent the phase actually present in the sample, are incomplete or do not exist. Poor agreement with published structure data is a common occurrence in mineralogical research where disorder exists and observed diffraction data deviate significantly from the ideal; this situation occurs with many of the clay minerals. The issue of incomplete or non-existent structure data can occur in almost any area where new materials are either synthesized or discovered. The growing demand for the analysis of materials from the nanotechnology community, where phases are at the boundary of what can be considered crystalline, serves to further highlight these limitations. Recent developments in diffraction methods have sought to address these issues and have used approaches that include the development of calibrated models or, where appropriate, the extension of existing structure data to incorporate systematic disorder such as stacking faults in clay minerals.

3.9.6.1. *Use of calibrated models*

Calibrated models are generally developed in one of two ways. The first (which uses what is referred to hereafter as an hkl_phase) is obtained *via* the use of partial structure information. Here the peak positions are constrained by a unit cell and space group but the relative intensities, in the absence of atom types and locations in the unit cell, are determined empirically from a pure sample or one where the phase is present in a mixture at a known concentration. The second method involves the use of a discrete set of peaks whose positions, intensities, width and shape are all determined empirically. Once determined using a standard sample, this group of peaks may then be scaled as a single unit and is referred to hereafter as a peaks_phase.

The software *SIROQUANT* (Taylor & Rui, 1992) employs the simultaneous use of observed and calculated standard profiles within the framework of the Rietveld method. It draws on a library of structures that are stored as lists of reflections and intensities (hkl files). These are calculated on a cycle-by-cycle basis for well described crystalline materials but are read directly from the hkl files for poorly defined materials such as clay minerals. This method still requires some knowledge of the crystal chemistry of all phases involved and that they be included within the programme's database. By the inclusion of reflection information in this way some aberrations such as preferred orientation may be allowed for. This approach to clay mineralogy also provides for the refinement of two sets of halfwidth parameters in order to model the co-existing sharp and broad reflections generated by such minerals.

A subsequent development of the whole-pattern approach is the 'partial or no known crystal structure' (PONKCS) method (Scarlett & Madsen, 2006). This method operates within the framework of the Rietveld method but replaces the traditional crystal structure of the phases in question with an empirical set of peaks (either as an hkl_phase or a peaks_phase). These can then be scaled as a single unit in the course of refinement in similar fashion to the set of structure factors derived from a crystal structure. Since the full structure information is not available, it is not possible to calculate the *ZMV* phase constant normally required for quantification *via* equation (3.9.26) (Hill & Howard, 1987); hence, an empirical value must be derived through calibration.

3.9.6.1.1. *Generation of calibrated PONKCS models*

The generation of a suitable PONKCS model requires that:

(1) The unknown phase is available as either a pure specimen or as a component of a mixture where its abundance is known (in some instances, this may be achieved by other means, such as the measurement of bulk and/or microchemical composition.)

(2) The unknown phase does not vary considerably from the material used to derive the relative intensities of the model. Preferred orientation and other sample-related effects may be compensated for based upon an indexed diffraction pattern.

The initial step in the generation of a PONKCS model is to describe the contribution to the diffraction pattern of the phase with a series of peaks. If the phase of interest has been indexed, the Le Bail or Pawley methods (see Chapter 3.5) can be used to constrain peak positions to the space group and unit-cell parameters while the individual reflection intensities are allowed to vary to best match the observed peaks (*i.e.* an hkl_phase). If the phase has not been indexed, a series of unrelated peaks can be refined using a standard material and scaled as a group during analysis (*i.e.* a peaks_phase). While this approach is effective in most cases, it restricts the refinable parameters that may be used in the treatment of systematic errors such as preferred orientation.

The next step is to calibrate the hkl_phase or peaks_phase and derive a 'phase constant' that is equivalent to the *ZMV* value in crystal-structure-based quantification. This is achieved by the preparation of a mixture in which there are known amounts W_α and W_s of the unknown and standard, respectively. Recalling equation (3.9.25), the ratio of the weight fractions is then given by

$$\frac{W_\alpha}{W_s} = \frac{S_\alpha (ZMV)_\alpha}{S_s (ZMV)_s}, \qquad (3.9.42)$$

where S_α and S_s are the refined scale factors for the unknown and standard, respectively.

Rearrangement of equation (3.9.42) then provides the means for determining an empirical value of $(ZMV)_\alpha$, which is required for the calibration of a peaks_phase:

$$(ZMV)_\alpha = \frac{W_\alpha}{W_s}\frac{S_s}{S_\alpha}(ZMV)_s. \qquad (3.9.43)$$

For an hkl_phase the value of V can be determined from the refined unit-cell parameters and hence can be removed from the phase constant resulting in

$$(ZM)_\alpha = \frac{W_\alpha}{W_s}\frac{S_s}{S_\alpha}\frac{(ZMV)_s}{V_\alpha}. \qquad (3.9.44)$$

Unlike the *ZMV* value derived from the unit-cell contents of a crystal structure, the phase constants derived using equations (3.9.43) and (3.9.44) have no physical meaning, since they have been derived by empirical measurement. For an hkl_phase, a more physically meaningful value of *ZM* can be obtained by deriving the true unit-cell mass from the measured phase density according to

$$(ZM)_{\alpha(\rm true)} = \frac{\rho_\alpha V_\alpha}{1.6604}. \qquad (3.9.45)$$

The empirical 'structure factor' values in the hkl_phase could then be scaled according to the relation $ZM_{\alpha(\rm true)}/ZM_\alpha$, making them approximate 'real' structure factors for the material. Note that this final step is not necessary for quantification, but may make the method more generally applicable.

3.9.6.1.2. *Application of the model*

The PONKCS method is applicable to any mixture in which there are one or more phases that are not fully characterized crystallographically, including essentially amorphous material, provided appropriate calibration samples can be obtained. In the mineralogical context, it may not be possible to obtain pure phase specimens typical of those found in the bulk mixtures, but it may be possible to concentrate them to a point where they can be used. Methods of achieving this may include gravity or magnetic separation, or selective chemical dissolution.

The original paper describing this method (Scarlett & Madsen, 2006) gives a detailed example based upon sample 1 from the IUCr CPD round robin on QPA (Madsen *et al.*, 2001; Scarlett *et al.*, 2002). There, corundum was regarded as the unknown phase, fluorite as an impurity of known crystal structure and zincite a standard material added at known weight fraction. In the same paper, there is a more realistic example regarding the poorly ordered clay mineral nontronite, which is of commercial significance but difficult to quantify *via* traditional structure-based Rietveld methodology. Further details regarding quantification of this mineral *via* the PONKCS method is given in articles detailing its importance in low-grade nickel laterite ores (Scarlett *et al.*, 2008; Wang *et al.*, 2011).

A calibration-based method such as PONKCS may also find increasing application with phases that have a known crystal structure. It has the greatest potential for accuracy, as the calibration process may obviate residual aberrations in the data such as microabsorption. Assuming that the sample suite has the same absorption characteristics as that used for calibration, such aberrations will be included in the calibration function and require no further correction during the sample analysis. This is a realistic scenario for routine analyses in industries as diverse as mineral processing, cement production and pharmaceutical production.

3.9.6.2. *Modelling of structural disorder*

One major challenge for QPA is the treatment of stacking disorder. An alternative to the use of calibrated models is to develop extended structure models that more effectively represent the phases present in the sample than the simple structure models. Stacking disorder occurs in layered structures where long-range order is present within the layers but there is only partial or even no relationship from one layer to another. It is a commonly occurring type of microstructure and is of great interest in various fields including mineralogy and material science.

The most common types of stacking faults in lamellar structures are:

(i) translational stacking faults, characterized by well defined translation vectors between successive layers;
(ii) rotational stacking faults, characterized by irregular but well defined rotation of adjacent layers in a stack; and
(iii) random stacking faults (turbostratic stacking), where there is no registry from one layer to another. This can be readily visualized as a stack of playing cards lying flat on top of each other but with no alignment between the edges (Fig. 3.9.11).

Mixed-layer (interstratified) systems contain different types of layers in a single stack, hence it is necessary to distinguish these from the types above. In this case, the layer types have different basal spacings and atomic coordinates (for example, illite–smectite interstratifications; Reynolds & Hower, 1970). Combinations of several of these types of disorder frequently occur in natural clay minerals. Intricate structural analysis using modelling techniques can give a reliable picture of the disorder of selected pure clay minerals, but such information is difficult to obtain from multiphase samples. Therefore, the type and degree of disorder of the components in natural rocks is one of the major unknowns when starting a quantitative analysis of such samples. The field of clay mineralogy represents a discipline where QPA has a long tradition, but has struggled with issues arising from a wide variety of disorder types. This complexity has led practitioners away from the use of crystallographic models and encouraged modification of the classical methods of quantitative analysis to incorporate empirical, calibration-based techniques such as those described earlier in this section.

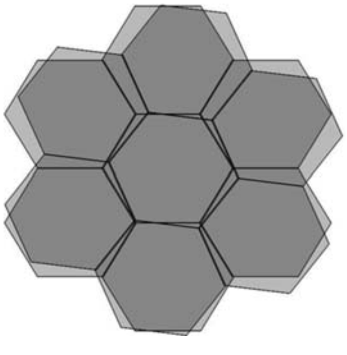

Figure 3.9.11
Turbostratic disorder, illustrated by the stacking of two hexagonal layers rotated by 7°.

An alternative approach is the application of a robust mathematical description of the observed features in the diffraction pattern, thus minimizing their impact on the QPA. In QPA, the existence of disorder contributes to inaccuracy through line broadening and shifting, which results in difficulties in the extraction of integral intensities or scale factors. A range of tools for the modelling of diffraction patterns of disordered layer structures has existed since the middle of the last century (Hendricks & Teller, 1942; Warren, 1941); these have been summarized by Drits & Tchoubar (1990).

In clay mineralogy, highly oriented samples are used for phase identification and characterization. One-dimensional diffraction patterns are collected initially from these, commonly air-dried, oriented samples and contain the information along **c*** that is characteristic of the type, composition and sequence of the layers comprising the clay. Based on this information, the clay minerals are classified into layer types, a classification which is a precursor to more precise identification of mineral species. Diffraction patterns are often collected again following various treatments of the oriented samples (*e.g.* solvation with ethylene glycol, heating to predetermined temperatures for specified times, wetting and drying cycles). Changes in peak positions, shapes and intensities between treatments are also diagnostic for identification of the clay mineral type present.

From a mathematical point of view, the one-dimensional calculation of intensities is much less laborious than a three-dimensional one, because only z coordinates are used and a–b translations and rotations are not considered. In 1985 Reynolds introduced the software package *NEWMOD* for the simulation of one-dimensional diffraction patterns for the study of interstratified systems of two clay minerals (Reynolds, 1985). This simulation was based upon a suite of parameters including instrumental, chemical and structural factors, and has been widely applied to the QPA of interstratified clays *via* the 'pattern-mixing' approach. An updated version (*NEWMOD+*; Yuan & Bish, 2010) has since been developed that incorporates improvements in clay-structure modelling, an improved GUI and the calculation of various fitting parameters that improve the operator's ability to estimate the quality of the profile fit.

The principal drawback of one-dimensional pattern approaches to QPA is that they are limited to the quantification of the ratio of layered structures only. Other minerals within the sample cannot be quantified at the same time. The degree of preferred orientation achieved in the oriented specimens may also differ between the mineral species present depending upon the method of sample preparation (Lippmann, 1970; Taylor & Norrish, 1966; Zevin & Viaene, 1990). This will affect the intensities of the observed peaks, which in turn affects the modelling of the relative proportions of the constituent minerals (Dohrmann *et al.*, 2009; Reynolds, 1989). Therefore, the quantification of minerals from severely oriented samples such as these is frequently inaccurate, as existing correction models are unable to describe the intensity aberrations adequately (Reynolds, 1989).

Quantification of clay minerals within multiphase specimens requires the modelling of the three-dimensional pattern of the randomly ordered clay. There are a number of approaches incorporated in various software packages for the calculation of these three-dimensional diffraction patterns of disordered structures. *WILDFIRE* (Reynolds, 1994) calculates three-dimensional diffraction patterns of randomly oriented illite and illite–smectite powders with various types and quantities of rotational disorder. This is limited, however, to specific mineral types (the procedure has provided much information about the structural disorder of illite, for example) and is computationally demanding. Another approach is the general recursive method of Treacy *et al.* (1991), which simulates diffraction effects from any crystal with stacking disorder. This uses the intensity calculations of Hendricks & Teller (1942) and Cowley (1976) along with Michalski's recurrence relations describing disorder (Michalski, 1988; Michalski *et al.*, 1988). The calculation process for this method is less time consuming than that of *WILDFIRE*, but has the drawback of requiring the user to define the complete stacking sequence including stacking-transition probabilities and interlayer vectors. The original software for this method, *DIFFAX* (Treacy *et al.*, 1991), was extended by a refinement algorithm to *DIFFAX*+ (Leoni *et al.*, 2004) and *FAULTS* (Casas-Cabanas *et al.*, 2006), but multiphase analysis is not possible within either package.

The application of Rietveld-based methods is widespread with many industrial applications, but their application to samples containing disordered materials is not yet routine. As the classical Rietveld method is based on the calculation of intensity for discrete reflections, the question of how the diffraction patterns of disordered phases may be modelled arises.

In principle, every atomic arrangement can be described in the space group $P1$ if the cell parameters are sufficiently large and a reflection-intensity calculation using the Rietveld method could then be performed. But the absence of symmetry in such 'large cell' models makes them inflexible, and parameters describing probabilities of translational and rotational stacking faults and layer-type stacking may not be directly included and refined. Nevertheless, some applications of such externally generated, large-cell structures in Rietveld phase analysis have been published; for example the phase analysis of montmorillonite (Gualtieri *et al.*, 2001).

The use of small, ideal cells in a traditional Rietveld approach for the calculation of diffraction patterns is hampered by the fact that the number of reflections generated by such models is insufficient to fit the asymmetric peak shapes of disordered layer structures. Standard anisotropic line-broadening models exist, such as ellipsoids (Le Bail & Jouanneaux, 1997), spherical harmonics (Popa, 1998) or the distribution of lattice metric parameters (Stephens, 1999), but these are typically unable to fit the patterns of disordered layered structures. They may also become unstable when physically unrealistic parameters are introduced, such as higher-order spherical harmonics. The application of such standard broadening models to clay minerals has therefore not proved successful.

Other Rietveld-based methods attempt to approximate the diffraction features of disordered layered materials by empirical enhancement of the number of reflections. The simplest method is the splitting of the reflections of a traditional cell into two or three separate reflections that can be separately broadened and shifted, following prescribed rules (Bergmann & Kleeberg, 1998). In this way, the broadening of special classes of peaks, for example reflections with $k \neq 3n$, can be modelled. This method is particularly suitable for structures showing well defined stacking faults, such as **b**/3 translations or multiples of 120° rotations. However, when structures show more complex disorder, such as turbostratic stacking, simple geometric dependencies of broadening and shifting are not sufficient to approximate their diffraction patterns.

Turbostratically disordered structures can be depicted in reciprocal space as infinite rods perpendicular to the *ab* plane and parallel to $\mathbf{c}^*$; see Fig. 3.9.12 (Ufer *et al.*, 2004). The diffraction features from such disordered materials consist of two-dimensional asymmetric bands, as can be observed typically for smectites and some other clay minerals (Brindley, 1980). One method for approximating the diffraction effects along the reciprocal-lattice rods within the Rietveld method is *via* the 'single-layer' approach (Ufer *et al.*, 2004). Here, a single layer is placed in a cell elongated along $\mathbf{c}^*$, which is effectively a 'supercell'. In doing this, an enhanced number of discrete lattice points are generated along the rods, according to the factor of elongation of the cell. This elongation generates a continuous distribution of additional *hkl* positions on the reciprocal rods. The inclusion of only a single layer in the supercell destroys periodicity, which is lacking in turbostratically disordered structures. By treating the pseudo-peaks of the supercell in the same manner as other structures within the Rietveld method (*i.e.*, introducing additional broadening, scaling the intensity) and separately calculating the peaks of the $00l$ series, the patterns of turbostratic structures like smectites can be reliably fitted. The model generated in this fashion can be used directly in phase quantification (Ufer, Kleeberg *et al.*, 2008; Ufer, Stanjek *et al.*, 2008).

However, this approach is limited to the turbostratic case. Moreover, the basal $00l$ series points are conventionally calculated, assuming rational diffraction from constant basal spacings in the stack. So the method cannot be applied to mixed-layered structures.

In order to overcome this limitation, Ufer *et al.* (Ufer, Kleeberg *et al.*, 2008; Ufer *et al.*, 2012) combined the recursive calculation method of Treacy *et al.* (1991) and the supercell approach in the structure-description code of the Rietveld software *BGMN* (Bergmann *et al.*, 1998). In this method a supercell is used to generate numerous discrete *hkl* spots along $\mathbf{c}^*$, but the partial structure factors are calculated by the recursive algorithm. This allows the refinement of structural parameters of mixed-layered structures and simultaneous Rietveld QPA to be performed (Ufer *et al.*, 2012). A broader introduction of such models in Rietveld phase analysis can be expected with the

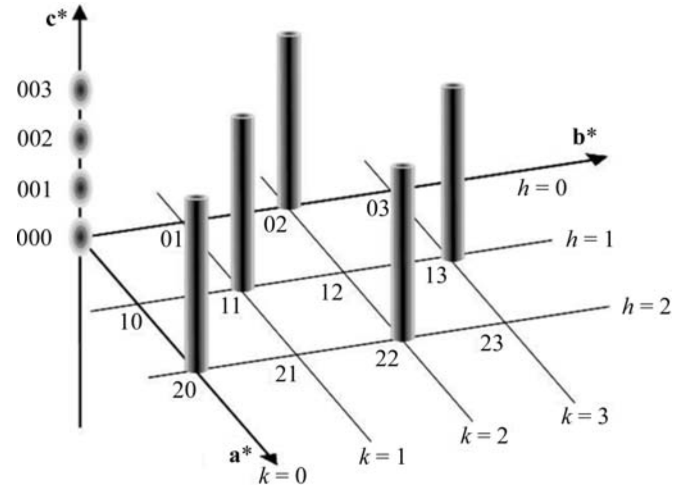

Figure 3.9.12
Section of the reciprocal lattice of a turbostratically disordered pseudo-hexagonal *C*-centred structure.

development of reliable structure models and enhanced computational power (Coelho *et al.*, 2016, 2015; Bette *et al.*, 2015).

3.9.6.3. *Quantitative determination of amorphous material*

Traditionally, most activity in diffraction-based QPA has been concerned with the assessment of the crystalline components. However, all materials possess a non-diffracting surface layer with some degree of disorder or contain some surface reaction products and adsorbed species. While such a layer can easily account for ~1 wt% of the entire sample in a finely divided solid, the fraction of this surface layer will increase as the particle size decreases (Cline *et al.*, 2011). In addition, some materials can contain separate phases that may be amorphous or at least poorly crystalline. The advent of nanotechnology has served to further blur the boundaries between what is defined by powder XRD as crystalline or amorphous.

During *in situ* studies, some phases undergo transformations *via* amorphous intermediate components; the presence of these phases has the potential to influence our understanding of reaction mechanisms. Given the potential for these amorphous components to influence bulk-material properties, the need to quantify them is an increasingly important issue for analysts using diffraction-based methods. Many of the traditional phase-quantification techniques described in this chapter fail to take into account the occurrence of amorphous material in the sample and, without careful attention by the analyst, its presence may remain undetected.

Madsen *et al.* (2011) recently reviewed a range of techniques for the determination of amorphous content and assessed their applicability for various analytical situations. The study used both single-peak and whole-pattern methodology and applied it in two distinct ways.

(1) The first method used an indirect approach; the crystalline components were quantified and put onto an absolute scale using either an internal- or external-standard method. The amorphous content was then determined by subtracting the sum of the absolute weight fractions of the crystalline components from unity.

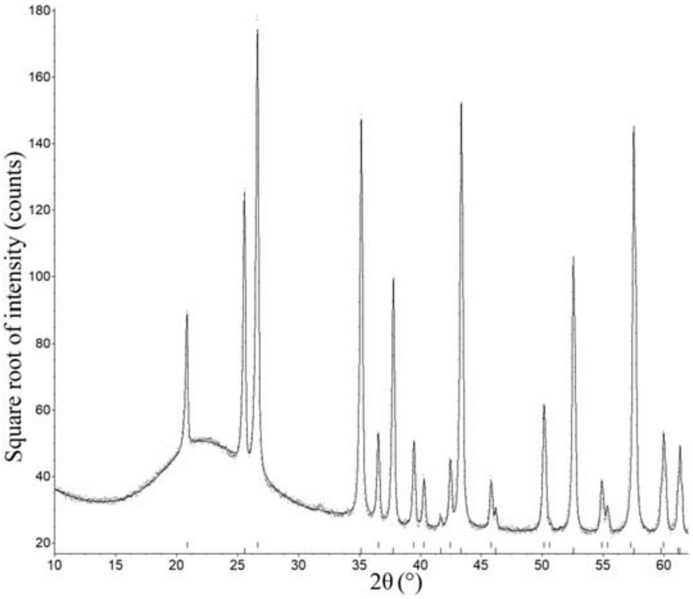

Figure 3.9.13
Output of Rietveld refinement of XRD data (Cu *Kα* radiation) for a synthetic sample containing a mixture crystalline and amorphous phases. The observed data are represented as grey dots and the calculated pattern as the solid black line overlaying them. The broad peak centred at ~22° 2θ is due to amorphous silica flour. The rows of tick marks at the bottom represent the positions of the Bragg reflections for quartz (upper) and corundum (lower).

(2) The second method used a direct approach; it relied on being able to 'see' the amorphous contribution in the diffraction and being able to obtain an estimate of its intensity during analysis (Fig. 3.9.13). Intensity contributions of amorphous phases are not always evident in the diffraction pattern, especially at low concentrations. Even when their presence is apparent, it can be difficult to resolve their contribution from other components of the diffraction pattern such as pattern background. However, once an intensity estimate is obtained, and an appropriate calibration constant derived, the amorphous phase can be included in the analysis along with the crystalline components.

In general, for the determination of amorphous material the problem will dictate the method(s) used. All methods discussed in the study of Madsen *et al.* (2011) are, in principle, capable of determining the concentration of amorphous material in mixtures with similar levels of accuracy and precision as is possible for crystalline phases (down to ~1% absolute or better). The limitations are similar to those for the QPA of crystalline phases, and are dictated by sample properties and the analytical techniques used.

A summary of the recommendations resulting from the study include:

(1) Where the intensity contribution of the amorphous content to the diffraction pattern is not evident, one of the indirect methods (internal or external standard) should be used. For indirect methods, any errors in the analysis of the crystalline phases will decrease the overall accuracy attainable since the amorphous phase abundance is determined by difference.

(2) Where intensity contributions of amorphous phases are evident in the diffraction pattern, any method based on the direct modelling of the amorphous component provides improved accuracy relative to the indirect methods.

(3) Calibration-based methods usually have the potential to achieve the highest accuracy, as residual aberrations in the data, such as microabsorption, are included in the calibration function. Caution is advised here as the magnitudes of these residual errors may change with different sample suites, and so a calibration function derived for one sample suite may not be generally applicable.

(4) A sample of pure amorphous material, or a sample where the amorphous content is high and its concentration known, is normally required to establish an accurate model for the direct methods.

Some materials contain more than one amorphous phase and there may be a desire to quantify these separately rather than as a group. This provides a significant challenge since their broad diffraction patterns will be highly overlapped, thus leading to a high degree of correlation during analysis. However, Williams *et al.* (2011) have demonstrated that, with careful experimentation and data analysis, it is possible to provide QPA for two poorly crystalline components in geopolymers.

Phase abundances reported in the literature are often provided in a manner that suggests they are absolute values. Where no specific allowance for amorphous content has been made and reported, it is better to assume that the reported phase abundances are correct relative to one another, but may be overestimated in an absolute sense. Therefore, standard practice in QPA should be to use methodology which produces *absolute* rather than *relative* phase abundances. Any positive difference between unity and the sum of the absolute weight fractions will alert the analyst to the presence of non-analysed material in the sample.

3.9.7. QPA from *in situ* experimentation

In situ analysis is a growth area in the field of powder diffraction (Ehrenberg *et al.*, 2013) and is dealt with in depth elsewhere in this volume (see Chapter 2.9). The technique is unparalleled in providing information about reaction mechanisms and kinetics under simulated operational conditions and without the artefacts potentially associated with post-mortem sampling or *ex situ* methods.

An *in situ* experiment collects dynamic, time-resolved data, which present unique challenges for QPA. The phase assemblages formed in such experiments may be quite complex and change dramatically over the course of the experiment. In addition, the data are generally of lower quality than those collected for *ex situ* samples at ambient conditions. This may be due to poor counting statistics resulting from the rapid counting times needed to follow various phase transitions. Data for *in situ* studies are often collected using area detectors, some of which are not photon-counting devices. Care should be taken in the error propagation and hence the weighting used during data analysis.

The data quality may also be affected by components in the sample chamber that are required in order to achieve the environmental conditions (temperature, pressure, solution or gaseous atmosphere, and so on) necessary for the experiment: these components may either attenuate the incident and diffracted beams or contribute features to the pattern resulting from scattering of the beam.

One very important issue that arises from *in situ* studies is the large number of data sets generated. The rapid counting times available at modern synchrotron and neutron facilities mean that hundreds or thousands of diffraction patterns can be collected over the duration of the *in situ* experiment.

3.9.7.1. *Data analysis*

There are usually a series of steps involved in the analysis of *in situ* diffraction data. Given the large number of data sets collected, it is generally not practicable to undertake detailed analysis of every pattern individually. Since any changes to the component phases are transitions generally observed in a sequence of patterns, data analysis focused on extracting QPA could be undertaken using the following steps:

(1) Cluster the data into a number of groups necessary to describe the major phase regions present during the reaction. This can be achieved (i) visually, using software that allows the plotting of three-dimensional data sets of the type shown in Fig. 3.9.14, or (ii) through the use of automatic clustering algorithms using, for example, principal-component analysis.

(2) Select the 'most typical' pattern of each cluster as well as the two 'least typical' patterns at the extreme ends of the cluster. These patterns are often identified by clustering software based on the statistical similarity between patterns in the cluster.

(3) Identify the phases present in each cluster using the most typical pattern. This is not always a trivial task since (i) new phases that are not currently present in databases may have been generated; (ii) effects such as thermal expansion or variation of chemical composition may have changed the peak positions so that search/match procedures are no longer successful; or (iii) impurity elements may have stabilized phases that are not expected from related phase-diagram studies.

(4) For the discussion here, it will be assumed that the quantification process will be *via* a whole-pattern method.
   (*a*) Develop appropriate (crystal structure or PONKCS) models for every phase observed within the data suite.
   (*b*) Optimize the pattern and phase-analysis parameters using the most typical pattern selected from each cluster.
   (*c*) Set the relevant parameter refinement limits using the least typical patterns. It is necessary to limit the range over which refined parameters can vary to avoid the return of physically unrealistic values.

(5) Owing to the large number of data sets, analysis for QPA will generally be approached as a batch process with limited refinement of structural parameters. This limitation on the total number of refinable parameters is necessary during batch processing in order to avoid instability in the refined values as the phases progress from major to minor concentration.

(6) Batch processing of data suites may be conducted in a variety of ways including:
   (*a*) Sequential refinement, beginning with either the first or final pattern of the suite and including all phases present in the entire suite. This methodology must be tempered by a means to either remove or severely restrict refinement of any phases that are not present in all patterns of the suite in order to avoid the reporting of 'false positives' where absent phases have been included. Some software packages allow phases to be removed from the analysis if their abundance is below a selected level or has an error that exceeds some predefined criteria (Bruker AXS, 2013).
   (*b*) Parametric Rietveld refinement (Stinton & Evans, 2007), where the entire suite of diffraction data is analysed simultaneously. Selected parameters are constrained to the applied external variable (*e.g.* temperature) with a function describing their evolution throughout the data sequence. For example, the unit-cell parameters for a phase can be constrained to vary according to their thermal coefficients of expansion. This method can bring stability to refined parameters and allows the refinement of noncrystallographic parameters such as temperature and reaction rate constants directly from the diffraction data. This methodology is particularly suited to relatively simple phase systems, but is difficult to develop for complex multiphase mineralogical systems.

(7) In selecting a model for use in QPA, it is highly recommended that one of the approaches that generate absolute phase abundances is used. Many reactions generate intermediate amorphous phases that convert to crystalline components later in the reaction. If relative phase abundances [such as those produced by the *ZMV* approach embodied in equation (3.9.26)] are used, the amounts of the crystalline phases will be overestimated and this will give misleading indications about the reaction mechanism and kinetics.

Whichever method is employed, it is always necessary to examine a sample of individual results as a test of veracity rather than just accepting the suite of numbers for parameter values and QPA resulting from batch processing.

The study of Webster *et al.* (2013) demonstrates many of these points by following the formation mechanisms of the iron-ore

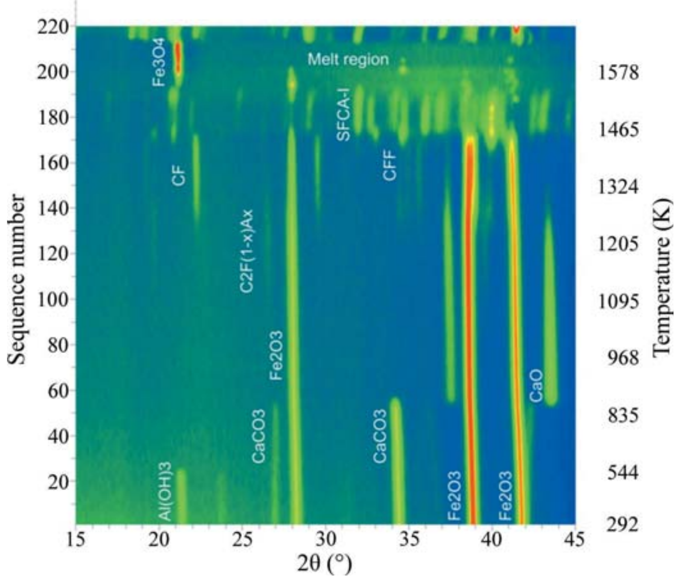

Figure 3.9.14
Raw *in situ* XRD data (Co $K\alpha$ radiation) collected during the synthesis of the iron-ore sinter bonding phase SFCA-I (Webster *et al.*, 2013). The data, collected as a function of heating temperature, are viewed down the intensity axis with red representing the highest intensity and blue the lowest intensity. The identified phases include gibbsite $Al(OH)_3$, calcite $CaCO_3$, haematite Fe_2O_3, lime CaO, calcium ferrites CF and CFF, calcium alumina-ferrite $C_2F_{1-x}A_x$, magnetite Fe_3O_4, and SFCA-I.

sinter bonding phase, SFCA-I, where SFCA = silico-ferrite of calcium and aluminium (Scarlett, Madsen *et al.*, 2004; Scarlett, Pownceby *et al.*, 2004; Webster *et al.*, 2013). The starting material, comprising a synthetic mixture of gibbsite, $Al(OH)_3$, haematite, Fe_2O_3, and calcite, $CaCO_3$, was heated to about 1573 K using an Anton Paar heating stage. The laboratory-based XRD data, collected using an Inel CPS120 diffractometer, are shown in Fig. 3.9.14, while the QPA results are shown in Fig. 3.9.15. Both figures show that there are several phase changes, including the formation of transient intermediate phases before the final production of SFCA.

In Fig. 3.9.15(*a*) the QPA results are derived using the Hill/Howard algorithm (Hill & Howard, 1987) in equation (3.9.26): this is the 'default' value reported by most Rietveld analysis software and normalizes the sum of the analysed components to 100 wt%. The apparent increase in haematite concentration at about 533 and 868 K results from the decomposition of gibbsite and calcite, respectively. There are no possible mechanisms in this system that could lead to an increase in haematite concentration at these temperatures; the reported increases are an artefact derived from normalizing the sum of all analysed phases to 100 wt%. Fig. 3.9.15(*b*) shows the correct result derived using the external-standard approach (O'Connor & Raven, 1988) embodied in equation (3.9.21), which has placed the values on an absolute scale. Fig. 3.9.15 demonstrates the importance of putting the derived phase abundances on an absolute scale for a realistic derivation of reaction mechanism and kinetics.

3.9.8. QPA using neutron diffraction data

One of the early papers detailing the application of the Rietveld method to quantitative phase analysis used neutron diffraction (ND) data (Hill & Howard, 1987). The reasons stated within this work define many of the advantages of neutrons over X-rays for diffraction in general and QPA in particular. One of the most significant advantages for QPA derives from the fact that neutrons interact weakly with matter, hence there is very little microabsorption with ND even in samples comprising a mixture of high- and low-atomic-number materials.

The high penetration capability of neutrons also enables the use of larger sample environments in *in situ* studies, thus enabling studies to be undertaken at, for example, higher pressures than would be possible with many X-ray sources. In addition, larger sample volumes can be investigated, which in turn produces better particle statistics and makes the technique less sensitive to grain size. It also makes ND a bulk technique in comparison with XRD, which is effectively surface-specific with a penetration depth of the order of microns or tens of microns.

The different strengths of ND and XRD mean that they can be exploited in combination to provide complementary information. For example, XRD generally has higher angular resolution and is therefore better at resolving small lattice distortions and heavily overlapped phases. However, the observed intensities in ND do not decrease as strongly with decreasing *d*-spacing. This results in ND providing more accurate determination of atomic displacement parameters and therefore the Rietveld scale factors; this then improves the accuracy of QPA derived from these scale factors (Madsen *et al.*, 2011).

Hill *et al.* (1991) have investigated the phase composition of Mg-PSZ (partially stabilized zirconia) using both ND and XRD. The surfaces of these materials were subjected to various treatments, which meant that they were no longer representative of the bulk. From the more highly penetrating ND data they obtained bulk properties including crystal structure and size and strain parameters of the components along with QPA. From XRD they were able to examine the surface of the samples to investigate the effects of surface grinding and polishing.

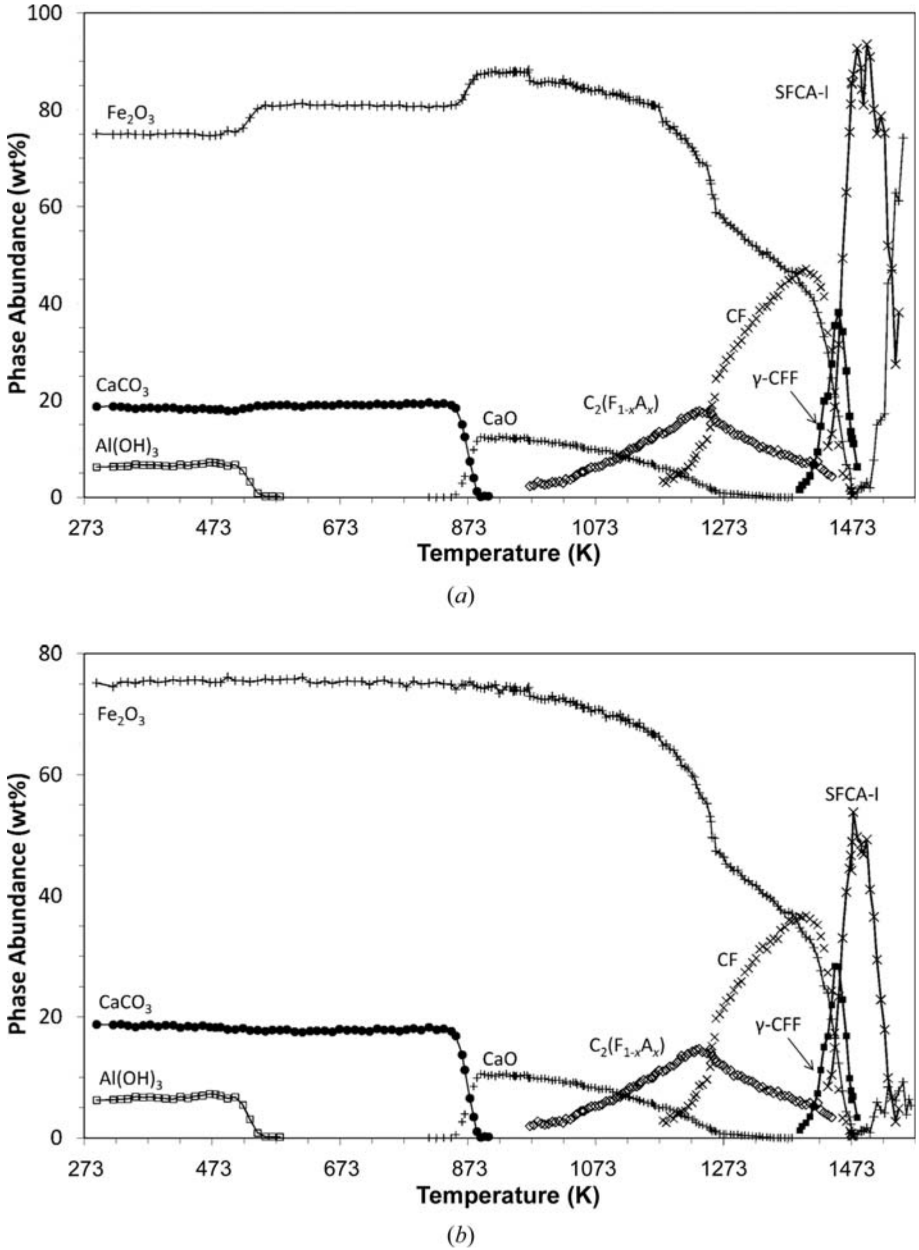
The majority of Rietveld-based QPA still relies on the use of accurate crystal structure models; consequently, it is of increasing importance that powder diffraction methods used for structure solution be robust and reliable. Combining laboratory or synchrotron XRD and ND has been shown to be of considerable benefit in the solution of complex structures *via* powder diffraction (Morris *et al.*, 1992). This joint-refinement approach has been used to determine the crystal structure of a component phase of Portland cement (De La Torre *et al.*, 2002) for subsequent use in Rietveld-based QPA.

One of the disadvantages of neutron sources is that they are much less accessible than laboratory X-ray sources and of much lower flux than either laboratory or synchrotron X-rays sources. In addition, larger samples are generally required; this is not always practical in the investigation of many materials.

In many phase systems, the presence of severe microabsorption in XRD data serves to limit the accuracy that can be obtained. The collection of ND data, where microabsorption is virtually absent, from selected samples provides more accurate QPA; selected ND-based values can therefore act as a benchmark for the more routine XRD-based studies.

3.9.9. QPA using energy-dispersive diffraction data

Energy-dispersive diffraction (EDD) involves the use of high-energy white-beam radiation, often from a synchrotron source. This provides very high penetration and is, therefore, ideal as a probe to examine the internal features of relatively large objects (Barnes *et al.*, 2000; Cernik *et al.*, 2011; Hall *et al.*, 1998, 2000). In an experimental arrangement such as that in Fig. 3.9.16, diffraction data can be measured by energy-dispersive detec-



(*a*)

(*b*)

Figure 3.9.15
Results of Rietveld-based QPA of the *in situ* data sequence shown in Fig. 3.9.14 (Webster *et al.*, 2013). The relative phase abundances (upper) are derived using the Hill/Howard algorithm (Hill & Howard, 1987) in equation (3.9.26), while the absolute phase abundances (lower) have been derived from the external-standard approach (O'Connor & Raven, 1988) embodied in equation (3.9.21).

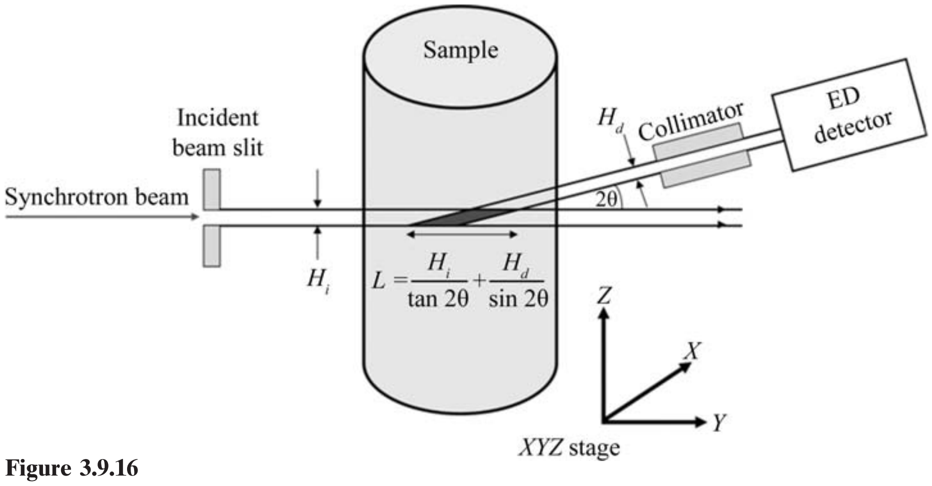


Figure 3.9.16
Basic experimental arrangement for energy-dispersive diffraction. The length of the active area or lozenge (dark grey region), L, is given by the function relating the incident- and diffracted-beam heights (H_i and H_d, respectively) and the angle of diffraction (2θ).

tors producing a spectrum of diffracted intensity as a function of energy.

Traditional angle-dispersive diffraction (ADD) satisfies Bragg's law by using a fixed wavelength and varying 2θ to map the d-spacings. In contrast, EDD data are collected directly on an energy scale at a constant 2θ and the energy is measured to map the d-spacings. This impinges upon the use of Rietveld methodology for QPA since, in contrast to ADD, the structure factors now vary as a function of energy. Energy is related to wavelength *via*

$$E\ (\mathrm{keV}) = \frac{hc}{\lambda} \simeq \frac{12.395}{\lambda}, \qquad (3.9.46)$$

where E is the energy of the incident radiation in keV, h is Planck's constant, c is the speed of light and λ is the wavelength associated with that energy in ångstroms. Rearrangement of equation (3.9.46) and substitution for λ in Bragg's law enables the mapping of the measured energy scale to d-spacings:

$$E\ (\mathrm{keV}) = \frac{6.197}{d \sin\theta}, \qquad (3.9.47)$$

where 2θ is the angle between the incident beam and the detector slit.

EDD data can be analysed using structureless profile-fitting methods such as those of Le Bail *et al.* (see Chapter 3.5) once the energy scale has been converted to a d-spacing scale (Frost & Fei, 1999; Larson & Von Dreele, 2004; Zhao *et al.*, 1997). If the distribution of intensities in the incident spectrum can be measured, it is possible to normalize the EDD data, correct for absorption and convert the pattern to an ADD form using a 'dummy' wavelength (Ballirano & Caminiti, 2001). Access to the incident spectrum, however, is not always possible, especially at synchrotron-radiation sources where the highly intense incident beam could damage the detector.

An alternative approach is to model the pattern directly on the energy scale *via* equation (3.9.47) (Rowles *et al.*, 2012; Scarlett *et al.*, 2009) and extract phase abundances using the methodologies described earlier in this chapter.

However, the major impediment to achieving this is the nonlinearity of the intensity distribution in the incident spectrum. This is due to (i) the nonlinear distribution of intensity as a function of energy in the incident beam, (ii) nonlinear detector responses (Bordas *et al.*, 1977) and (iii) absorption along the beam path (by the sample and air), which skews the energy distribution to the higher energies. This overall nonlinearity can be modelled empirically by functions such a lognormal curve (Bordas *et al.*, 1977; Buras *et al.*, 1979) or by an expansion of a power function (Glazer *et al.*, 1978). Alternatively, it may be determined experimentally by the use of standards measured under the same conditions as the experiment (Scarlett *et al.*, 2009). This latter approach allows some separation of the contributions from the instrument and the sample, and allows some degrees of freedom in the refinement of sample-related parameters that may be of benefit in dynamic experiments. Other contributions to the diffraction pattern that must also be accounted for include any fluorescence peaks arising from the sample or shielding or collimators, and any detector escape peaks from both diffracted and fluorescence peaks. Fluorescence peak positions and relative intensities should be constant throughout the measurement and may therefore be modelled using a fixed 'peak group' whose overall intensity can be refined during analysis. Escape peaks can be accounted for by the inclusion of a second phase identical to the parent phase but with an independent scale factor and a constant energy offset determined by the nature of the detector (Rowles *et al.*, 2012).

Currently, few Rietveld software packages are capable of dealing directly with the differences between EDD and ADD, specifically (i) the variance of structure factors as a function of energy, (ii) the nonlinear distribution of intensity in the incident beam as a function of energy further modified by a nonlinear detector response, and (iii) the preferential absorption of lower-energy X-rays by the sample/air. *TOPAS* (Bruker AXS, 2013) embodies algorithms that allow the pattern to be modelled directly on the energy scale and also the inclusion of equations to account for intensity variations arising from the experimental conditions. This allows quantification from such data to be achieved directly using Rietveld-based crystal-structure modelling incorporating the Hill and Howard algorithm in equation (3.9.26) (Hill & Howard, 1987). The application of *TOPAS* to a complex EDD experiment investigating the changes to the anode during molten-salt electrochemistry conducted in molten $CaCl_2$ at about 1223 K has been described by Rowles *et al.* (2012) and Styles *et al.* (2012).

3.9.10. Improving accuracy

There are many factors that influence the accuracy and precision of QPA results where (i) accuracy is defined as the agreement between the analytical result and the true value, and (ii) precision is the agreement between results if the analysis is repeated under the same conditions. Precision may further be split into (i) repeatability, which is the agreement between repeated measurement and analysis of the same specimen, and (ii) reproducibility, which additionally includes re-preparation, measurement and analysis of the sample.

3.9.10.1. *Standard deviations and error estimates*

Determination of the actual accuracy of an analysis is not a trivial task in a standardless method. In fact, it cannot be achieved without recourse to another measure of the sample that does incorporate standards. Too often, analysts will report Rietveld errors calculated in the course of refinement as the errors in the final quantification. However, these numbers relate purely to the mathematical fit of the model and have no bearing on the accuracy of the quantification itself.

Consider, for example, a three-phase mixture of corundum, magnetite and zircon. Such a sample was presented as sample 4 in the IUCr CPD round robin on QPA (Scarlett *et al.*, 2002). Its components were chosen with the deliberate aim of creating a sample in which severe sample-related aberrations occur. Table 3.9.4 shows the weighed amounts of each component and the results of replicate analyses of three different sub-samples of this material.

Table 3.9.4
Comparison of errors generated during the analysis of XRD data (Cu $K\alpha$ radiation) from three sub-samples of sample 4 from the IUCr CPD round robin on QPA (Scarlett *et al.*, 2002)

The bias values are (measured − weighed) while the values denoted XRF are the phase abundances generated from elemental concentrations measured by X-ray fluorescence methods.

	Phase		
$n = 3$	Corundum	Magnetite	Zircon
Weighed	50.46	19.46	29.90
Mean XRD measured wt%	56.52	17.06	26.42
Mean of Rietveld errors	0.15	0.11	0.11
Standard deviation of measured wt%	0.63	0.41	0.35
Mean of bias	6.06	−2.58	−3.48
XRF	50.4(2)	19.6(1)	29.5(1)

It is apparent that the standard deviation of the mean abundances of the three replicates, which represents the expected precision in the analysis, is 3 to 4 times greater than the errors reported by the Rietveld software. The good level of fit achieved in conducting these analyses (evidenced by low *R* factors) could lead the analyst to conclude that the mean value ± the standard deviation of the mean is an adequate measure of the phase abundances and their errors.

However, both the Rietveld errors and the precision are at least an order of magnitude smaller than the bias. The large bias, in this case due to the presence of severe microabsorption, represents the true accuracy that can be achieved in this example. Unfortunately, there is nothing in the XRD data and Rietveld analysis process that indicates that there may be a problem. It is only when the QPA is compared with other estimates, in this case derived from XRF chemical-analysis results, that the problem becomes apparent. The analyst must take further steps to identify sample-preparation and/or data-collection protocols that may improve accuracy and, importantly, seek ways to verify the results.

3.9.10.2. *Minimizing systematic errors*

The fundamental measured quantities in a diffraction pattern are the integrated intensities of the observed peaks. The precision of these measurements can be improved by: (i) increasing the primary intensity of the diffractometer using optics or higher-power X-ray sources; (ii) using scanning linear detectors (see Chapter 2.1), which have multiple detector elements to collect individual intensities many times; these are then summed to achieve higher accumulated counts; (iii) increasing the number of counts accumulated at each step, that is increasing the step counting time *T*; and (iv) increasing the number of points, *N*, measured across the peak.

Often, the temptation is to collect data with large values of *N* and *T* to maximize counting statistics. However, the resulting increased precision is only useful up to the point where counting variance becomes negligible in relation to other sources of error; thereafter data-collection time is wasted. For example, if the sample is affected by the presence of severe sample-related aberrations, the collection of highly precise data will not improve the accuracy of the resulting analysis significantly.

Therefore, the most important approach to improving the accuracy of an analysis is to eliminate the systematic errors. Given that the largest sources of error in QPA are experimental (Chung & Smith, 2000) and relate to sampling and specimen preparation, then this is the area on which the most careful attention needs to be focused. A detailed discussion of sample preparation and data-collection procedures is beyond the scope of this chapter but further details can be found in Chapter 2.10, and in Hill & Madsen (2002) and Buhrke *et al.* (1998).

3.9.10.3. *Minimizing sample-related errors*

3.9.10.3.1. *Crystallite-size issues*

Crystallite size is considered here as the length of a coherent scattering domain and should not be confused with the terms grain or particle size used frequently in powder diffraction to describe the macroscopic size of the components in the sample. The macroscopic size of the particle is somewhat irrelevant (as in ceramics or other solid pieces of samples) as long as the crystallites (or domains) that comprise the particle are (i) sufficiently small to ensure that there are enough crystallites contributing to the diffraction process (Smith, 1992) and (ii) randomly oriented, thus ensuring a true powder-average representation of intensities. However, for large domains or crystallites this assumption is usually not fulfilled and therefore it is necessary to reduce the crystallite size by reducing the size of the particles or grains that constitute the macroscopic objects of a powder.

Most issues in sample preparation are related to crystallite size and preferred orientation of the particles in the sample holder. For QPA a representative sampling of all possible orientations of crystallites with respect to the diffraction geometry is required. Rotation of the sample improves the particle statistics, since more crystallites can satisfy the diffraction condition (Elton & Salt, 1996).

Large-crystallite issues are easily detected using two-dimensional (2D) detectors, where the Debye rings show a 'spotty' intensity distribution. However, most QPA measurements are performed using 0D (point) or 1D (strip) detectors. The effect of large crystallites in a 1D pattern is that a few crystallites may contribute to irregularly high intensities for selected reflections. In the diffraction pattern, this situation is usually identified by intense reflections having a sharp peak profile compared with the surrounding peaks in the pattern. Furthermore, in a Rietveld refinement this situation is manifested by large intensity differences between the observed and calculated pattern that may not be associated with a particular crystallographic direction and hence to preferred orientation. Another way of detecting inhomogeneous crystallite distributions is to measure a series of scans from the same specimen at various rotation angles and comparing the relative peak intensities. It is worth noting that the push towards ever higher resolution in both laboratory and synchrotron instruments serves to further exacerbate the crystallite-size issue. This arises from the use of beams with decreased divergence, resulting in fewer crystallites likely to satisfy the diffraction condition.

There is no simple mathematical correction for large-crystallite issues and the effect is often misinterpreted in Rietveld refinement as preferred orientation. In this case, the correction would typically involve use of several directions for March–Dollase-type functions (Dollase, 1986) or an increasing order of spherical-harmonics coefficients (Ahtee *et al.*, 1989). In any case, this is an improper use of these corrections and the necessity to do so clearly points to deficiencies in the sample preparation and data-collection regime.

The best way to minimize the large-crystallite issue is to reduce the crystallite size through grinding of the sample. However, size-reduction methods need to be carefully assessed, since overgrinding can cause peak broadening due to (i) a decrease of long-range order and hence crystallite size and (ii) the introduction of microstrain (Hill & Madsen, 2002). The practical effect of peak broadening is increasing peak overlap, which may complicate the phase identification. For whole-pattern-based QPA, overgrinding is not as serious as long as it does not yield nanometre-sized particles or amorphous materials. This is because the integral intensity of the peaks is preserved. It should be noted that some phases can undergo transformation to other polymorphs or decompose to other phases during grinding (Hill & Madsen, 2002).

In practice, there is no generally applicable comminution strategy. For each material, a suitable milling device and grinding strategy needs to be identified. Inhomogeneous materials such as ores, concentrates and other mineralogical materials may have very different comminution properties for their constituents, leading to size fractionation during grinding. Large-crystallite issues are frequently observed for hard minerals (*e.g.* quartz, feldspar) while the grain size of soft minerals (*e.g.* talc) is reduced more rapidly.

A practical way of finding a best compromise for the milling conditions of a mixture may be the analysis of a series of samples of the same material where, for example, the grinding time is successively increased and the quantification results are compared. Fig. 3.9.17 shows the variation of analysed wt% with grinding time for two minerals: a stable result is eventually obtained.

There is a more extensive discussion of the impact of large-crystallite size on observed diffraction data (Smith, 1992) and ways to minimize its effect (Elton & Salt, 1996) in the published literature.

3.9.10.3.2. *Preferred orientation*

In order to generate peak intensities that accurately represent the intensity-weighted reciprocal lattice, the crystallites in the powder must not only be sufficient in number, but they must also be randomly oriented. In other words, each crystal orientation should have the same probability of diffracting. Preferred orientation can arise when particles align in the sample holder according to their morphology. This is most common with platy or

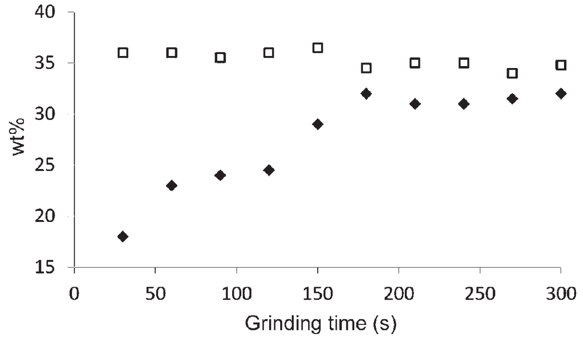

Figure 3.9.17
Variation of the magnetite (filled diamonds) and quartz (open squares) concentration of an iron-ore sample with grinding time. Stable conditions are obtained after about 180 s. Data courtesy ThyssenKrupp – Resource Technologies (Knorr & Bornefeld, 2013).

needle-like materials and the effect on the diffraction pattern is the observation of enhanced intensity along specific crystallographic directions with a subsequent decrease of intensity along other directions.

A number of sample-presentation methods can be used to minimize preferred orientation. For flat specimens, back pressing and side drifting into the sample holder can be effective. These methods tend to produce much less preferred orientation than front-mounted samples, but tend not to be very effective for chronic preferred orientation such as that exhibited by phases like clays, feldspars and chlorite. Reducing the size of the crystallites improves the probability of achieving random alignment of the crystallites in the sample holder. Gradually milling a sample and monitoring the preferred-orientation coefficients as a function of grinding time may again help to find the correct, or at least reproducible, grinding conditions (Fig. 3.9.18).

A major advantage of whole-pattern-based QPA over single-peak methods is that all classes of reflections are considered in the calculation. In this sense, the method is less prone to preferred orientation of a particular class of peaks. Furthermore, orientation effects may be corrected by applying March–Dollase (Dollase, 1986) or spherical-harmonics (Ahtee *et al.*, 1989) corrections. A properly applied correction may be of high importance for QPA in cases where a phase is present at low concentration and only a few peaks can clearly be identified in the pattern. If those peak(s) are affected by preferred orientation, the March–Dollase coefficient correlates strongly with scale factors and leads to biased QPA results. Examples of this effect occur with layered materials that have sheet-like morphology perpendicular to the *c* axis, including mica and clay minerals, which typically show stronger than expected intensity for the $00l$ reflections.

The crucial factor seems to be to what extent the orientation parameters correlate with the Rietveld scale factor. An example where the correlation is only minor is sample 2 from the IUCr CPD round robin on QPA (Scarlett *et al.*, 2002). In that example, brucite [$Mg(OH)_2$] shows strong preferred orientation along the $00l$ direction. This may be corrected by the March–Dollase model, which returns a refined value of 0.66. However, the introduction of this preferred-orientation correction only changes the brucite concentration from 35 to 36 wt% (weighed = 36.36 wt%); this is surprising because the orientation is strong and the weighted residual $R_{\rm wp}$ changes from 30 to 15%. Close examination of the correlations reveals a strong correlation between the brucite scale factor and preferred-orientation factor. However, the correlation of the brucite preferred-orientation parameter to the other scale factors (zincite, corundum and fluorite) is close to zero; this explains why in this example the QPA is not highly dependent on preferred orientation. In cases of strong correlation between the orientation parameter of one phase and the scale factors of other phases, preferred orientation should probably not be refined, or at least it should be verified carefully. It is worth noting that, in all Rietveld-based analyses, users should examine the correlation matrix as a matter of general practice to establish which parameters might be affecting parameters of interest.

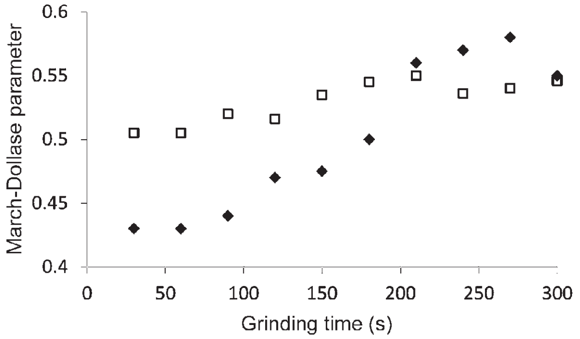

Figure 3.9.18
Increase of the March–Dollase (Dollase, 1986) parameter and related decrease of the degree of preferred orientation with grinding time for the two amphibole species actinolite (filled diamonds) and grunerite (open squares) in an iron ore. Data courtesy ThyssenKrupp – Resource Technologies (Knorr & Bornefeld, 2013).

It should be noted that sample rotation around the scattering vector (typically employed in flat-plate Bragg–Brentano geometry) during the scan does not reduce preferred orientation, since there is no change between the preferred-orientation direction and the diffraction vector. Using capillaries in transmission geometry assists in the reduction of preferred orientation, but the time-consuming nature of packing capillaries makes this technique infeasible in industrial applications where diffraction-based QPA is used for routine quality control.

3.9.10.3.3. *Microabsorption*

The strongest on-going impediment to accuracy in QPA using XRD data is microabsorption. The microabsorption effect occurs when a multiphase sample contains both low- and highly absorbing phases. For the highly absorbing phases, the X-ray beam is more likely to be absorbed in the surface layers of the grain; thus, the fraction of the grain contributing to the diffraction pattern will decrease as the size of the grain increases above the beam-penetration depth. For the low-absorbing phases, the beam penetrates further into the particle resulting in a greater likelihood of the desired 'volume diffraction' occurring (Brindley, 1945). The overall effect is the observation of a disproportionate amount of observed intensity from individual grains relative to what would be expected for the average absorption of the sample; the highly absorbing phases are under-represented relative to the low-absorbing phases. There is extensive discussion of the microabsorption issue in Zevin & Kimmel (1995).

Brindley (1945) has described the particle absorption contrast factor τ_α as

$$\tau_\alpha = (1/V)\int\limits_0^V \exp\left(-(\mu_\alpha - \bar{\mu})\right) {\rm d}v, \qquad (3.9.48)$$

where V is the particle volume, and μ_α and $\bar{\mu}$ are the linear absorption coefficients of phase α and the entire sample, respectively. While it is relatively easy to calculate the absorption coefficients, equation (3.9.48) implies knowledge of the *particle* size of each component; this information is only available through independent microscope or light-scattering characterization.

This correction term is commonly incorporated into QPA through a modification to equation (3.9.26) of the form

$$W_\alpha = \frac{S_\alpha(ZMV)_\alpha/\tau_\alpha}{\sum_{k=1}^n S_k(ZMV)_k/\tau_k}. \qquad (3.9.49)$$

Brindley has also devised criteria by which to assess whether a microabsorption problem is likely to be present or not. Calculation of μD (where μ is the linear absorption coefficient and D is the particle diameter) yields the following criteria:

(i) $\mu D < 0.01$ – fine powder. There is negligible microabsorption and hence no correction is necessary.

Table 3.9.5

Calculated values of μD (where μ is the linear absorption coefficient and D is the particle diameter) for Cu $K\alpha$ X-rays for corundum, magnetite and zircon with a range of particle sizes

Diameter (µm)	μD		
	Corundum, Al_2O_3 (μ = 125 cm^{-1})	Magnetite, Fe_3O_4 (μ = 1167 cm^{-1})	Zircon, $ZrSiO_4$ (μ = 380 cm^{-1})
0.1	0.001	0.012	0.004
0.2	0.003	0.023	0.008
0.5	0.006	0.058	0.019
1	0.013	0.117	0.038
2	0.025	0.233	0.076
5	0.063	0.584	0.190
10	0.125	1.167	0.380
20	0.251	2.334	0.759

(ii) $0.01 < \mu D < 0.1$ – medium powder. Microabsorption is likely to be present and the normal Brindley correction model can be applied.

(iii) $0.1 < \mu D < 1.0$ – coarse powder. A large microabsorption effect is present. The Brindley model can only be used to provide an approximate correction provided that μD is closer to the lower limit of the range.

(iv) $\mu D > 1.0$ – very coarse powder. This indicates that severe microabsorption is likely to be present and that any correction is well beyond the limits of the model.

It is difficult for the analyst encountering a new sample to determine whether a correction for microabsorption is required without first obtaining additional information. A minimum requirement should be to calculate μD for each phase present. However, this requires knowledge of the particle size which, in a multiphase sample, can be very difficult to obtain unambiguously. Even when the particle size is measured by, for example, dynamic light scattering or optical or SEM image analysis, the applicability of the correction can still be unclear. In addition, the correction factor embodied in equations (3.9.48) and (3.9.49) makes the assumption that the particles of the phase of interest are spherical and of uniform size. This assumption is unrealistic in almost all samples; in reality, each phase is likely to be present at a wide range of particle sizes and the particles are highly unlikely to be spherical.

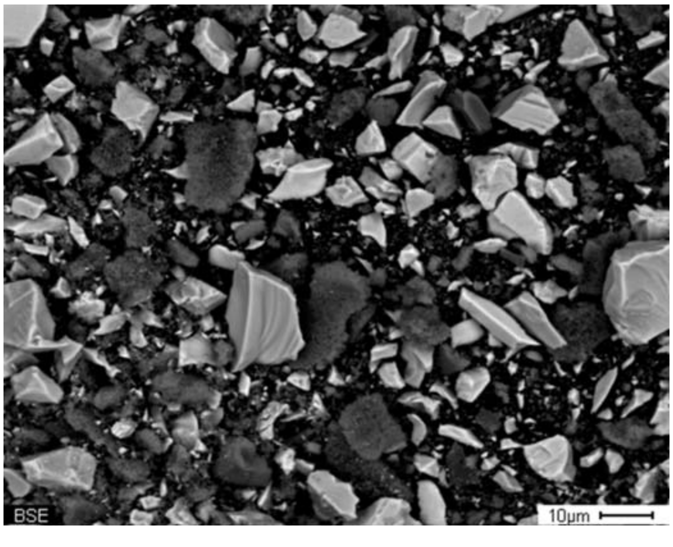

Figure 3.9.19

Backscattered-electron SEM image of a mixture of approximately equal amounts of corundum (dark grey), magnetite and zircon (lighter grey). Note the wide range of particle sizes present for each of the three phases.

Table 3.9.5 shows the calculated values of μD for Cu $K\alpha$ radiation for some commonly encountered phases in mineralogical analysis. For the least absorbing phase (corundum), the upper range of applicability of the Brindley model (medium powder) is reached at about 5 µm; by 8 µm, the coarse powder criterion has been reached and the correction model is no longer applicable. For magnetite, these limits are reached an order of magnitude earlier at about 0.5 and 0.9 µm, respectively.

Fig. 3.9.19 shows an SEM image of a mixture of approximately equal amounts of corundum, magnetite and zircon. The individual components of the sample were weighed and the mixture ground in ethanol in a McCrone micronizing mill (McCrone Research Associates, London) for 10 min g^{-1}. This approach to sample preparation is generally accepted as best practice for powder XRD because it minimizes structural damage during grinding (Hill & Madsen, 2002). After decanting and drying, the sample was back-packed into a cavity sample holder for XRD data collection; the same sample was then used to obtain the SEM image in Fig. 3.9.19. Visual observation shows a wide range of particle sizes (from submicron to greater than 10 µm) and shapes that do not even approximate spheres. Even if this information is obtained, selection of a particle size that best represents each individual phase is a difficult task. In addition, in many sample suites, the component phases exhibit a range of hardness resulting in different rates of grinding and hence difference size ranges. Regrettably, what happens too often in practice is that analysts will micronize the sample and then select an arbitrary particle size in order to derive a 'preferred' value for the final analysis. Therefore, caution is advised in the application of these correction models. The IUCr CPD round robin on QPA (Madsen *et al.*, 2001; Scarlett *et al.*, 2002) showed that many participants severely degraded their results by applying a correction when none was necessary.

Equation (3.9.48) shows that there two ways to minimize microabsorption. The first is to reduce the absorption contrast by, for example, changing the X-ray wavelength. While corundum and magnetite have very different linear absorption coefficients for Cu $K\alpha$ radiation (126 and 1123 cm^{-1}, respectively), the difference is reduced to 196 and 231 cm^{-1}, respectively, for Co $K\alpha$ radiation. The second approach is to reduce the particle size in order to meet Brindley's fine- or medium-powder criteria.

However, even these steps may not be sufficient to eliminate the microabsorption effect. Slightly different absorption coefficients, or different particle sizes for phases with the same absorption coefficients, may still introduce a bias between expected and analysed concentrations. In this situation, it may be better to use a calibrated hkl_phase or peaks_phase (Section 3.9.6) instead of a Rietveld, structure-based phase. The calibration step involved in the generation of such a phase incorporates the microabsorption problem into the calibration constant.

Fig. 3.9.20 shows the bias between known concentrations (derived from chemical analysis) and QPA-determined concentrations for a series of salt samples. The samples contain halite (NaCl), sylvite (KCl) and kieserite ($MgSO_4{\cdot}H_2O$) as major phases and small amounts of anhydrite ($CaSO_4$), langbeinite [$K_2Mg_2(SO_4)_3$] and carnallite [$KMgCl_3{\cdot}6(H_2O)$]. The linear absorption coefficient of sylvite (254 cm^{-1}) is much higher than halite (165 cm^{-1}). Using crystal-structure-based analysis, there is a systematic deviation of up to 3% with an overestimation of the low absorber (halite) and an underestimation of the high absorber (sylvite). After replacing sylvite by a calibrated hkl_phase, the bias is reduced to about 1% and does not show systematic deviations.

It should be noted, however, that the phase constants developed using such a calibration approach will only be applicable to the sample suite and preparation conditions for which it was developed. The calibration process will need to be repeated if there are significant changes to the sample suite or sample-preparation conditions.

3.9.10.3.4. *Whole-pattern-refinement effects*

One of the distinct advantages of structure-based whole-pattern fitting for QPA is that no standards need to be prepared because the structure for each phase provides the phase constant *ZMV*; the unit-cell dimensions allow the calculation of the cell volume *V* and the unit-cell contents provide the mass *ZM* (Bish & Howard, 1988; Hill & Howard, 1987). These values are used, along with the Rietveld scale factor *S*, in equation (3.9.26) to derive the phase abundance. This is especially useful for complex systems where the preparation of multiple standards would add considerably to the analytical complexity.

An additional advantage is the ability to refine the crystal structure (unit-cell dimensions and site-occupation factors, for example), when the data are of sufficiently high quality, in order to obtain the best fit between observed and calculated patterns. In addition to updating the *ZMV* value, the site occupancies are contained in the structure-factor calculation and, therefore, will change the relative reflection intensities and have an impact on the scale factor and QPA. Other structural parameters that have a strong effect on the scale factor and QPA are the atomic displacement parameters (ADPs). Strong correlation between the ADPs and amorphous material concentration has been shown by Gualtieri (2000) and Madsen *et al.* (2011).

This leads to the question: which crystal structure should be selected for QPA? Databases contain multiple entries for the same phase with the structures determined using different methods. While ADPs and site-occupation factors determined using neutron diffraction and single-crystal analysis should be favoured over those determined using X-ray powder data, many database entries do not have refined ADPs for all (and in some cases, any) atoms. Often, arbitrarily chosen default values of 0.5 or 1.0 Å^2 for $B_{\rm eq}$ are entered for all atoms, but this should be viewed or used with great caution. There is clearly a need to carefully evaluate the crystal-structure data used for QPA. This is particularly worth mentioning in view of the advent of new 'user-friendly' software that automatically assigns crystal structures after having performed the phase identification.

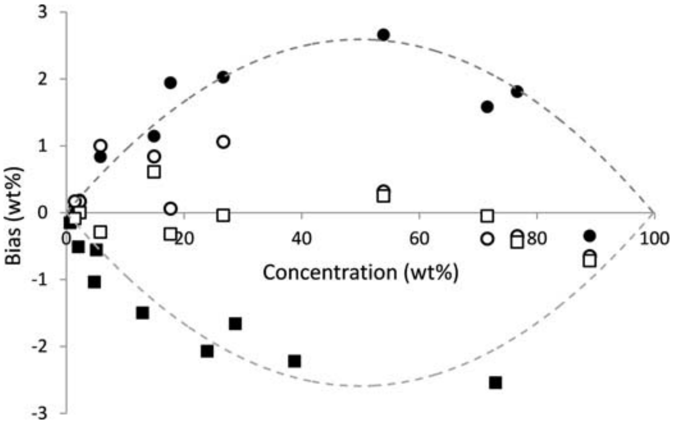

Figure 3.9.20
Bias as a function of phase concentration for industrial salt samples for (i) structure-based QPA (filled symbols) and (ii) calibrated hkl_phase (open symbols) for halite (circles) and sylvite (squares). The broken lines indicate the trend of the bias for structure-based QPA. Data are courtesy of K+S AG, Germany.

Empirical profile-shape models contribute significantly to the complexity (and correlations) of whole-powder-pattern fitting for QPA because of the large number of phases and multiple parameters required to model the profile shape of each phase. The use of convolution-based profile fitting [in, for example, *BGMN* (Bergmann *et al.*, 1998, 2000) and *TOPAS* (Bruker AXS, 2013)] greatly reduces the number of parameters, because the instrument-resolution function (which is constant for a given setup) can be separated from sample-related peak broadening. The instrument component can be refined using a standard and then fixed for subsequent analysis. The sample contribution to peak width and shape can then be related directly to crystallite size and microstrain using a minimal number of parameters. The reduction of the total number of parameters reduces the refinement complexity and the chance of parameter correlation.

The choice of the function used to model the pattern background may also have a strong influence on amorphous content (Gualtieri, 2000; Madsen *et al.*, 2011). Given that the intensities of both the background and the amorphous contribution vary slowly as a function of 2θ, it is inevitable that there will be a high degree of correlation between them. Hence, any errors in determining the true background will result in errors in amorphous phase determination. A simple approach is to use a background function with a minimal number of parameters. A more exact approach requires the separation of the amorphous contribution from background components such as Compton scattering and parasitic scattering by the sample environment and air in the beam path. This is routinely done in pair distribution function (PDF) analysis; details can be found in Chapter 5.7 in this volume and in Egami & Billinge (2003).

Another parameter that correlates with the pattern background is the width of broad peaks for phases of low concentration. If allowed to refine to very large width values, the peaks are 'smeared' over a broad range of the pattern with no clear distinction between peaks and background. The same issue applies when there is a high degree of peak overlap, particularly at high angles, leading to severe under- or over-estimation of the phase. The careful use of limits for either crystallite size or corresponding parameters in empirical peak-shape modelling assists in minimizing this effect.

There can be a subtle interplay between the profile-shape function and the pattern background that has an impact on whole-pattern fitting (Hill, 1992). The data in Fig. 3.9.21, collected using a Cu tube and an Ni $K\beta$ filter, exhibit low-angle truncation of the peak tails at the β-filter absorption edge. On the high-angle side, the anatase peak displays a wide tail which extends to the position of the strongest rutile peak at about 27.5° 2θ. In this case, rutile is present as a minor phase and the error in the background determination using conventional peak-profile modelling (Fig. 3.9.21*a*) introduces about 0.5% bias in the rutile QPA. The use of a more accurate profile model that incorporates the effect of the β-filter absorption edge (Fig. 3.9.21*b*) serves to improve the accuracy (Bruker AXS, 2013).

3.9.10.3.5. *Element analytical standards*

XRD-based derivation of elemental abundances relies on (i) the QPA abundances, and (ii) the assumed or measured stoichiometry of the crystalline phases. The accuracy of the QPA

result may then be evaluated by comparing the calculated elemental abundances with those determined by traditional chemical-analysis techniques. However, for the best level of agreement, this method requires that the composition of the crystalline phases be well defined. A complication, in particular for minerals, is that idealized compositions may be reported but do not necessarily match the actual composition of the species present in the sample. Where possible, detailed phase analysis using microbeam techniques should be undertaken to establish the true composition for each phase. A complication that serves to decrease the agreement is that chemically based compositional analysis does not distinguish between crystalline and amorphous phase content, while the diffraction-based QPA usually measures only the crystalline phases. Generally, the composition of amorphous phases may not be known accurately and even highly crystalline material can contain amorphous components because of non-diffracting surface layers of the grains (Cline *et al.*, 2011).

An example demonstrating the level of agreement that can be achieved is that of the iron-ore certified reference material SX 11–14 from Dillinger Hütte (Fig. 3.9.22). The material is moderately complex and consists of nine distinct mineral species. The data were measured with Co $K\alpha$ radiation and analysed using Rietveld-based QPA in *TOPAS* (Bruker AXS, 2013). The phase abundances are converted to elemental and oxide compositions for comparison with the certified elemental analyses (Table 3.9.6). There is excellent agreement between the XRD results and the chemical analysis with bias values better than ±1 wt%.

3.9.10.3.6. *Phase-specific methods: diffraction SRMs, round-robin samples and synthetic mixtures*

In contrast to elemental compositional analysis, where standard reference materials (SRMs) are widespread, there are only a very limited number of SRMs available for diffraction-based QPA. Prominent examples are SRMs for the cement industry [NIST reference material clinker 8486 (Stutzman & Leigh, 2000) and ordinary Portland cement NIST SRM 2686] or ceramics materials (silicon nitride CRM BAM-S001) (Peplinski *et al.*, 2004). Similar to elemental standards, the certified values do not necessarily represent the true composition. Rather, they are published values that are typically averaged over the results from different independent methods, instruments and laboratories. Therefore, confidence limits of concentrations are provided that may be much larger than estimated standard deviations of concentrations within a single laboratory.

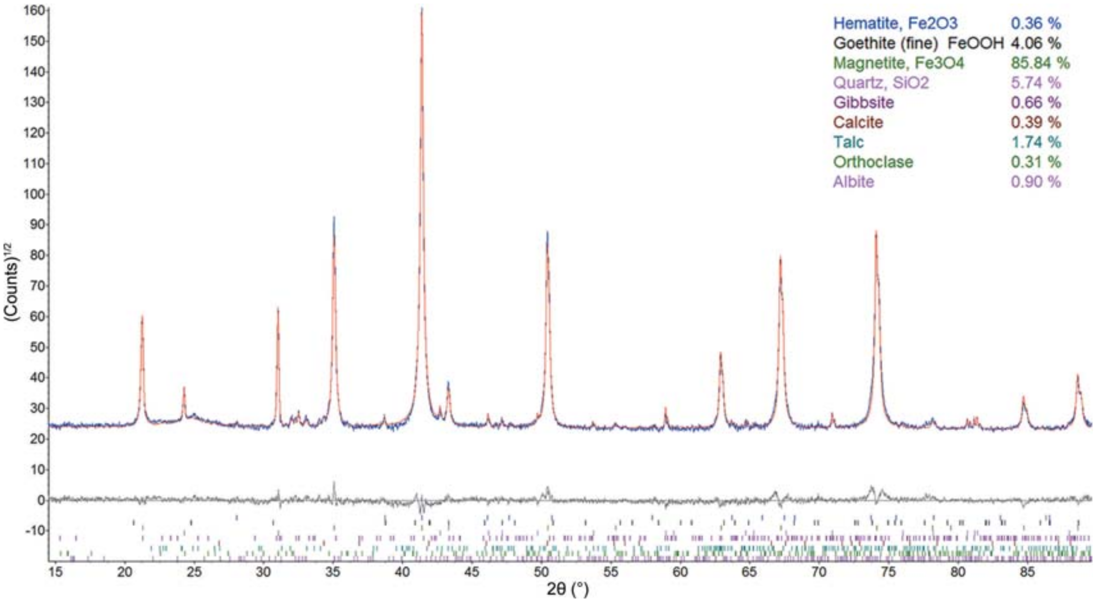

Figure 3.9.22

Output of Rietveld refinement and results of QPA for the iron-ore certified reference material SX 11–14 from Dillinger Hütte. The data were measured with Co $K\alpha$ radiation.

Finally, a number of inter-laboratory tests, or round robins, have been conducted on synthetic mixtures in order to set benchmarks for particular materials and/or the application of methods. Examples range from well ordered, high-symmetry phases discussed in earlier sections of this chapter (Madsen *et al.*, 2001; Scarlett *et al.*, 2002) to standard mixtures of geological material, granite and bauxites (Bish & Post, 1993), and technical products like artificial Portland cements (De la Torre & Aranda, 2003) where relative biases of 2–3% for the main phases and 5–10% for minor phases were found.

Very recently, the precision and accuracy of QPA for the analysis of Portland clinker and cement were determined for synthetic mixtures and commercial samples. The scatter of the results from the inter-laboratory comparison, and the fact that individual errors are much smaller than the standard deviations of all submitted results, points to the widespread presence of user-dependent systematic errors (Léon-Reina *et al.*, 2009).

One of the most challenging round robins is the Reynolds Cup (Ottner *et al.*, 2000; McCarty, 2002; Kleeberg, 2005; Omotoso *et al.*, 2006; Raven & Self, 2017), organized biannually since the year 2000 by the Clay Minerals Society. Synthetic mixtures representing typical sedimentary rock types are analysed and require a very high level of sample preparation and analytical skills because of the presence of a variety of clay minerals.

While most round robins have dealt with inorganic materials, one for pharmaceutical materials was organised by the International Centre for Diffraction Data (ICDD) together with the Pharmaceutical Powder XRD symposium series (PPXRD) (Fawcett *et al.*, 2010). A major outcome was the identification of operator errors in all steps of the analysis to be the largest source of error. This highlights the importance of reducing systematic errors for improving accuracy in QPA.

As a concluding remark, a variety of factors may influence the precision and accuracy of QPA. Nonetheless, better than 1 wt% agreement may be achieved for simple systems of well crystallized material. Moderately complex mixtures such as those routinely observed in cement plants and in the mining industry can be typically analysed at a 1 wt% level of accuracy provided that the analyst chooses the most appropriate sample-preparation, data-collection and analysis methodologies for the samples in question.

3.9.11. Summary

The value in using diffraction-based methods for the determination of phase abundance arises from the fact that the observed data are derived directly from the crystal structure of each phase. Knowledge of phase abundance is valuable in many fields including (i) mineral exploration, where the type and amount of major minerals serve as indicators for valuable minor minerals, (ii) mineral extraction, where the performance of the process line is governed by the mineralogy, not the commonly used elemental compositions, (iii) *in situ* studies, where the mechanism and kinetics of phase evolution resulting from the application of an external variable can be examined and (iv) the optimization of production conditions for advanced materials.

The methodology of QPA is fraught with difficulties, many of which are experimental or derive from sample-related issues. Hence, it is necessary to verify diffraction-based phase abundances against independent methods. This should include calculation of the expected sample element composition (using the QPA and an assumed or measured composition of each phase) and comparing these values with the measured element composition. In those circumstances where this is not possible, the QPA values should be regarded only as semi-quantitative. While such values may be useful for deriving trends within a particular system, they cannot be regarded as an absolute measure.

3.10. Accuracy in Rietveld quantitative phase analysis with strictly monochromatic Mo and Cu radiations

L. León-Reina, A. Cuesta, M. García-Maté, G. Álvarez-Pinazo, I. Santacruz, O. Vallcorba, A. G. De la Torre and M. A. G. Aranda

3.10.1. Introduction

Most industrial materials are multiphase systems and the accurate determination of their phase assemblage is key to understanding their performances. There are different approaches to carrying out quantitative phase analysis (QPA; see Chapter 3.9); however, nowadays, the Rietveld method is the most widely employed methodology for QPA of crystalline materials (Madsen *et al.*, 2001; Scarlett *et al.*, 2002), including cements (Stutzman, 2005; León-Reina *et al.*, 2009; Chapter 7.12).

The factors affecting the accuracy and precision of Rietveld quantitative phase analysis (RQPA) results can be gathered into three main groups: (i) instrument related, (ii) sample-preparation related and (iii) data-analysis protocol(s). The Rietveld method is a standardless methodology which uses the crystal-structure descriptions of each crystalline component to calculate its powder pattern. For this reason, the correct choice of crystal-structure description for each phase in multiphase materials is key (Zevin & Kimmel, 1995; Madsen *et al.*, 2001, 2011). The influence of the instrument type on RQPA has previously been evaluated (Madsen *et al.*, 2001) and the main conclusion was that neutron and synchrotron powder diffraction yielded the best results owing to larger irradiated volumes and also to the minimization of microabsorption effects.

High-energy (short-wavelength) X-rays contribute (i) to minimize absorption and microabsorption effects, (ii) to the measurement of a higher number of Bragg peaks and (iii) to increase the irradiated volume of the specimen. Figs. 3.10.1(*a*) and 3.10.1(*b*) show the irradiated volumes bathed by X-rays when using flat samples for Mo and Cu radiations in transmission geometry, and Fig. 3.10.1(*c*) shows the irradiated volume for Cu in reflection mode (Cuesta *et al.*, 2015). Mo radiation combined with a flat sample in transmission geometry allows an irradiated volume of close to 100 mm^3; meanwhile, for Cu radiation (flat samples in reflection and transmission geometries) the irradiated volumes are close to 5 mm^3 (Cuesta *et al.*, 2015). In this context, it is worth mentioning that the absorption correction for flat-

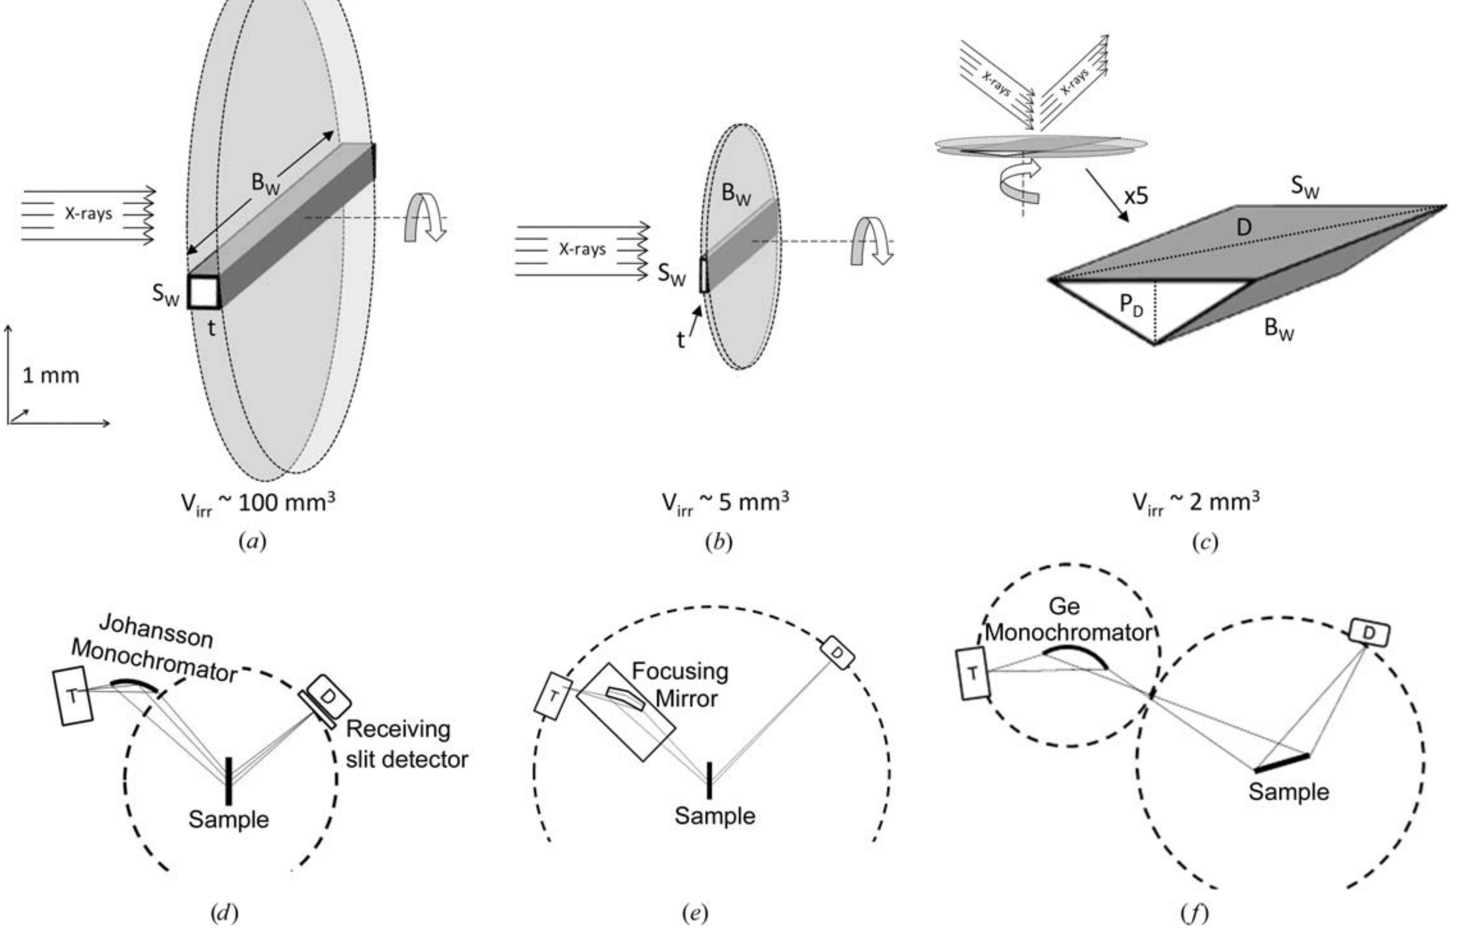

Figure 3.10.1
Irradiated volume for a flat sample holder in transmission mode using (*a*) Mo radiation and (*b*) Cu radiation, and (*c*) reflection mode using Cu radiation. Diffraction-geometry sketches: (*d*) transmission geometry with primary monochromator, (*e*) transmission geometry with focusing mirror and (*f*) reflection geometry with primary monochromator. $SrSO_4$	$SrSO_4$	22322	299	187	40/—	Garske & Peacor (1965)

sample transmission geometry is conceptually similar to that for flat-plate reflection geometry, but the length of the scattered beam path has to be properly defined. The corresponding equation is given in section A5.2.5 of Egami & Billinge (2003).

It must also be noted that Mo radiation has a major drawback when compared with Cu radiation. The λ^3 dependence of diffraction intensity favours the use of Cu radiation by a factor of 10.2. Thus, a detector receives approximately ten times as many diffracted X-ray photons with Cu than with Mo (this calculation neglects the different fractions of photons lost in the diffractometer optical paths). This fact can be partially overcome in modern X-ray detectors by increasing the counting time for patterns collected with Mo radiation without reaching prohibitively long times.

As discussed in Chapter 3.9, there are many factors that affect the accuracy and precision of QPA results. It must be recalled that accuracy is the agreement between the analytical result and the true value, and precision is the agreement between results for analyses repeated under the same conditions. Precision may be further divided into repeatability, the agreement between analyses derived from several measurements on the same specimen, and reproducibility, the agreement including re-preparation, re-measurement and data re-analysis of the same sample. Since the largest sources of errors in RQPA are experimental, sample preparation is key, as the reproducibility of peak-intensity measurements is mainly governed by particle statistics (Elton & Salt, 1996). It is generally accepted that the diffraction intensities have to be collected with an accuracy close to ±1% to obtain patterns that are suitable for good RQPA procedures (Von Dreele & Rodriguez-Carvajal, 2008). Milling the sample to reduce the particle size is an approach that should be exercised with care to avoid peak broadening or amorphization (Buhrke *et al.*, 1998). In order to improve particle statistics, a very common practice is to continuously spin the sample during data collection. A much less developed approach is to use high-energy, highly penetrating laboratory X-rays.

Another important issue in the QPA of mixtures is the limit of detection (LoD) and the limit of quantification (LoQ). In this context, the LoD can be defined as the minimal concentration of analyte that can be detected with acceptable reliability (Zevin & Kimmel, 1995), *i.e.* for which its strongest (not overlapped) diffraction peak in the powder pattern has a signal-to-noise ratio larger than 3.0. The 'reliability' criterion is flexible and may be defined by regulatory agencies, as is mainly the case for active pharmaceutical ingredients. Evidently, the LoD can be reduced (improved) by increasing the intensity of the X-ray source, for example using synchrotron radiation. In this context, the LoQ can be defined as the minimum content of an analyte that can be determined with a value at least three times larger than its standard deviation and determined to an acceptable reliability level. For RQPA, this type of approach can be straightforward, although the accuracy for minor phases may be quite poor.

The main aim of the study described here was to test whether the use of high-energy Mo radiation, combined with high-resolution X-ray optics, could yield more accurate RQPA than well established procedures using Cu radiation. In order to do so, three sets of mixtures with increasing amounts of a given phase (the spiking method) were prepared and the corresponding RQPA results were evaluated with calibration curves (least-squares fits) and quantitatively by statistical analysis based on the Kullback–Leibler distance (KLD; Kullback, 1968). The three series were (i) crystalline inorganic phase mixtures with increasing amounts of an inorganic phase, (ii) crystalline organic phase mixtures with increasing amounts of an organic compound and (iii) a series with an increasing content of amorphous ground glass. This last series is the most challenging case because the amorphous content is derived from a small overestimation of the internal standard employed. Amorphous content determination is important for many industries, including cements, glasses, pharmaceuticals and alloys.

3.10.2. Compounds and series

3.10.2.1. *Single phases*

Table 3.10.1 provides information about the phases used in this work. Further details can be found in the original publication (León-Reina *et al.*, 2016). All of the mixtures were prepared by grinding the weighed phases by hand in an agate pestle and mortar for 20 min to ensure homogeneity.

3.10.2.2. *Crystalline inorganic series*

A constant matrix of calcite (C), gypsum (Gp) and quartz (Q) was prepared. Six samples with known increasing amounts of insoluble anhydrite (i-A) were then produced and were labelled CGpQ_*x*A, where *x* repesents the target i-A content: 0.00, 0.125, 0.25, 0.50, 1.0, 2.0 or 4.0 wt%.

3.10.2.3. *Crystalline organic series*

A constant matrix of glucose (G), fructose (F) and lactose (L) was prepared. Six samples with known increasing amounts of xylose (X) were then produced and labelled GFL_*x*X, where *x* represents the target X content: 0.00, 0.125, 0.25, 0.50, 1.0, 2.0 or 4.0 wt%.

3.10.2.4. *Variable amorphous content series*

A constant matrix of calcite (C) and zincite (Z) was prepared. Five samples with increasing contents of amorphous ground glass (Gl) were then prepared. The elemental composition of the ground glass is given in García-Maté *et al.* (2014). The mixtures were labelled CZQ_*x*Gl, where *x* indicates 0, 2, 4, 8, 16 or 32 wt% Gl. The amorphous content was determined by adding ~20 wt% quartz (Q) as an internal standard.

3.10.3. Analytical techniques

All phases and mixtures were studied with Mo $K\alpha_1$ (transmission geometry) and Cu $K\alpha_1$ (reflection geometry) monochromatic radiation. Table 3.10.1 shows the X-ray linear absorption coefficients for all of the phases, as microabsorption is always a concern in RQPA. A microabsorption correction was not applied in this work, but readers must be aware that this effect, if relevant, is one of the greatest source of inaccuracy in RQPA (Madsen *et al.*, 2001; Scarlett *et al.*, 2002). All of the phases were also characterized by scanning electron microscopy (see Fig. 3.10.2).

3.10.3.1. *Mo $K\alpha_1$ laboratory X-ray powder diffraction (LXRPD)*

Mo $K\alpha_1$ powder patterns were collected in transmission geometry in constant irradiated volume mode, in order to avoid any correction of the measured intensities, on a D8 ADVANCE (Bruker AXS) diffractometer (188.5 mm radius) equipped with a Ge(111) primary monochromator, which gives monochromatic Mo radiation (λ = 0.7093 Å). The X-ray tube operated at 50 kV and 50 mA. The optics configuration was a fixed divergence slit (2°) and a fixed diffracted anti-scatter slit (9°). A LYNXEYE XE 500 µm energy-dispersive linear detector, optimized for high-energy radiation, was used with the maximum opening angle. Using these conditions, the samples were measured between 3 and 35° 2θ with a step size of 0.006° and with a total measurement time of 3 h 5 min. The flat samples were placed into cylindrical holders between two Kapton foils (Cuesta *et al.*, 2015) and rotated at a rate of 10 revolutions per minute during data collection. Moreover, the absorption factor of each sample was experimentally measured by comparing the direct beam with and without the sample (Cuesta *et al.*, 2015). The amount of sample loaded (which determines the height of the cylinder) in the holders was adjusted to obtain a total absorption (μt) of ~1, which corresponds to an absorption factor of ~2.7 or 63% of direct-beam attenuation. For the organic samples this criterion was not followed as it would lead to very thick specimens. In this case, the maximum holder thickness was used (1.7 mm).

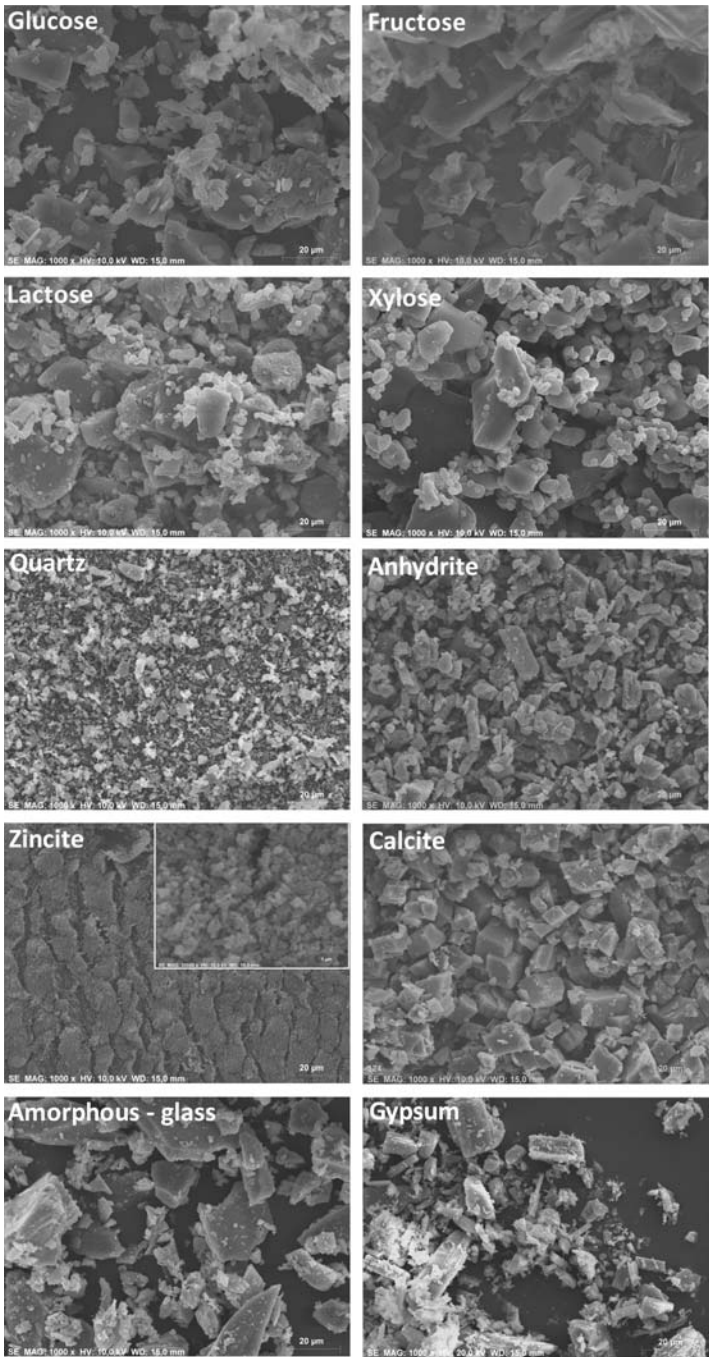

Figure 3.10.2
Scanning electron microscopy micrographs for the studied phases (×1000). The inset in the zincite micrograph shows the powder at higher magnification (×20 000).

3.10.3.2. *Cu $K\alpha_1$ laboratory X-ray powder diffraction (LXRPD)*

Cu $K\alpha_1$ powder patterns for exactly the same samples were recorded in reflection geometry ($\theta/2\theta$) on a X′Pert MPD PRO (PANalytical B.V.) diffractometer (240 mm radius) equipped with a Ge(111) primary monochromator, which gives monochromatic Cu radiation (λ = 1.54059 Å). The X-ray tube was operated at 45 kV and 40 mA. The optics configuration was a fixed divergence slit (0.5°), a fixed incident anti-scatter slit (1°), a fixed diffracted anti-scatter slit (0.5°) and an X′Celerator RTMS (real-time multiple strip) detector operating in scanning mode with the maximum active length. Using these conditions, the samples were measured between 6.5 and 81.5° 2θ with a step size of 0.0167° and a total measurement time of 2 h 36 min. The flat samples were prepared by rear charge of a flat sample holder in order to minimize preferred orientation and were rotated at a rate of 10 revolutions per minute.

The lowest analyte content samples, CGpQ_0.12A and GFL_0.12X, were measured three times using both radiations, Mo $K\alpha_1$ and Cu $K\alpha_1$, for a precision (reproducibility) assessment. Therefore, regrinding and reloading of the mixtures in the sample holder was carried out prior to every measurement.

3.10.3.3. *Transmission synchrotron X-ray powder diffraction (SXRPD)*

Powder patterns for the lowest analyte content samples, CGpQ_0.12A and GFL_0.12X, were also measured using synchrotron radiation. SXRPD data were collected in Debye–Scherrer (transmission) mode using the powder diffractometer at the ALBA Light Source (Fauth *et al.*, 2013). The wavelength, λ = 0.77439 (2) Å, was selected with a double-crystal Si(111) monochromator and was determined using the NIST SRM640d Si standard (a = 5.43123 Å). The diffractometer is equipped with a MYTHEN-II detector system. The samples were loaded into glass capillaries 0.7 mm in diameter and were rapidly rotated during data collection to improve the diffracting-particle statistics. The data-acquisition time was 20 min per pattern to attain a very good signal-to-noise (S/N) ratio over the angular range 1–35° 2θ. Three patterns, taken at different positions along the capillaries, were collected for each sample.

SXRPD data for the amorphous content series, CZQ_*x*Gl, were also measured at the ALBA Light Source. The experimental setup was the same as described above but the working wavelength was λ = 0.49591 (2) Å.

3.10.4. Powder-diffraction data analysis

All powder patterns were analysed by the Rietveld method using the *GSAS* software package (Larson & Von Dreele, 2000) with the pseudo-Voigt peak-shape function (Thompson *et al.*, 1987) for RQPA. The refined overall parameters were phase scale factors, background coefficients (linear interpolation function), unit-cell parameters, zero-shift error, peak-shape parameters and preferred-orientation coefficient, when needed. The March–Dollase preferred-orientation adjustment algorithm was employed (Dollase, 1986). The modelling direction must be given as input for the calculations. In this case, the directions for the different phases were taken from previous studies. Alternatively, this direction can be extracted from the pattern from an analysis of the differences between observed and calculated intensities for non-overlapped diffraction peaks. The crystal structures used are reported in Table 3.10.1.

In order to provide a single numerical assessment of the performance of each analysis, a statistic based on the KLD distance was used (Kullback, 1968). This approach was previously used to evaluate the accuracy of RQPA applied to standard mixtures (Madsen *et al.*, 2001; Scarlett *et al.*, 2002; León-Reina *et al.*, 2009). Both phase-related KLD distances and absolute values of the Kullback–Leibler distance (AKLD) were calculated. Accurate analyses are mirrored by low values of AKLD.

The overall amorphous content was determined from the internal standard methodology approach (De la Torre *et al.*, 2001; Aranda *et al.*, 2012) with quartz as an internal standard [using isotropic atomic displacement parameters (ADPs) of 0.045 and 0.0087 Å^2 for Si and O, respectively]. If the original sample contains an amorphous phase, the amount of standard will be overestimated in RQPA. From the (slight) overestimation of the standard, the amorphous content of the investigated sample can be derived (De la Torre *et al.*, 2001). The important role of the values of the ADPs in the results of RQPA mainly in amorphous content determinations using the internal-standard method has been discussed previously (Madsen *et al.*, 2011).

3.10.5. Crystalline single phases

All of the single phases were selected according to several parameters, such as relevance to selected applications, purity, particle size of the powder and preferred orientation. In order to check the suitability of the crystal structures used, all of the phases were first studied using powder diffraction with Mo $K\alpha_1$ radiation. These preliminary studies were of special interest for organic phases, as the CIF files obtained from the Cambridge Structural Database (CSD) did not contain the atomic displacement parameters (ADPs). For lactose and fructose, the ADPs were obtained from the original publications and were introduced manually into the *GSAS* control file. For glucose and

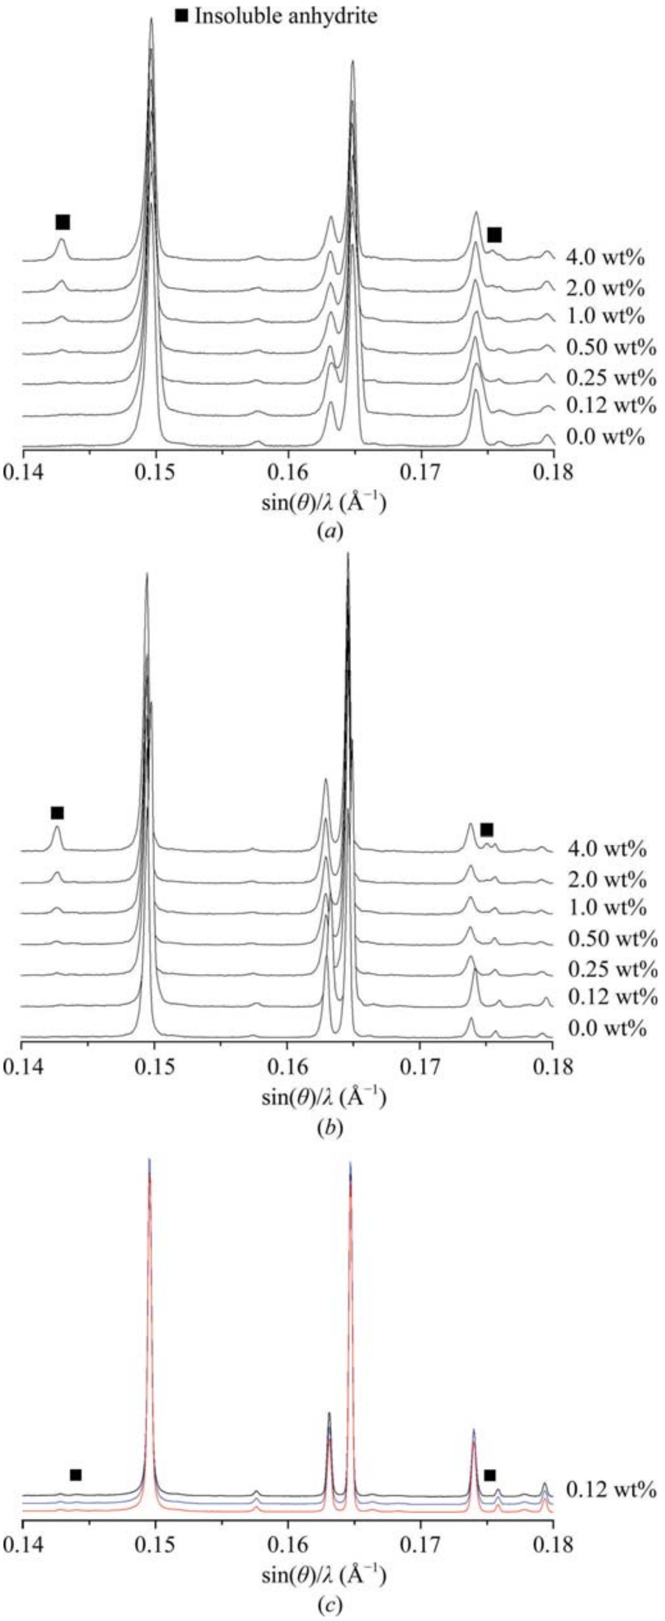

Figure 3.10.3

(*a*) Raw Mo $K\alpha_1$ powder patterns for the inorganic series composed of a constant matrix of calcite, gypsum and quartz, and increasing amounts of insoluble anhydrite (peaks highlighted with a solid square). (*b*) Raw Cu $K\alpha_1$ powder patterns for the same inorganic series. (*c*) Raw SXRPD patterns for CGpQ_0.12A collected at three different positions of the capillary (red, black and blue traces). The intensity values in (*c*) have been artificially offset to show the three different patterns.

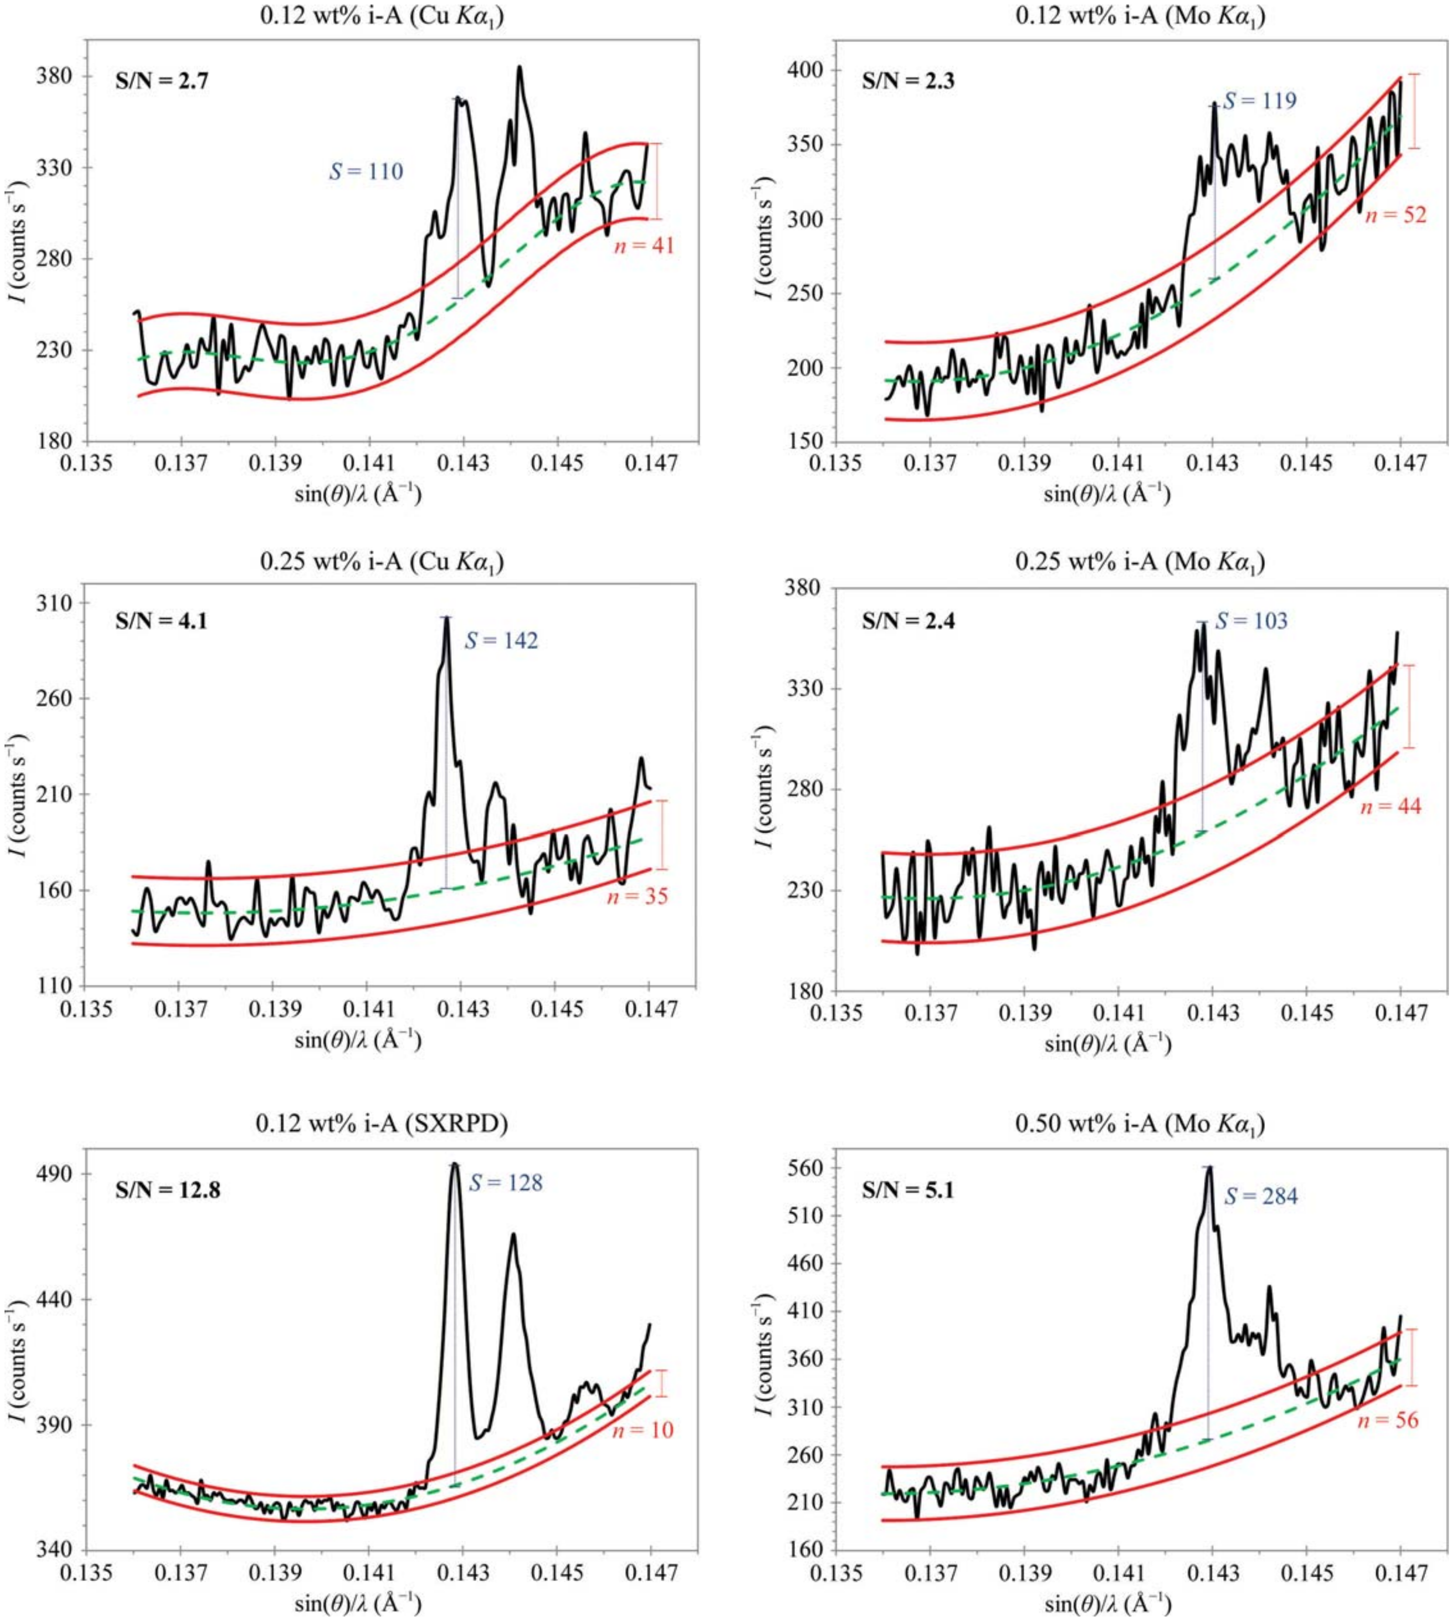

Figure 3.10.4

Selected region of the powder patterns showing the main diffraction peak of insoluble anhydrite for the low-content samples to investigate the limit of detection. Top left: Cu $K\alpha_1$ pattern for CGpQ_0.12A. Middle left, Cu $K\alpha_1$ pattern for CGpQ_0.25A. Bottom left, SXRPD pattern for CGpQ_0.12A. Top right, Mo $K\alpha_1$ pattern for CGpQ_0.12A. Middle right, Mo $K\alpha_1$ pattern for CGpQ_0.25A. Bottom right, Mo $K\alpha_1$ pattern for CGpQ_0.50A. The main peak of anhydrite, $(\theta)/\lambda = 0.143$ Å^{-1}, is located at 25.4, 11.6 and 12.7° 2θ for Cu $K\alpha_1$, Mo $K\alpha_1$ and synchrotron radiations, respectively. The peak at $\sin(\theta)/\lambda = 0.1445$ Å^{-1} is due to the soluble anhydrite from gypsum (constant content in all the samples). The very tiny peak at $\sin(\theta)/\lambda = 0.1457$ Å^{-1}, which is slightly visible only in the SXRPD pattern, arises from $SrSO_4$ (0.39 wt%) from gypsum.

xylose, the ADP values were not reported in the original publications. Hence, they were obtained from the fits to the Mo $K\alpha_1$ patterns for the single phases. Three groups of isotropic ADPs were refined: those for O, C and H atoms. The final ADP values are given in León-Reina *et al.* (2016) as well as the R_F values before and after optimization, showing the improvements in the fits. For RQPA of all of the mixtures the ADPs were kept fixed.

Preferred orientation was modelled by the March–Dollase algorithm along the [001] axis for both glucose and lactose. Since microparticle sizes and distributions for different phases may result in some sample-related effects, such as preferred orientation, microabsorption and 'rock-in-the-dust/graininess' effects, all powders were characterized by scanning electron microscopy (SEM). Fig. 3.10.2 shows SEM micrographs for all of the phases. All inorganic samples were single phases except for gypsum and insoluble anhydrite. The impurity-phase contents for these two samples were reported in León-Reina *et al.* (2016).

Both organic and inorganic phases were also measured using Cu $K\alpha_1$ radiation in reflection mode. As expected, a transparency effect was observed in the Cu $K\alpha_1$ patterns for organic samples (Buhrke *et al.*, 1998).

3.10.6. Limits of detection and quantification

LoD and LoQ are two important quantities in the validation of any analytical method. LoD/LoQ are terms that are used to describe the smallest concentration of an analyte that can be reliably detected/assessed by an analytical procedure, as discussed in Section 3.10.1. In techniques such as Rietveld analysis, the approach of having a powder pattern with its strongest (not overlapped) diffraction peak with an S/N ratio of larger than 3.0 is not straightforward because the full powder pattern is evaluated.

Fig. 3.10.3 shows Mo $K\alpha_1$ and Cu $K\alpha_1$ raw patterns for the inorganic series with increasing amounts of insoluble anhydrite (labelled with solid squares) and Fig. 3.10.4 shows the strongest diffraction peak for i-A in the mixtures containing 0.123 wt% anhydrite (CGpQ_0.12A) and 0.25 wt% anhydrite (CGpQ_0.25A) to evaluate the limits of detection in the conditions reported in Section 3.10.5. For CGpQ_0.12A, both laboratory powder patterns yielded peaks with S/N ratios lower than 3.0 (top panels in Fig. 3.10.4). For CGpQ_0.25A, the Cu $K\alpha_1$ pattern yielded a clear peak with S/N = 4.1; therefore, it can be concluded that the LoD for insoluble anhydrite with this radiation in this mixture is slightly lower than 0.2 wt%. For Mo $K\alpha_1$ radiation, the CGpQ_0.25A and CGpQ_0.50A samples yielded patterns with peaks with S/N ratios of 2.4 and 5.1, respectively. Hence, it can be concluded that the LoD for i-A with this radiation in this mixture is quite close to 0.3 wt%.

The LoQ for i-A in this matrix was also studied. Three Mo $K\alpha_1$ and Cu $K\alpha_1$ patterns were collected for CGpQ_0.12A. For the three Mo $K\alpha_1$ patterns, the average analysis result for i-A was 0.28 (2) wt%, but the accuracy of the obtained value is poor, as the expected value was 0.12 wt%. Similarly, the average value for the analyses of three Cu $K\alpha_1$ patterns was 0.24 (2) wt%. The RQPA results are given as supporting information in León-Reina *et al.* (2016). It was concluded that i-A can be quantified in this mixture at the level of 0.12 wt%, but with a relative error close to 100%. If the 'acceptable reliability' criterion in the analysis is taken into consideration, the LoQ value would be close to 1.0 wt% in order to have a relative associated error lower than 20%.

CGpQ_0.12A was also studied by SXRPD. Fig. 3.10.3(*c*) shows the SXRPD patterns collected at three different positions of the capillary, which were almost identical, and Fig. 3.10.4 (bottom left) shows the main diffraction peak of anhydrite. The S/N ratio for the strongest diffraction peak of anhydrite was 12.8 and hence the limit of detection for i-A with synchrotron radiation in this matrix is below 0.10 wt%.

To quantify the accuracy of the analyses, the KLD methodology was used. The AKLD values for each analysis as well as the KLD values for i-A are reported in León-Reina *et al.* (2016). The synchrotron analyses clearly had better accuracy than those using laboratory radiation. Moreover, the Mo $K\alpha_1$ radiation analyses were slightly better than those obtained using Cu $K\alpha_1$ radiation.

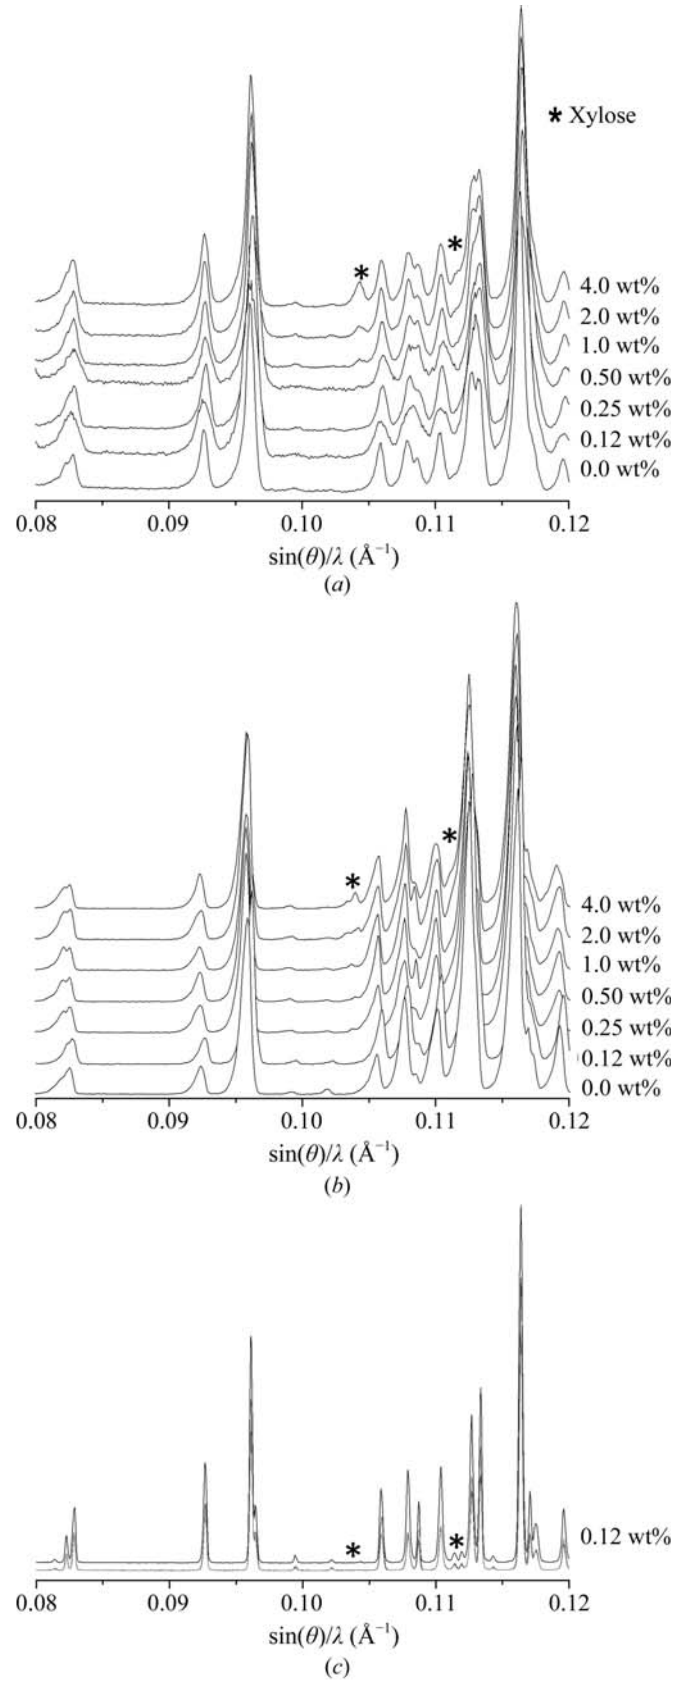

Figure 3.10.5

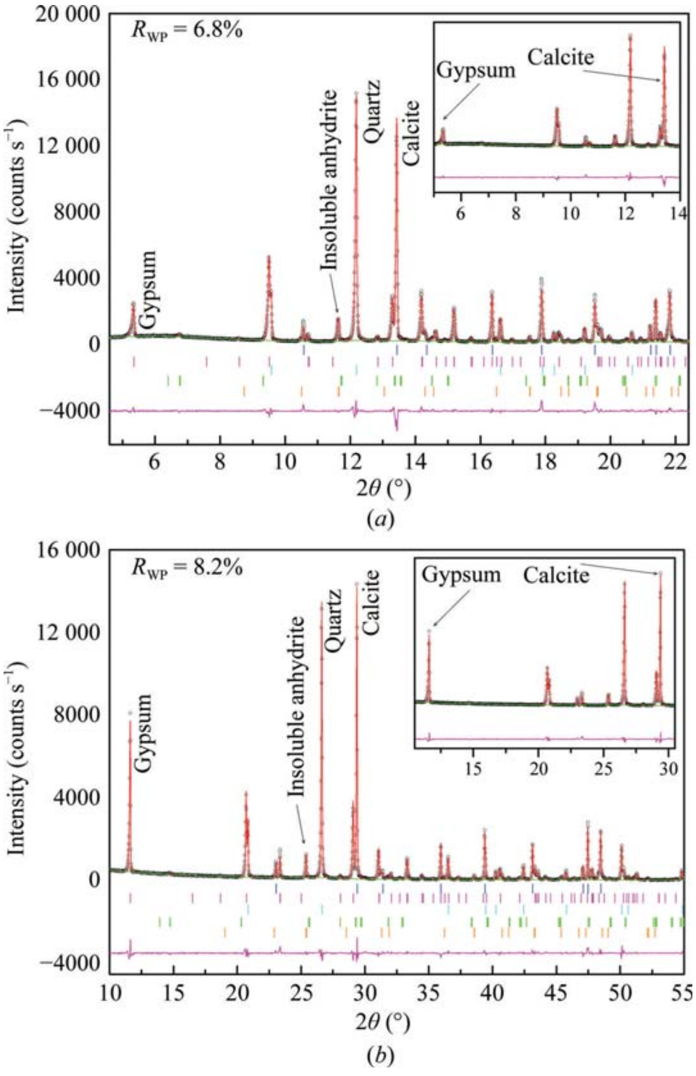

Figure 3.10.6
Selected range of the Rietveld plots for CGpQ_4.0A: (*a*) Mo $K\alpha_1$ and (*b*) Cu $K\alpha_1$ patterns. The inset highlights the effect of preferred orientation for gypsum and calcite.

Fig. 3.10.5 shows Mo $K\alpha_1$ and Cu $K\alpha_1$ raw patterns of the organic mixtures with increasing amounts of xylose. The strongest powder-diffraction peak for xylose in the GFL_0.12X patterns (with both Mo and Cu radiations) was not observed. The corresponding peak was observed in the GFL_0.25X patterns. Therefore, the LoD can be established as close to 0.25 wt%. The analysis results for xylose in GFL_0.25X were reported in León-Reina *et al.* (2016). These values showed that the results from Mo $K\alpha_1$ powder diffraction were slightly more accurate.

The LoQ for xylose was also studied. Once again, three Mo $K\alpha_1$ and Cu $K\alpha_1$ patterns were collected for GFL_0.12X. The average value for the analysis of the three Mo patterns was 0.18 (8) wt%. Similarly, the average result for the analyses of three Cu patterns was 0.34 (6) wt%. Full RQPA results are reported in the supporting information of León-Reina *et al.* (2016). The LoQ for xylose in this mixture for the two radiations can be established as close to 0.12 wt%. Indeed, if one applies an ‘acceptable reliability’ criterion, the LoQ would be much higher at above 1 wt%. The output of this study was that Cu $K\alpha_1$ radiation yielded a slightly less accurate result than that obtained from the Mo $K\alpha_1$ data.

GFL_0.12X was also studied by SXRPD in a rotating glass capillary in transmission mode. Fig. 3.10.5(*c*) shows SXRPD patterns for GFL_0.12X collected at three different positions of the same capillary. The powder patterns showed quite different peak ratios. It is important to bear in mind that filling a glass capillary with organic compounds is sometimes not easy due to electrostatic charge effects. For this reason, the phase ratio within the part of capillary bathed by the X-rays might not be the same as that of the sample under study. The behaviour observed in Fig. 3.10.5(*c*) could be explained by inhomogeneous capillary filling. Hence, in this case, the RQPA results are unreliable. Even in ‘well behaved’ samples, inhomogeneous filling of small capillaries could result in problems. Readers should be aware of this, and the authors strongly recommend that at least three patterns should be collected along the capillary and superimposed. If there is inhomogeneous filling the patterns will differ, and extreme care has to be exercised when filling capillaries in order to minimize this problem.

3.10.7. Increasing inorganic crystalline phase content series

Table 3.10.2 reports the RQPA results for six inorganic mixtures with increasing amounts of i-A measured with Mo $K\alpha_1$ (transmission) and Cu $K\alpha_1$ (reflection). The Rietveld plots of the mixture with 4 wt% i-A are shown in Fig. 3.10.6. For most of the samples, the AKLD values (see Table 3.10.2) for Mo $K\alpha_1$ radiation are slightly smaller than the corresponding values obtained for Cu $K\alpha_1$ radiation. For this reason, we can conclude that the Mo $K\alpha_1$ analyses are slightly better than those derived using Cu $K\alpha_1$ radiation.

	Mo $K\alpha_1$ trm.	Cu $K\alpha_1$ refl.

Slope	1.02 (2)	0.98 (5)	0.89 (3)
Intercept	−0.4 (3)	3.7 (8)	10.0 (6)

Figure 3.10.7

Rietveld quantification results for (*a*) the insoluble anhydrite series (within an inorganic crystalline matrix), (*b*) the xylose series (within an organic crystalline matrix) and (*c*) the ground-glass series (within an inorganic crystalline matrix) as a function of the weighed amount of each phase. Open symbols represent the derived amorphous contents in the mixtures without any added glass. The results of the least-squares fits are also shown.

On the other hand, calcite and gypsum presented preferred orientations, with the axes being [104] and [010], respectively. This effect was modelled using the March–Dollase algorithm. Preferred orientation makes the $0l0$ reflections for gypsum have higher intensities in the Cu $K\alpha_1$ patterns, and smaller intensities in the Mo $K\alpha_1$ patterns, than those calculated from the crystal structure (see insets in Fig. 3.10.6). As a consequence, the refined values for flat samples in reflection and transmission geometries were smaller and larger than 1.0, respectively (Cuesta *et al.*, 2015). Although preferred orientation is present in all patterns, the Cu $K\alpha_1$ patterns were recorded in reflection geometry (flat samples), while the Mo $K\alpha_1$ measurements were collected in transmission (also flat samples). This results in opposite diffraction intensity changes and points towards another (possible) fruitful use: joint refinement of these two types of patterns to counterbalance the effects of preferred orientation in RQPA.

Fig. 3.10.7(*a*) shows the quantified i-A contents (wt%), as determined by the Rietveld methodology, as a function of the weighed i-A amount. The two R^2 values for the fits are very close to 1.00, and the intercept values are very close to zero, showing the appropriateness of the Rietveld methodology for quantifying crystalline materials. Furthermore, the slopes of the calibration curves are also 1.00 in both cases. Consequently, this study allows it to be concluded that RQPA for crystalline inorganic phases using powder-diffraction patterns collected using Mo $K\alpha_1$ radiation yields results that are as accurate as those obtained from the well established method using Cu $K\alpha_1$.

3.10.8. Increasing crystalline organic phase content series

Table 3.10.3 shows RQPA results for six mixtures prepared with G, F, L and an increasing amount of X measured with Mo $K\alpha_1$ (transmission) and Cu $K\alpha_1$ (reflection). In general, the values obtained using both radiations are quite similar to the weighed values. The AKLD values and the KLD values for the xylose phase are also reported in Table 3.10.3. The AKLD values from Mo $K\alpha_1$ and Cu $K\alpha_1$ radiations are relatively similar. The main problem for RQPA of organic mixtures measured in reflection geometry is related to the low X-ray absorption of the samples and the transparency effects that lead to poor peak shapes and even some split peaks in the powder patterns, as discussed previously (León-Reina *et al.*, 2016).

Fig. 3.10.7(*b*) shows the quantified xylose contents (wt%) as determined by the Rietveld methodology as a function of the weighed amount of xylose added to the mixtures. The results were plotted to obtain the calibration lines with increasing content of the analyte. Both plots gave R^2 values close to 1.0. However, the slope values were 0.92 and 0.82 for Mo $K\alpha_1$ and Cu $K\alpha_1$ radiations, respec-

tively. Slope values close to 1.0 mirror accurate analyses. Furthermore, the *y*-intercept values were 0.04 and 0.30 for Mo $K\alpha_1$ and Cu $K\alpha_1$ radiations, respectively. A *y*-intercept value close to 0.0 mirrors accurate analyses. Hence, it can be concluded that slightly more accurate analyses are obtained for Mo $K\alpha_1$ powder diffraction in transmission when compared with Cu $K\alpha_1$ powder diffraction in reflection for organic crystalline samples.

3.10.9. Increasing amorphous content series within an inorganic crystalline phase matrix

Fig. 3.10.8 shows Mo $K\alpha_1$ (transmission), Cu $K\alpha_1$ (reflection) and SXRPD (transmission) raw patterns for the mixtures with increasing amounts of glass. It is important to highlight that the increase in the background due to the glass is very modest even for ∼32 wt% of glass. Table 3.10.4 shows the RQPA of these mixtures, prepared with C, Z and an increasing amount of Gl, for the three radiations. The glass-free sample may contain amorphous material from the employed phases. Hence, we used the SXRPD data to calculate a correction factor for quartz to yield zero amorphous content for the glass-free sample (León-Reina *et al.*, 2016).

The linear fit to the amorphous content values obtained using SXRPD was very good, $R^2 = 0.998$, with the slope being 1.00 within the errors (see Fig. 3.10.7*c*). This plot also shows the quantified amorphous contents, in weight percentage, as a function of the amount of added ground glass, measured with Mo $K\alpha_1$ and Cu $K\alpha_1$ radiations. Open symbols indicate the derived amorphous contents obtained with the internal-standard method in the mixture without any added glass, CZQ_0Gl. Both R^2 values are quite close to 1.00, showing the consistency of the internal-standard methodology. However, the slope values were 0.98 and 0.89 for Mo $K\alpha_1$ and Cu $K\alpha_1$ radiations, respectively. Furthermore, the *y*-intercept values were 3.7 and 10.0 for Mo $K\alpha_1$ and Cu $K\alpha_1$ radiations, respectively. Again, slope values close to 1.0 and *y* intercepts close to 0.0 mirror accurate analyses. It must also

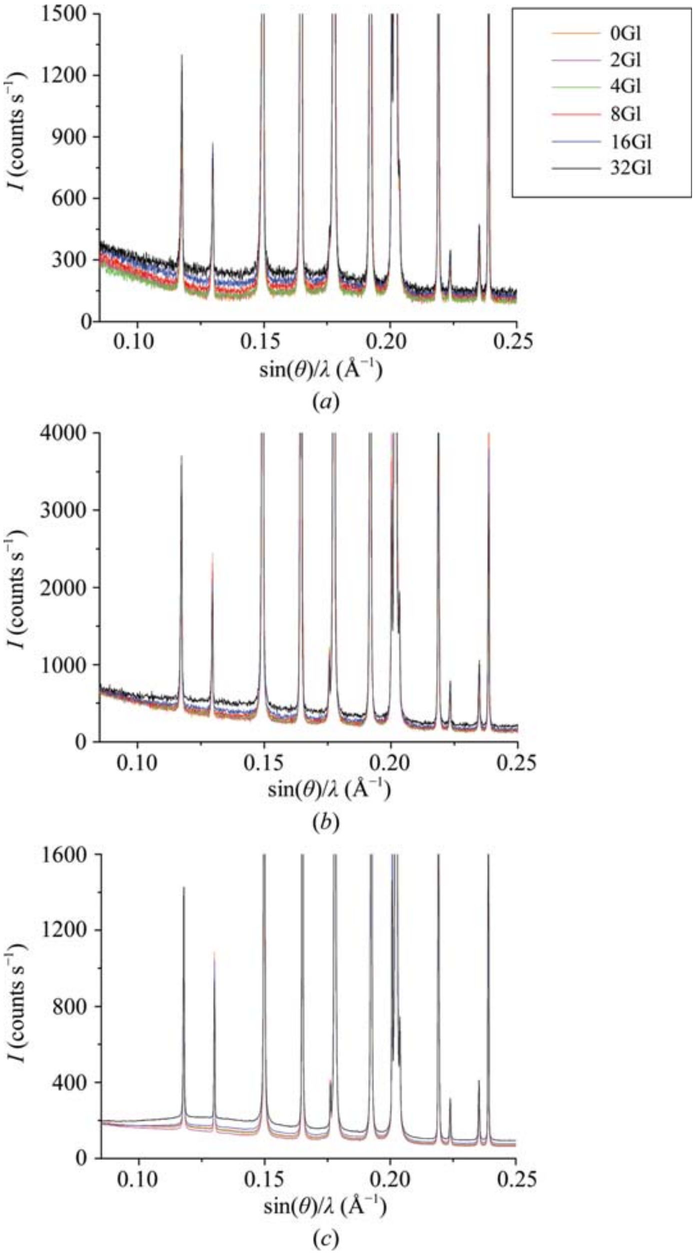

Figure 3.10.8
Raw powder patterns for the amorphous-material-containing series composed of a constant matrix of calcite and zincite, and increasing amounts of ground glass. Quartz was added as internal standard. (*a*) Mo $K\alpha_1$, (*b*) Cu $K\alpha_1$ and (*c*) SXRPD radiations. The intensities of the patterns have been rescaled to highlight the contributions of the glass to the background.

be pointed out that for the Mo $K\alpha_1$ analyses the value from the measurement of the Gl-free sample, 3.5 wt%, matches the value from the *y* intercept of the plot, 3.7 wt%, very well. Meanwhile, there is a much larger discrepancy for the similar Cu-based analyses, 12.0 and 10.0 wt%, respectively, which is quite far from zero. Hence, it is concluded that the amorphous contents derived from Mo $K\alpha_1$ data are more accurate than those derived from Cu $K\alpha_1$ data. However, it is not possible to reliably quantify amorphous contents below ~8–10 wt% from Mo $K\alpha_1$ and Cu $K\alpha_1$ diffraction data (see Table 3.10.4) with the internal-standard method.

On the contrary, SXRPD reliably allows quantification of amorphous contents down to ~2 wt% for this relatively simple mixture. In addition, the AKLD and the KLD values reported in Table 3.10.4 demonstrate that the synchrotron analyses are indeed much better than the laboratory analyses.

3.10.10. Conclusions

(i) We have thoroughly studied the limit of detection for a well crystallized inorganic phase in an inorganic compound matrix. We have determined the following LoDs for insoluble anhydrite: ~0.2 wt%, ~0.3 wt% and lower than 0.1 wt% for Cu $K\alpha_1$, Mo $K\alpha_1$ and synchrotron radiations, respectively. We conclude that the LoD is slightly better for Cu $K\alpha_1$ than for Mo $K\alpha_1$ because the λ^3 dependence of the diffraction intensity, with similar acquisition times, yielded slightly better signal-to-noise ratios in the Cu patterns. Of course, detector efficiencies also play a role in the measured signal-to-noise ratios.

(ii) We have also studied the limit of quantification for a well crystallized inorganic phase using laboratory X-ray powder diffraction. This phase could be quantified at the level of 0.12 wt% in stable fits with repeatable outputs and good precision. However, the accuracy of these analyses was quite poor, with relative errors close to 100%. Only contents higher than 1.0 wt% yielded analyses with relative errors lower than 20%.

(iii) The Rietveld quantitative phase analysis results from high-resolution Mo $K\alpha_1$ powder diffraction (transmission geometry) and high-resolution Cu $K\alpha_1$ powder diffraction (reflection geometry) were quite similar for a series of crystalline inorganic phase samples. We inferred the validation of the Mo-based analyses procedure from this initial study, as it yielded results very close to well established high-resolution Cu radiation analyses (see Fig. 3.10.7*a*). From the comparison of the AKLD values for the two types of analyses, it was demonstrated that the Mo $K\alpha_1$ analyses were slightly better than those using Cu $K\alpha_1$.

(iv) Comparison of the results obtained from Mo-based and Cu-based patterns for a series of crystalline organic phase mixtures showed that the Mo $K\alpha_1$ analyses gave slightly more accurate values. This conclusion was drawn because the calibration curve obtained from Mo patterns with increasing content of xylose gave an R^2 value closer to 1.0, a slope closer to 1.0 and an intercept value close to 0.0 (see Fig. 3.10.7*b*). The slightly poorer results from Cu $K\alpha_1$ analyses are very likely to be due to the transparency effects in reflection geometry.

(v) Comparison of the results obtained from Mo $K\alpha_1$ and Cu $K\alpha_1$ patterns for a series containing increasing amounts of amorphous glass also indicated that the Mo-based analyses were slightly more accurate than the corresponding Cu $K\alpha_1$ analyses. This conclusion was drawn because the obtained calibration curve from the Mo data has (1) a slope closer to 1.0, (2) a smaller amorphous value for the glass-free sample and (3) a closer agreement between the intercept from the least-squares fit and the determined amorphous value for the glass-free sample (see Fig. 3.10.7*c*). The AKLD analysis confirmed this outcome. Furthermore, the results from synchrotron data have the best accuracy, as shown by the calibration plot and the AKLD analysis.

Finally, we conclude that for the challenging quantification analyses studied here, the results derived from high-energy Mo $K\alpha_1$ patterns were slightly more accurate than those obtained from Cu $K\alpha_1$ patterns. We justify this conclusion based on the larger tested volume for Mo $K\alpha_1$ analyses, which led to better statistics/accuracy in the recorded powder-pattern intensities. The minimization of microabsorption in the Mo $K\alpha_1$ transmission data is very likely to be an additional factor in the improved accuracy.

This chapter is based on an article *Accuracy in Rietveld quantitative phase analysis: a comparative study of strictly monochromatic Mo and Cu radiations* by León-Reina *et al.* [(2016), *J. Appl. Cryst.* **49**, 722–735]. The work was supported by Spanish MINECO through BIA2014-57658-C2-2-R, which is co-funded by FEDER, and BIA2014-57658-C2-1-R research grants. Funding from Junta de Andalucía (grant P11-FQM-07517) is also acknowledged. We thank CELLS-ALBA (Barcelona, Spain) for providing synchrotron beam time on the BL04-MSPD beamline. 4.1. An overview of currently used structure determination methods for powder diffraction data

K. Shankland

4.1.1. Introduction

The two chapters that follow this one deal in detail with reciprocal- and real-space methods of crystal structure determination from powder diffraction data (SDPD). The purpose of this chapter is to provide an overview and summary of the wide variety of methods that are available for SDPD; no single method is discussed in great depth, and the reader should refer to the subsequent chapters for fuller descriptions of the main methodologies.

The paucity of structural information contained in a powder diffraction data set, relative to a single-crystal data set, means that considerable ingenuity may be required to determine structural models that can serve as starting points for subsequent Rietveld refinement. The most significant issues for SDPD method development are (*a*) the relatively small number of structure amplitudes that are measured in the powder experiment (typically several hundred) compared with the several thousand of a typical single-crystal experiment; and (*b*) accidental reflection overlap, particularly at larger diffraction angles (smaller *d*-spacings) where each individual peak in the diffraction pattern no longer equates to a single reflection intensity. Furthermore, those reflection intensities that are well determined rarely extend to atomic resolution. It therefore comes as no surprise that conventional direct methods of structure determination developed for single-crystal experiments do not normally perform well with intensities extracted from powder diffraction data using simple profile fitting. Rather, it is adaptations of direct methods that are specifically tailored to powder diffraction data, or methods that incorporate a significant amount of prior information about the structure under study, that have come to dominate the field of SDPD. For particularly complex or challenging structure determinations, it is often a combination of analytical methods (*e.g.* powder diffraction and electron microscopy, or powder diffraction and nuclear magnetic resonance, NMR) that is required to solve the crystal structure.

This introduction to the limitations of powder diffraction data inevitably contains some generalizations, to which there are a great many exceptions. For example, many materials (typically those containing heavy atoms in high-symmetry systems) scatter strongly to high resolution; many neutron-diffraction experiments using powder samples may be able to access Bragg diffraction peaks at atomic resolution because of the lack of a form-factor fall-off with diffraction angle; many synchrotron-based powder diffractometers possess extremely good instrumental resolution that allows closely spaced reflections to be resolved, even at high diffraction angles. Nevertheless, the intrinsic limitations of powder diffraction data, imposed by the collapse of the three dimensions of reciprocal space onto the single dimension of a powder diffraction pattern, are such that SDPD is rarely as straightforward as its single-crystal equivalent.

4.1.2. Methods used in SDPD

The origins of SDPD can be traced to the first half of the 20th century, with the structures of many simple crystalline materials (such as rock salt) being determined from powder diffraction data. In the late 1940s, Zachariasen (1948) solved the structures of several uranium salts using an essentially trial-and-error approach, establishing the principle of varying atomic positions and comparing the resultant calculated reflection intensities with those observed in the diffraction data. The 1960s saw the first applications of direct and Patterson methods in the field, and the

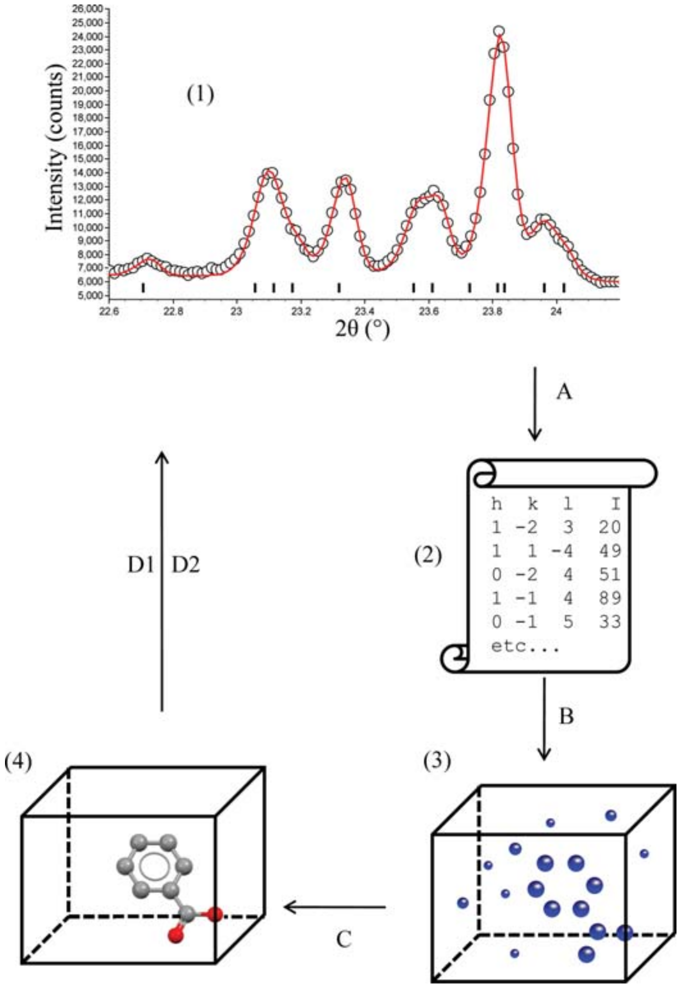

Figure 4.1.1
A generalized scheme for structure determination from powder diffraction data. A powder diffraction pattern (1) consists of a series of observed intensities (open circles) as a function of angle. The calculated intensities (red line) can be obtained either from a structure-independent Pawley or LeBail-type fit (A) to the data, or from a structure-dependent Rietveld-type fit (D1) to the data. Model-independent fits can be used to extract a list of reflection intensities (2) from the data and once phases have been assigned (B) to the structure amplitudes, a density map can be calculated (3). The structure (4) can then be identified (C) from the map and used as the basis of a Rietveld-type fit (D1) to the pattern in order to refine the structure. Alternatively, a structural fragment (4) may be identified and incorporated (D2) into a Pawley or LeBail-type fit in order to extract a more accurate set of reflection intensities for subsequent use in step B. In the global optimization approach to SDPD, a trial structural model (4) is constructed using a molecular model and the known unit cell, and assessed using a Rietveld-type fit (D1) to the pattern.

advent of the Rietveld method (Rietveld, 1969) established not only the *de facto* procedure for structure refinement, but also laid the foundation of the Pawley and LeBail approaches for decomposition of powder diffraction patterns into individual reflection intensities. From the early 1990s onwards, significant effort has been expended in developing methods for SDPD and these have been reviewed on a regular basis – see, for example, Meden & Radosavljevic Evans (2015). Implementation of these methods has been greatly facilitated by advances in computing power that have allowed the automation of trial-and-error-type methods and also the use of increasingly complex direct-methods-type approaches.

For simplicity, in the sections that follow we assume the use of X-ray radiation sources and the determination of corresponding electron-density maps, though many of the methods described are equally applicable to neutron diffraction and electron diffraction. Fig. 4.1.1 summarizes several key generic steps in the SDPD process and representative examples of structures solved using the methods described below are presented in Table 4.1.1.

4.1.3. Conventional direct methods of structure determination

One of the most powerful features of direct methods of crystal structure determination is that they do not require any *a priori* knowledge of the connectivity or coordination of any of the atoms in the structure. Rather, such connectivity is derived from the electron-density map that is generated at the end of the process of assigning phases to the structure amplitudes. As such, direct methods can be brought to bear on diffraction data collected from crystalline materials of known and unknown composition; indeed, it is not uncommon for the composition and three-dimensional structure of a material under examination to differ significantly from a chemist's expectations. As the density map is the Fourier transform of a set of structure factors, the quality and interpretability of the map are a reflection of the accuracy (in terms of amplitude and phase angle) and resolution of those structure factors. For a typical single-crystal experiment, the quality of the map is not normally of concern, derived as it is from thousands of well defined structure amplitudes collected to sub-ångström resolution. With a typical powder diffraction experiment however (for the reasons mentioned in Section 4.1.1), map quality and interpretability are major issues. Accordingly, many early attempts at crystal structure determination from powders focused on collecting very high quality diffraction data with a view to extracting a set of structure amplitudes that could be input into one of the many standard direct-methods packages available at the time. Key to the success of this approach is the ability to extract a sufficient number of accurate structure amplitudes to near-atomic resolution; for powder diffraction experiments, this is a non-trivial task.

The crystal structure determination of the monoclinic form *A* of the anti-ulcer drug cimetidine (Table 4.1.1) is a good example of a moderately complex molecular crystal structure solved in this manner (Cernik *et al.*, 1991). Usable powder diffraction data were collected to 70° 2θ ($d_{\min} = 1.273$ Å; $\lambda = 1.4599$ Å) at Station 8.3 of the Daresbury synchrotron-radiation source. The presence of the sulfur atom aids structure determination by contributing strongly to Bragg scattering at high 2θ, and 561 intensities were extracted, with 204 rejected as unobserved. Even so, conventional direct-methods programs failed to yield a recognizable structure; the structure was eventually solved by taking the top 17 peak positions of the best E map returned by *SIR* (Burla *et al.*, 1989) and then applying several cycles of Fourier synthesis and least-squares refinement using the *CRYSTALS* package (Watkin *et al.*, 1985). Interestingly, a retrospective examination of the best initial E map showed that all the non-hydrogen-atom locations were in fact present in the map, but they had not been located by the automatic peak-search routines. This is not surprising: medium-resolution E maps, generated from small numbers of (not particularly accurate) structure factors, lack the clarity required to make atom assignment straightforward.

The significance of cimetidine as an early exemplar of SDPD is twofold: (*a*) as a molecule of pharmaceutical interest, it alerted the industry to the fact that powder diffraction had a structural utility that went beyond the 'fingerprinting' of physical forms; (*b*) aside from the use of synchrotron radiation, the structure determination used an entirely conventional approach. It also served to highlight some of the obvious limitations of applying unmodified single-crystal tools to powder diffraction data, and it is unsurprising that most successes using this standard approach have come either with relatively simple structures, with structures that contain strongly scattering atoms, or with high-resolution neutron-diffraction data (Ibberson *et al.*, 1997; Ibberson, Yamamuro & Matsuo, 2000; Ibberson, Morrison & Prager, 2000).

Some effort has been put into devising strategies for collecting powder diffraction data that are more 'single-crystal-like'. These include the exploitation of texture in samples (McCusker *et al.*, 2001) and inducing differential thermal expansion in crystals (Shankland *et al.*, 1997; Brunelli *et al.*, 2003). These approaches aim to overcome the reflection overlap problem experimentally and have been shown to work well, but have yet to make a substantial impact in terms of structure determination and their use cannot yet be described as routine.

4.1.4. Modified direct methods of structure determination

The extensive modifications that have been applied to adapt standard direct methods of structure solution to the specifics of powder diffraction data are dealt with in Chapter 4.2 and are only briefly considered here. Important gains in performance are achieved mainly by incorporating structural information obtained during the phasing process into the intensity-extraction stage. For example, consider two closely overlapping reflections $\mathbf{h}$ and $\mathbf{h}'$ that appear as a single peak in a powder diffraction pattern. In the absence of any prior information, only the summed intensity $I_{\mathbf{h}} + I_{\mathbf{h}'}$ is extracted in the powder pattern decomposition process, and this intensity is split equally between the two contributing reflections for an attempt at a direct-methods solution. Once a partial structure has been identified from this trial, it can be used to calculate a more probable partitioning of the observed intensities, based on the calculated values. This modified partitioning can then be used as the starting point for a more accurate decomposition of the pattern and the newly extracted intensities fed into another (hopefully improved) attempt at direct-methods solution (Altomare *et al.*, 2009). Important gains have also been realized using strategies devised to overcome the limitations of Fourier maps generated from powder diffraction data, with impressive results (Altomare *et al.*, 2012, 2013). Most importantly, modified direct methods of the type exemplified by the *EXPO* software package (Altomare *et al.*, 2013) are applicable to a broad range of problems that include inorganic, organic and organometallic structures using diffraction data collected on standard laboratory instrumentation, as well as high-resolution synchrotron instruments.

4.1.5. The direct-methods sum function

The direct-methods modulus sum function, S, is an example of a particular implementation of direct methods that is well suited to powder diffraction data (Rius, 1999). The value of the function S should be a maximum for the correct set of structure-factor phases and, as such, its use in structure determination requires an effective maximization process (Rius, 1993). Both a modified tangent formula and a fast Fourier transform (FFT) approach to function maximization have been used; the latter has also been combined with a 'Shake-and-Bake'-type approach (Rius & Frontera, 2007). As implemented in the *XLENS* program, distributed as part of the *Fullprof* suite (Rius, 1999; Rodriguez-Carvajal, 2013), the sum function has been used to solve a range of structures from powders, but has found particular utility in the solution of challenging framework-type structures such as ITQ-22 (Corma *et al.*, 2003).

4.1.6. The Patterson function

The Patterson function, $P(\mathbf{u})$, has one main advantage over conventional direct methods in the context of structure determination: it is calculated using only squared values of the observed structure amplitudes, $|F_{\mathbf{h}}|^2$, as coefficients and thus no phasing is required. Its biggest disadvantage is that the peaks in the resultant Patterson map represent interatomic vectors in the crystal structure rather than atomic positions. The map for a structure containing N atoms is 'crowded' with $N^2 - N$ non-origin peaks and is therefore difficult to interpret, usually with only vectors between any heavy atoms present showing up clearly. Interpretation issues are particularly acute with low-resolution maps derived from powder data and they have been addressed using sharpened Patterson functions (*e.g.* with $|E_{\mathbf{h}}|^2$ coefficients), maximum entropy (David, 1990) and the symmetry minimum function (Estermann, 1995). The Patterson function has also been used to improve the accuracy of individual intensities obtained from the partitioning of overlapped reflections prior to the application of direct methods (Estermann & Gramlich, 1993). Despite the elegance of many of the Patterson-based structure determination methods, they have not been widely used for SDPD purposes recently, having been largely superseded by both modified direct methods and global-optimization strategies. However, the introduction of Patterson-type direct methods (Rius, 2011) may well signal a renaissance. In this approach, a sum function, S_P, is maximized using a Patterson-function tangent formula that considers overlapping reflections in the phasing process and so is well suited to both powder and single-crystal diffraction data. The structure determination of the $(S)(+)$ form of ibuprofen from synchrotron powder diffraction data ($d_{\min}$ = 1.1 Å; Rius, 2011) is a convincing demonstration of the effectiveness of this approach.

4.1.7. Resonant (anomalous) scattering

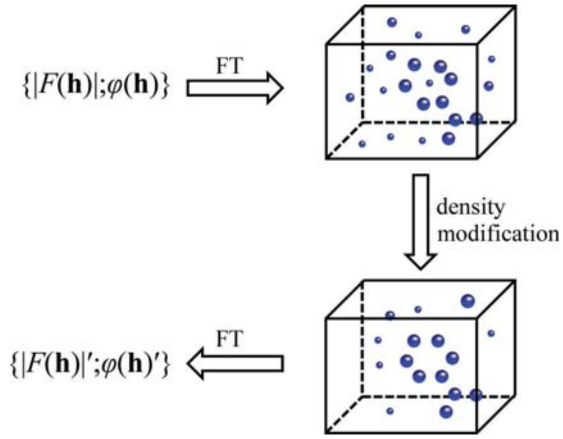
Whilst anomalous-scattering techniques are very well established in the field of single-crystal protein structure determination, their use in the context of powder diffraction appears at first glance to be counterintuitive, as Friedel pairs **h** and −**h** overlap *exactly* in a single powder line. Nevertheless, ingenious methods for exploiting differences in the average intensity $\overline{I}(\lambda_i)$ of a powder line as a function of more than one wavelength have been used in combination with maximum-entropy methods to solve the orthorhombic structure of $SrSO_4$ (Burger *et al.*, 1998). The requirement for a source of incident X-rays that can be tuned to wavelengths suitable for the atoms in the sample being studied restricts such experiments to being performed at synchrotron sources.

4.1.8. Isomorphous replacement

Isomorphous replacement is a well established method for the solution of protein crystal structures. In this approach, heavy atoms are introduced into a structure with a consequent effect upon the reflection intensities. There is an assumption that this introduction does not affect the scattering from the native (*i.e.* original, unmodified) structure and that the heavy atoms occupy sites within the structure previously occupied by, for example, lighter ions or solvent molecules. Differences in scattering between the derivative and native structures are therefore attributable to the heavy atoms, and maps computed using these differences can be used to directly obtain the heavy-atom locations. These locations are then used to calculate likely phase angles for the native structure factors, with the most reliable estimates coming from measurements where more than one derivative structure has been prepared and measured. An excellent example of the application of this approach to powder diffraction data is given by determination of the secondary structure of hen egg-white lysozyme (Basso *et al.*, 2010), obtained using diffraction data collected from the native protein plus its gadolinium and holmium derivatives.

4.1.9. Maximum-entropy methods

The process of constrained entropy maximization (*i.e.* maximizing a function of the form $-\sum_{i=1}^{n} p_i \log p_i$, subject to a set of constraints) can be applied to Fourier-type maps where p_i is the pixel density at some point within the map and the constraints are such that an inverse Fourier transform must regenerate the original input structure amplitudes and phases used to generate the map. As the entropy-maximization process results in a modified electron-density map, the inverse Fourier transform also returns amplitudes and phases for structure factors *that were not part of the original input* (Fig. 4.1.2). The quality of these so-called *extrapolated* structure factors can be evaluated by the use of likelihood functions that assess the level of agreement between calculated and observed amplitudes. Entropy maximization and associated likelihood calculations form the basis of a distinct approach to structure determination from powders that is embodied in the *MICE* computer program (Gilmore *et al.*, 1991; Bricogne, 1991). This program has been successfully applied to a number of powder structure problems (Gilmore *et al.*, 1991; Tremayne, Lightfoot, Mehta *et al.*, 1992; Tremayne, Lightfoot, Glidewell *et al.*, 1992) but the approach has not been widely adopted; entropy maximization is computationally demanding and it is only relatively recently that computing power has advanced to the point where calculations can be run on timescales that are competitive with other approaches. Entropy maximization has also been used in combination with Rietveld refinement in structure completion. A good example is provided by the crystal structure determination of the steroid prednisolone succinate (Nishibori *et al.*, 2008). The initial structure solution, returned from a genetic-algorithm global-optimization procedure, had the succinate side chain incorrectly oriented; subsequent omit-type maximum-entropy maps were used to determine the correct orientation, permitting successful refinement.



$\{|F(\mathbf{h})|;\varphi(\mathbf{h})\}$

density modification
FT
$\{|F(\mathbf{h})|';\varphi(\mathbf{h})'\}$

Figure 4.1.2
A set of structure factors is Fourier transformed to yield a density map. Once the map is modified (*e.g.* by entropy maximization, histogram matching or charge flipping) the inverse transform returns a modified set of structure factors. Note that the size of the two sets need not necessarily be equal.

4.1.10. Charge flipping

The iterative charge-flipping algorithm (Oszlányi & Sütő, 2008; Palatinus, 2013) has been used extensively in single-crystal structure determination (Palatinus & Chapuis, 2007) and has also been adapted for use in a powder diffraction context (Baerlocher, McCusker & Palatinus, 2007). In common with direct methods of structure determination, it attempts to reconstruct electron density directly from structure amplitudes. Furthermore, it exploits the fact that most of the unit cell is characterized by very low electron density, whilst the regions of high electron density (corresponding to atoms) occupy only a very small part of the cell. The standard charge-flipping algorithm is relatively straightforward and does not require a knowledge of crystallographic symmetry. A set of observed structure amplitudes is assigned random starting phases; unobserved amplitudes are additionally assigned a magnitude of zero. The electron-density map calculated from the structure factors is modified by changing the sign of (*i.e.* 'flipping') any density points that lie below a certain threshold value, δ. A Fourier transform of this modified map returns a new set of structure factors whose phases are assigned to the corresponding observed structure amplitudes. This updated set of observed structure factors is then used in the next iteration of the process and the cycle is repeated until convergence, which is assessed by an R factor that compares observed amplitudes with amplitudes returned by the Fourier transform of the 'flipped' map. Note that there is no map interpretation involved until the algorithm has converged. The process is normally carried out in the complete unit cell (*i.e.* $P1$ symmetry; the true space-group symmetry is determined or confirmed subsequent to the actual structure solution) and typically only the δ threshold parameter needs to be adjusted across problems. As might be expected for a method that relies heavily on the use of modification of electron density, charge flipping performs well with atomic resolution data and data where the structure amplitudes are well determined. As such, and similarly to conventional direct methods, it does not perform particularly well (by default) with the majority of powder diffraction data sets. Modified charge-flipping procedures for powder data have been suggested and demonstrated; see, for example, the structure of zeolite catalyst IM-5 (Baerlocher, Gramm *et al.*, 2007) or the implementation of charge flipping incorporating tangent refinement (Coelho, 2007). Charge flipping has been used in combination with histogram matching (Baerlocher, McCusker & Palatinus, 2007) and also with maximum-entropy methods to improve the imaging of structural disorder in density maps (Samy *et al.*, 2010) and to optimize *SUPERFLIP* (Palatinus & Chapuis, 2007) input parameters for powder diffraction problems (Sisak *et al.*, 2012).

4.1.11. Molecular envelopes

Restrictions on the possible location of atoms within the unit cell, that can aid in automated searches and model-building approaches, can be obtained by correctly phasing a few strong, low-index reflections. These phased reflections are used to generate surfaces (formally, periodic nodal surfaces) within the unit cell that define an envelope into which the atoms of the structure must fit. The process of phasing the reflections is not straightforward but can be highly effective (McCusker *et al.*, 2001; Brenner *et al.*, 1997, 2002) in restricting possible solutions and benefits from the fact that low-index reflections in powder diffraction are those that are least likely to suffer from accidental reflection overlap.

4.1.12. Model building

Manual model building can be considered to be an optimization method, where chemical knowledge and crystallographic experience are used in place of automated trial and error. A model is constructed and placed in the unit cell to give a suitable starting point for a Rietveld refinement, using the agreement between the observed and calculated powder patterns as a guide to correctness. During model construction and placement, various factors may be taken into consideration, including: (*a*) molecular symmetry and special positions, *e.g.* the centre of symmetry of a benzene molecule may be coincident with a crystallographic centre of symmetry; (*b*) functional groups, *e.g.* carboxylic acid groups frequently form hydrogen-bonded dimers with other carboxylic acid or amide groups. Many specific examples of model building may be found in the literature (Seebach *et al.*, 1997; Freyhardt *et al.*, 1996). Although near-exhaustive automated searches have largely replaced this manual approach, it may still have a role to play in particularly complex cases and when the quality of the powder data is especially poor, such as is frequently the case with polymeric materials.

4.1.13. Molecular replacement

Molecular replacement (Rossmann, 1990) is a well established method for the solution of protein crystal structures. In this approach, an unknown structure is solved by placing a model of a closely related structure (typically >30% sequence identity, but this figure is constantly reducing as methods improve) in the unit cell of the unknown structure and then performing a series of discrete rotation and translation searches, aimed at maximizing the agreement between calculated and observed Patterson functions. The search problem is aided by the fact that *intramolecular* vectors in the map depend only upon the orientation of the model; once the best orientation of this model within the unit cell is found, it is used in a translation search to find the best agreement with the *intermolecular* vectors in the map. At this point, the optimal location of the model within the cell has been found and a structure refinement can be attempted. Most modern programs for molecular replacement now use likelihood-based rotation and translation functions (McCoy *et al.*, 2005; Storoni *et al.*, 2004). Encouragingly for powder diffraction, molecular replacement does not require atomic resolution data. It has been applied mainly to the problem of protein structure determination from powder diffraction data; an excellent example is that of the second SH3 domain of ponsin, solved using *MOLREP* (Vagin & Teplyakov, 2010) with high-quality synchrotron data that exploited anisotropic peak shifts to improve the quality of the extracted structure amplitudes (Margiolaki *et al.*, 2007). However, it has also been applied in the context of small molecule crystallography. For example, after initial direct-methods attempts from synchrotron powder diffraction data failed, the crystal structure of form I clarithromycin was solved by molecular replacement using a molecule derived from the form 0 structure (Noguchi *et al.*, 2012). The basis for this attempt was the observation that the molecular conformation of the clarithromycin moiety in previously reported crystal structures showed little structure-to-structure variance. Intensities were extracted from the powder data using *EXPO2009* (Altomare *et al.*, 2013) and the molecular replacement performed using *MOLREP* and data to 3 Å resolution.

The use of molecular replacement tools developed for single-crystal data (Scapin, 2013) does not always prove to be effective in the case of protein structure determination from powder diffraction data (Doebbler & Von Dreele, 2009*b*). In such circumstances, modified versions of programs developed specifically to solve small-molecule structures from powder data (see Section 4.1.14) can be used to good effect. By performing simultaneous translation/rotation searches of a known model inside the cell of the unknown structure, solutions can be obtained for sizeable problems, *e.g.* hen egg-white lysozyme (Doebbler & Von Dreele, 2009*a*). Whether applied to proteins or small molecules, the extent of the similarity between the known and unknown structures is key to the success of molecular replacement; if the model structure has a considerably different shape from that of the unknown, then the chances of obtaining a solution that can be used as a starting point for refinement are low.

4.1.14. Global optimization

The molecular replacement approach just outlined for protein structure determination from powder diffraction data may be considered to be a subset of the global-optimization procedures described in detail in Chapter 4.3. In this larger class of methods, a structural model is adjusted within the previously determined unit cell of the crystal structure under investigation, but the position and orientation of the model are adjusted simultaneously. There is no general requirement that the model is held rigid, *i.e.* a molecular conformation does not need to be known in advance. The problem of finding the best agreement between the observed and calculated intensities is that of locating the global minimum on an agreement-factor (*e.g.* $R_{\rm wp}$ or χ^2) hypersurface, whose dimensionality equals the number of structural variables in the problem. For example, in the case of a molecular organic crystal structure, these variables (or degrees of freedom) are typically: 3 to describe the position of the molecule in the unit cell, 3 to describe its orientation and n to describe the number of freely rotating torsion angles in the molecule. Such hypersurfaces encompass a multitude of stationary points and locating the global minimum is a non-trivial exercise. A plethora of approaches, including simulated annealing, genetic algorithms, evolutionary algorithms, random searches, grid searches, particle swarm and the hybrid Monte Carlo method, have been applied in the context of SDPD; these methods and their application to structural problems in powder diffraction have been comprehensively reviewed (*e.g.* David & Shankland, 2008; Harris, 2012; David *et al.*, 2002; Shankland *et al.*, 2013). Atom positions can be optimized as independent variables, but the more usual practice is to make use of prior information about the system under study, *e.g.* a description of molecular connectivity, or the coordination state of a metal ion. Obtaining this information is not generally a serious impediment. Where there are ambiguities in the model being optimized, multiple trials using distinct starting models can be used to decide upon the correct description. Alternatively, it is also possible to use maximum-likelihood methods to defer a precise description of certain components of a starting model until such time as the main component of the model has been correctly located in the unit cell. This is discussed more fully in Section 4.1.15 and Chapter 4.3.

4.1.15. Maximum-likelihood methods

Figures of merit used to assess the level of the agreement between the observed and calculated intensities in global-optimization methods are generally predicated on the assumption that the model under investigation is a complete and accurate description of the contents of the asymmetric unit. There are, however, many reasons why this assumption may not hold during a structure solution; for example, hydrogen atoms may have been omitted from the input model and only isotropic temperature factors used to describe the vibrational behaviour of atoms. Such relatively minor approximations will not normally prevent successful structure solution, but more substantial omissions from the input model will. Typical scenarios for the latter situation would be the deliberate omission of a molecular counter-ion or some solvent of crystallization from an input model in order to reduce the dimensionality of the problem search space. In their absence, calculated intensities cannot match the observed intensities and, as a consequence, the structure cannot be solved. The maximum-likelihood approach to structure solution does not ignore the omitted fragments; rather (whilst not adjusting them in the optimization) it treats their scattering contribution as a 'blur' that is randomly distributed throughout the unit cell. This effectively adds an uncertainty to the *calculated* intensities that has to be taken into consideration by the figure of merit along with the usual uncertainties in the observed intensities (Markvardsen *et al.*, 2002; Favre-Nicolin & Cerny, 2004*a*). A major advantage of this approach is that it allows complex multi-fragment structures to be solved in a sequential manner by global optimization.

4.1.16. Local minimization

It is also possible to use local-minimization methods, such as quasi-Newton or conjugate gradient, to locate the global minimum on a given hypersurface. In this approach, the use of a large number of minimizations, each starting from a different random point, compensates for the very low probability that any single minimization will terminate in the global minimum. This approach has the twin advantages of speed and simplicity, and has been demonstrated to be at least competitive with simulated annealing in the cases of solving the structures of famotidine and capsaicin from powder diffraction data (Shankland *et al.*, 2010). Simplex optimization (Nelder & Mead, 1965) can be used in a similar fashion, but requires many more function evaluations and can be slow to converge. A local-minimization approach has also been adopted in the *TALP* program (Vallcorba *et al.*, 2012) and has been used to solve a number of molecular crystal structures, including several from a test suite of laboratory-based powder diffraction data (Florence *et al.*, 2005).

4.1.17. Active use of prior information for particular structural classes

It is possible to tailor structure determination strategies to a particular class of materials in order to improve the chances of solving an unknown structure belonging to that class. Such tailoring works best where the class contains well defined structural motifs; for example, protein structure determination procedures exploit the fact that regions of α-helix and β-sheet can generally be quickly identified in an electron-density map. In the area of powder diffraction, a good example comes from the study of zeolites and zeolite-like materials, where a clearly defined framework topology (*e.g.* faujasite, mordenite) is expected in any electron-density map that corresponds to a likely solution. These electron-density maps may be searched passively (*i.e.* assign atoms to peaks in the map and then see what, if any, topology is evident) or actively (*i.e.* the map is searched for particular topologies). The computer program *FOCUS* (Grosse-Kunstleve *et al.*, 1997), which implements both types of search, has been applied successfully to the determination of several framework structures (see Chapter 4.6) (Smeets *et al.*, 2013) and has also been adapted to utilize three-dimensional electron-diffraction data when available (Smeets *et al.*, 2015).

The histogram-matching method (Yong *et al.*, 1990) also exploits features that are characteristic of particular classes of materials. The histogram in question is an electron-density probability distribution that captures the commonality (*e.g.* distribution of atom types, interatomic distances and angles) of different structures belonging to a particular class of materials. Originally utilized as an aid to phase determination and refinement in the field of protein crystallography (Zhang & Main, 1990), it seeks to modify the distribution of electron density in a map of the structure under investigation such that it matches that of an idealized histogram. It is important to realize that obtaining a match is a necessary, but not a sufficient, condition in the identification of the correct structure, *i.e.* there are many *incorrect* maps that still match the ideal histogram (Zhang, 2003). Nevertheless, obtaining a match is a highly effective constraint on a solution and it has been used in SDPD in order to improve the partitioning of the intensities of overlapping reflections. Specifically, after the process of histogram matching has resulted in modification of the electron-density map, a Fourier transform will return modified structure factors that are likely to be a more accurate representation of the true structure amplitudes. The reference histogram can be obtained from the electron-density map of a known structure belonging to the same class of materials, ideally obtained with approximately the same resolution as the unknown structure (Baerlocher, McCusker & Palatinus, 2007).

In the case of global optimization of molecular structures, the initial model is constructed using well characterized bond lengths and angles derived from the large ensemble of previously determined molecular crystal structures. Information about the distribution of torsion angles within molecular structures is also present in this ensemble and can, in principle, be used to restrict the search space that needs to be explored in the global-optimization step. A trivial example is that of an acyclic amide bond, where partial double-bond character results in a planar group, with the *trans* configuration [$R-\mathrm{C}(=\mathrm{O})-\mathrm{NH}-R' \simeq 180^\circ$] being observed much more frequently than the *cis* configuration. As such, the torsion angle of this bond can be treated as a fixed ($\tau = 180^\circ$) entity, removing one degree of freedom from the search problem. The *Mogul* molecular-geometry knowledge base (Bruno *et al.*, 2004), derived from the Cambridge Structural Database (CSD), is an invaluable tool for the quick and efficient retrieval of torsion-angle distributions for particular molecular motifs within the structure of interest. Only rarely does an observed distribution allow a particular torsion angle to be restricted to a narrow range, but large areas of space can often be safely eliminated from the global search. Any derived distribution information must be used with care, as applying excessive weight to such distributions will tend to exclude the possibility of solving structures that do not conform to expectation values. The utility of this particular approach to SDPD has been demonstrated (Florence *et al.*, 2009) but only recently has it been fully explored, with promising results, against a test suite of more than 100 molecular organic crystal structures (Kabova *et al.*, 2017).

The *IsoStar* knowledge base of intermolecular interactions (Bruno *et al.*, 1997) present in the CSD permits the rapid evaluation of probable distance and angle distributions for specified search motifs, and these distributions can be used actively in SDPD. A simple example is that of the $R-\mathrm{NH_3}^+\cdots\mathrm{Cl}^-$ motif found in many hydrochloride salts, where the $\mathrm{N}^+\cdots\mathrm{Cl}^-$ distance can be restricted to 3.2 Å on the basis of over 1000 observations in the CSD. Again, the utility of employing such restrictions has been demonstrated in isolated cases (Nowell *et al.*, 2002), but has yet to make a significant impact on SDPD in general.

Solid-state NMR has also been used in combination with powder diffraction in the structure determination of, for example, zeolites (Brouwer *et al.*, 2005) and molecular organic materials (Harper *et al.*, 2005; Dudenko *et al.*, 2013; Middleton *et al.*, 2002). Beyond the obvious application of determining Z' for a crystal structure, solid-state NMR chemical shift tensor data can yield detailed three-dimensional information that can, for example, be used in combination with computational modelling to generate more accurate or constrained models for subsequent optimization or refinement.

Further discussion of the use of supplementary information in the context of SDPD can be found in Chapter 4.4.

4.1.18. Combined figures of merit

In trial-and-error-type solution approaches such as global optimization, it may be advantageous to include in the figure-of-merit calculation terms other than those that are based purely on diffraction data. The most obvious additional contribution is an energetic one: the global minimum in the diffraction hypersurface is expected to be coincident with a minimum in the crystal energy landscape. Several computer programs for SDPD [*e.g.* *Endeavour* (Putz, 2001), *ORGANA* (Brodski *et al.*, 2005), *FOX* (Favre-Nicolin & Cerny, 2004*b*)] implement such a multi-objective approach and 'Pareto optimization' of the figures of merit has been successfully applied to problems in inorganic (Putz *et al.*, 1999) and organic structure determination (Pop *et al.*, 2002). The combined figure of merit, C, is often calculated as a simple weighted sum $\alpha\mathrm{FOM}_{\mathrm{Energy}} + (1-\alpha)\mathrm{FOM}_{\mathrm{Diffraction}}$ with α as a variable in the range 0–1 depending upon the desired relative weighting. The energy terms employed are usually relatively straightforward to calculate (*e.g.* Lennard-Jones type), the main restrictions being (*a*) the availability of suitable parameter sets for the particular system under investigation and (*b*) the computational cost associated with the evaluation of each new trial structure. The logical extension of this approach in which α is set to 1 equates to crystal-structure prediction (CSP), discussion of which lies outside the scope of this chapter. However, it is worth noting that when CSP returns multiple structures with very similar crystal lattice energies, a *post hoc* comparison of calculated powder patterns with experimental powder data can be a useful indicator of predictive power. In any such comparison, it must be remembered that predicted structures at 0 K will generate powder patterns that may, at first glance, appear to differ substantially from those collected at room temperature as a result of the effects of thermal expansion upon the unit cell. CSP-derived structures can also be of value in finalizing the details of structures solved from powder diffraction data; see, for example, hydrogen-atom positioning in the crystal structure determination of a simple 1:1 co-crystal (Wu *et al.*, 2013).

4.2. Solving crystal structures using reciprocal-space methods

A. Altomare, C. Cuocci, A. Moliterni and R. Rizzi

4.2.1. Introduction

The aim of this chapter is to provide the necessary theoretical background and the practical tools for solving crystal structures from powder-diffraction data using reciprocal-space (RS) methods.

RS methods are so called because they work in reciprocal space in the following general way:

(1) The unit-cell dimensions are assumed to be known or calculated and the space group is (in general, but not always, see Section 4.2.6) determined. There may be ambiguities with respect to the space group, in which case all possibilities may need to be explored. The unit-cell contents are also needed, but these can be approximate.
(2) The structure-factor moduli $|F_{\mathbf{h}}|$ associated with each reflection $\mathbf{h}$ are extracted from the experimental diffraction profile.
(3) The phases $\varphi_{\mathbf{h}}$ of structure factors $F_{\mathbf{h}} = |F_{\mathbf{h}}| \exp(i\varphi_{\mathbf{h}})$ are estimated by phasing methods which use the experimental moduli. This is the core of direct methods.
(4) Finally, an electron-density map is calculated using $T^{-1}[F_{\mathbf{h}}]$, the inverse Fourier transform of the structure factors, determined in terms of both moduli and phases.

Until about 25 years ago, powder-diffraction methods were mainly used for qualitative and quantitative analysis. Attempts to solve crystal structures using powder-diffraction data started for several reasons: improvements in diffraction experimental techniques (*e.g.* the availability of synchrotron sources) and the availability of more powerful computers made it feasible, and there is a need to know the crystal structure of materials of chemical, technological, biological, pharmaceutical and geological interest. Early structures were solved using software packages designed for single-crystal data. Later RS methods were modified and improved to deal with the specific problems that occur with powder data, making the solution process more straightforward (David *et al.*, 2002). Around the end of the last century, direct-space methods became a viable alternative to reciprocal-space methods.

The main differences between RS methods and direct-space methods are that RS methods are model-free and do not need prior structural information, but they require the extraction of the integrated intensities from the experimental powder-diffraction pattern; direct-space methods use some prior knowledge about the structure (in particular, information on the molecular geometry), but they do not need the integrated intensities. When it is not possible to predict anything about the structure, RS methods are the obligatory choice.

For single-crystal data, RS methods have numerous advantages: they are fast, reliable, easy to use and able to solve the structure of any type of compound – inorganic, organic or organometallic. Small- and medium-size structures up to small proteins can be solved provided that good-quality, complete data to about 1.1 Å resolution are available. In the case of powders, however, the solution process is not so straightforward because three-dimensional reciprocal space is collapsed into the one-dimensional experimental pattern. This unavoidable situation results in a loss of experimental information and has serious consequences: Bragg diffraction peaks overlap and the individual intensity associated with each reflection cannot be accurately determined. In addition, other effects can add to the problem: the background cannot be always unambiguously modelled; the presence of preferred orientation modifies the intensity ratios; and scattering decay at high diffraction angles and/or large peak overlap reduces the achievable limit of experimental resolution. The peak-overlap problem also causes a significant reduction in the number of statistically independent experimental observations contained in the diffraction profile (Altomare *et al.*, 1995; David, 1999). Thus we are very far from the conditions of well estimated observed structure-factor moduli at a resolution better than 1.1 Å; these are rarely attained, particularly in the case of conventional laboratory diffractometer X-ray data.

4.2.2. Intensity extraction for RS methods

RS methods require that the integrated intensities associated with each reflection in the experimental profile must be evaluated. The intensity-extraction process is usually carried out by one of the two following approaches: the iterative Le Bail method usually combined with a profile-fitting procedure, or the least-squares-based Pawley method (Pawley, 1981; see also Chapter 3.5). The Le Bail method can be improved by exploiting the following additional information: pseudotranslational symmetry (Altomare, Foadi *et al.*, 1996), preferred orientation (Altomare *et al.*, 1994; Altomare, Burla *et al.*, 1996), triplet invariant relationship estimation (Carrozzini *et al.*, 1997), the Patterson function (Altomare, Foadi *et al.*, 1998), and the location of a partial structure fragment (Altomare, Giacovazzo *et al.*, 1998). The problem of peak overlap is the major difficulty. Synchrotron data are less affected by this than laboratory data, but the problems of intrinsic peak broadening from the sample itself still remain. Different strategies, both methodological and experimental, have been adopted. The simplest (but still effective) one is to equipartition the intensity of a cluster of overlapping reflections among the single reflections belonging to the cluster, and preferred orientation can be exploited for decomposing overlapping peaks by combining information contained in diffraction patterns collected on sample oriented in different ways (Wessel *et al.*, 1999; Baerlocher *et al.*, 2004). In the case of anisotropic thermal expansion, multiple temperature measurements can be used for obtaining a better estimate of the individual reflection intensities (Shankland *et al.*, 1997; Fernandes, 2006). Despite great efforts to improve extraction procedures, whatever the method used to calculate them (Le Bail or Pawley), the experimental structure-factor moduli, especially of overlapping reflections, are not often well determined and errors of about 40% are quite common in good-quality laboratory X-ray data. Consequently, the phasing process using RS methods may be not always successful. A successful outcome strongly depends on the quality of the extracted structure-factor moduli and on the experimental resolution. Structure complexity and the compound type also play an important role. Organic structures are more difficult to solve because the rapid decay in scattering factors for

Copyright © 2019 International Union of Crystallography

light atoms with diffraction angle further limits the experimental resolution.

4.2.3. Direct methods

The aim of direct methods (DM) is contained in their name: to derive the phases of reflections *directly* from the observed integrated intensities, through mathematical relationships. DM theory is based on two main assumptions about the electron density $\rho(\mathbf{r})$:

(1) positivity: $\rho(\mathbf{r})$ is everywhere positive; and
(2) atomicity: $\rho(\mathbf{r})$ corresponds to discrete atoms.

Harker & Kasper (1948) first demonstrated that phase information can be retrieved *via* inequalities involving unitary structure factors $U_{\mathbf{h}}$ (see Section 4.2.7 for a definition of $U_{\mathbf{h}}$). Later Sayre (1952) derived Sayre's equation, an algebraic expression among structure factors, by using the relationship between $\rho(\mathbf{r})$ and its square:

$$F_{\mathbf{h}} = \frac{f_{\mathbf{h}}}{g_{\mathbf{h}} V} \sum_{\mathbf{h}'} F_{\mathbf{h}'} F_{\mathbf{h}-\mathbf{h}'}, \qquad (4.2.1)$$

where $f_{\mathbf{h}}$ and $g_{\mathbf{h}}$ are the scattering factors for the normal and squared electron density, respectively, V is the unit-cell volume and the summation spans the whole of reciprocal space. It was derived for structures of equal resolved atoms and applied to the centrosymmetric case, and leads to the following relationship, which involves the signs of the structure factors (Cochran, 1952; Zachariasen, 1952):

$$s(\mathbf{h}) \approx s(\mathbf{h}')s(\mathbf{h}-\mathbf{h}'), \qquad (4.2.2)$$

where $s(\mathbf{h})$ is the sign of reflection $\mathbf{h}$ (+ is 0° and − is 180°) and we are using $\approx$ to mean 'probably equals'. The likelihood that (4.2.2) is true increases with the magnitudes of the three associated structure factors. The sign relationships were used for solving centrosymmetric structures or centrosymmetric projections of noncentrosymmetric structures. The probabilistic form of (4.2.2) suggested that it could be of practical use.

The first important probabilistic approach was proposed by Wilson (1942, 1949). Centric and acentric probability distributions of structure-factor moduli were derived by assuming that the atomic positions are random variables uniformly distributed over the unit cell. The comparison between theoretical and observed distributions enables one to establish whether there is an inversion centre in the crystal structure.

4.2.3.1. *Normalized structure factors*

Direct methods do not work with structure factors directly but with normalized structure factors $E_{\mathbf{h}}$. The diffraction intensities $|F_{\mathbf{h}}|^2_o$ provided by X-ray diffraction experiments are on a relative scale and the normalization process corrects for this as well as the attenuation in intensity with diffraction angle *via* the formula

$$|F_{\mathbf{h}}|^2_o = K|F_{\mathbf{h}}|^2 = K|F^0_{\mathbf{h}}|^2 \exp(-2Bs^2), \qquad (4.2.3)$$

where K is the scale factor, $|F^0_{\mathbf{h}}|$ is the observed structure-factor amplitude on an absolute scale for atoms at rest, B is related to the average displacement parameter (assumed equal for all the atoms) and $s = \sin\theta/\lambda$. The values of K and B can be determined by the Wilson method (Wilson, 1942), in which the observed diffraction data are divided into ranges of s (s is almost constant in the range) and the expectation value of the intensity in each shell is calculated:

$$\left\langle |F_{\mathbf{h}}|^2_o \right\rangle_s = K\left\langle |F^0_{\mathbf{h}}|^2 \right\rangle_s \exp\left(-2B\langle s^2\rangle\right) = K\sum_s^0 \exp\left(-2B\langle s^2\rangle\right). \quad (4.2.4)$$

In the absence of any structural information $\sum_s^0 = \sum_{j=1}^N \left(f_j^0\right)^2$, computed by using the tabulated values of f_j for atoms at rest and for $s = \langle s^2\rangle^{1/2}$. From equation (4.2.4) we obtain

$$\ln\left(\frac{\left\langle |F_{\mathbf{h}}|^2_o \right\rangle_s}{\sum_s^0}\right) = \ln K - 2Bs^2. \qquad (4.2.5)$$

A plot of the left side of (4.2.5) *versus* s^2 should yield a straight line, for which the intercept with the vertical axis would give $\ln K$ (and hence K) and the slope would give the value of $-2B$ and hence B.

In practice, owing to structural regularities (the atoms are not randomly located in the unit cell), the experimental values used in equation (4.2.5) for deriving K and B do not fully satisfy the linear condition: the best evaluation of K and B is then usually obtained by calculating a least-squares line.

The scattering factor f_j varies with θ and the expected intensity is

$$\left\langle |F_{\mathbf{h}}|^2_o \right\rangle = \varepsilon(\mathbf{h}) \sum_{j=1}^N f_j^2, \qquad (4.2.6)$$

where $\varepsilon(\mathbf{h})$ is a statistical weight due to the space-group symmetry (Rogers, 1980). The expected intensity is thermal-motion and resolution dependent. This means that reflections measured at different θ values cannot be compared directly. In order to overcome this, normalized structure factors $|E_{\mathbf{h}}|$ can be calculated according to

$$|E_{\mathbf{h}}|^2 = \frac{|F_{\mathbf{h}}|^2_o}{\left\langle |F_{\mathbf{h}}|^2_o \right\rangle} = \frac{|F_{\mathbf{h}}|^2_o}{K\varepsilon(\mathbf{h})\sum_{j=1}^N \left(f_j^0\right)^2 \exp(-2Bs^2)}. \qquad (4.2.7)$$

It follows that

$$\left\langle |E_{\mathbf{h}}|^2 \right\rangle = 1 \qquad (4.2.8)$$

for all regions of θ. The E values are independent of the scattering angle θ and correspond to an idealized point-atom structure. The largest $|E_{\mathbf{h}}|$ reflections (the strong reflections) play a major role in the phasing process (not only in DM, but also in all RS methods).

The distribution of $|E_{\mathbf{h}}|$ values is different for centrosymmetric and noncentrosymmetric space groups (Wilson, 1942, 1949); the probability distribution functions are, respectively,

$$P_{-1}(|E|) = (2/\pi)^{1/2} \exp\left(-|E|^2/2\right) \quad \text{(centrosymmetric)}, \qquad (4.2.9)$$

$$P_1(|E|) = 2|E| \exp\left(-|E|^2\right) \quad \text{(noncentrosymmetric)}, \qquad (4.2.10)$$

which are independent of the structure complexity. These expressions can be used to identify the correct space group for single-crystal data, but are unusable for powder data because the distribution of $|E_{\mathbf{h}}|^2$ values is strongly dependent on the algorithm used to decompose the powder-diffraction pattern into single integrated intensities (Pawley or Le Bail) (Giacovazzo, 1996). Owing to the inherent tendency of the Le Bail algorithm to equipartition the overall intensity among the severely overlapping reflections, the distribution of the extracted integrated intensities will be biased towards the noncentric distribution. In contrast, Pawley-based methods often provide negative intensities for strongly overlapped reflections, and consequently generate a high percentage of extreme $|E|$ values. Furthermore, the distributions of the normalized structure-factor moduli can be strongly affected by pseudotranslational symmetry and by preferred-orientation effects. Information about these effects can be used *a priori* to perform a better powder-pattern decomposition, so improving the efficiency of DM (see Section 4.2.4).

4.2.3.2. *Structure invariants*

We now need the concept of structure invariants. A structure factor (whether normalized or not) referred to a new unit-cell origin $\mathbf{x}_0$ takes the form $E'_{\mathbf{h}} = E_{\mathbf{h}}\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}_0)$, *i.e.*, the phase $\varphi_{\mathbf{h}}$ changes according to $\varphi'_{\mathbf{h}} = \varphi_{\mathbf{h}} - 2\pi\mathbf{h}\cdot\mathbf{x}_0$, while the modulus remains unchanged ($|E'_{\mathbf{h}}| = |E_{\mathbf{h}}|$). A basic question now arises: since the origin can be arbitrarily chosen and phase values depend on the chosen origin, how can DM derive phases directly from the observed diffraction moduli? From the moduli we can obtain information only on combinations of phases, which are the structure invariants: products of *n* structure factors which remain invariant whatever the origin. They may be written as

$$E_{\mathbf{h}_1}E_{\mathbf{h}_2}\ldots E_{\mathbf{h}_n} = |E_{\mathbf{h}_1}E_{\mathbf{h}_2}\ldots E_{\mathbf{h}_n}|\exp[i(\varphi_{\mathbf{h}_1}+\varphi_{\mathbf{h}_2}+\ldots+\varphi_{\mathbf{h}_n})]. \qquad (4.2.11)$$

Any invariant satisfies the condition that the sum of the indices is zero:

$$\mathbf{h}_1+\mathbf{h}_2+\ldots+\mathbf{h}_n=\mathbf{0}. \qquad (4.2.12)$$

Structure invariants do not change when the origin is moved by a general vector $\mathbf{x}_0$. In fact, because of condition (4.2.12), the product in equation (4.2.11) remains unchanged:

$$E'_{\mathbf{h}_1}E'_{\mathbf{h}_2}\ldots E'_{\mathbf{h}_n} \equiv E_{\mathbf{h}_1}E_{\mathbf{h}_2}\ldots E_{\mathbf{h}_n}. \qquad (4.2.13)$$

Simple structure invariants are:

(*a*) $n = 2$, $E_{\mathbf{h}}E_{-\mathbf{h}} = |E_{\mathbf{h}}|^2$ (doublet invariants);

(*b*) $n = 3$, $E_{\mathbf{h}}E_{\mathbf{k}}E_{-\mathbf{h}-\mathbf{k}} = |E_{\mathbf{h}}E_{\mathbf{k}}E_{-\mathbf{h}-\mathbf{k}}|\exp[i(\varphi_{\mathbf{h}}+\varphi_{\mathbf{k}}+\varphi_{-\mathbf{h}-\mathbf{k}})]$ (triplet invariants);

(*c*) $n = 4$, $E_{\mathbf{h}}E_{\mathbf{k}}E_{\mathbf{l}}E_{-\mathbf{h}-\mathbf{k}-\mathbf{l}} = |E_{\mathbf{h}}E_{\mathbf{k}}E_{\mathbf{l}}E_{-\mathbf{h}-\mathbf{k}-\mathbf{l}}|\exp[i(\varphi_{\mathbf{h}}+\varphi_{\mathbf{k}}+\varphi_{\mathbf{l}}+\varphi_{-\mathbf{h}-\mathbf{k}-\mathbf{l}})]$ (quartet invariants).

Hauptman & Karle (1953) laid the probabilistic foundations of DM. They first proposed the calculation of joint probability distributions from which the conditional distribution function $P(\Phi|\{R\})$ is derived, where Φ is a structure invariant and $\{R\} = \{|E_{\mathbf{h}}|\}$ is a suitable set of normalized structure-factor moduli. $P(\Phi|\{R\})$ enables us to estimate Φ given the set $\{|E_{\mathbf{h}}|\}$. The *nested neighbourhoods principle* formulated by Hauptman (1975) defines a rule for optimally selecting the $\{|E_{\mathbf{h}}|\}$ to be used for estimating Φ. A more general concept, *representation theory*, has been formulated by Giacovazzo (1977, 1980). For more details see Giacovazzo (1998, 2001, 2013) and Woolfson & Fan (1995).

4.2.3.3. *Triplet invariants*

Triplet invariants (or simply 'triplets') play a central role in DM. A probabilistic formula for estimating triplets was first given by Cochran (1955), who derived the following von Mises (1918) type of function:

$$P(\Phi_{\mathbf{h},\mathbf{k}}) = (1/L)\exp(G_{\mathbf{h},\mathbf{k}}\cos\Phi_{\mathbf{h},\mathbf{k}}), \qquad (4.2.14)$$

where $G_{\mathbf{h},\mathbf{k}} = (2/N^{1/2})|E_{\mathbf{h}}E_{\mathbf{k}}E_{-\mathbf{h}-\mathbf{k}}|$ for equal atoms and $G_{\mathbf{h},\mathbf{k}} = 2\sigma_3\sigma_2^{-1/2}|E_{\mathbf{h}}E_{\mathbf{k}}E_{-\mathbf{h}-\mathbf{k}}|$ for non-equal atoms, $\sigma_n = \sum_{j=1}^{N} Z_j^n$, L is a normalization term depending only on $G_{\mathbf{h},\mathbf{k}}$ and $\Phi_{\mathbf{h},\mathbf{k}} = \varphi_{\mathbf{h}}+\varphi_{\mathbf{k}}+\varphi_{-\mathbf{h}-\mathbf{k}}$. The trend of equation (4.2.14) is very similar to that of a Gaussian and, for different values of $G_{\mathbf{h},\mathbf{k}}$, $P(\Phi_{\mathbf{h},\mathbf{k}})$ is always a maximum when $\Phi_{\mathbf{h},\mathbf{k}} = \varphi_{\mathbf{h}}+\varphi_{\mathbf{k}}+\varphi_{-\mathbf{h}-\mathbf{k}} = 0$ ($\Phi_{\mathbf{h},\mathbf{k}} \simeq 0$ corresponds to positive triplets, $\Phi_{\mathbf{h},\mathbf{k}} \simeq \pi$ to negative triplets), that is $\varphi_{\mathbf{h}} = -\varphi_{\mathbf{k}} - \varphi_{-\mathbf{h}-\mathbf{k}}$. The distribution curves become increasingly sharp with increasing values of $G_{\mathbf{h},\mathbf{k}}$, *i.e.* the variance decreases. The consequence of this is that the estimate $\Phi_{\mathbf{h},\mathbf{k}} = 0$ is only reliable for large values of $G_{\mathbf{h},\mathbf{k}}$ and so only the phases of large normalized structure factors can be determined, in general, by DM. This is shown diagramatically in Fig. 4.2.1.

Representation theory, as proposed by Giacovazzo (1977, 1980), indicates how the information contained in all of reciprocal space can be used to improve the Cochran's estimate of $\Phi_{\mathbf{h},\mathbf{k}}$. The $P_{10}(\Phi_{\mathbf{h},\mathbf{k}})$ conditional probability distribution (Cascarano *et al.*, 1984) has a von Mises expression and explores reciprocal space by means of a ten-node figure. P_{10} is more powerful than Cochran's formula because of its simultaneous use of strong and weak $|E|$ values, enabling one to estimate negative triplets as well.

4.2.3.4. *How direct methods work*

DM carries out the following main steps (see Fig. 4.2.1):

(1) *Normalization*. This process estimates the scale factor and the overall isotropic displacement factor, *B*; it normalizes the experimental structure-factor moduli and analyses the $\{|E_{\mathbf{h}}|\}$ distribution, which can assist with space-group determination.

(2) *Structure invariants*: The main structure invariants (*i.e.*, triplets) are calculated by considering the set of strong reflections and their Φ values are estimated.

(3) *Phasing process*: The phasing process has two parts: the assignment of initial phases to some or all of the normalized reflections, and the generation of new and/or refined phases.

Assignment of initial phases: There are two basic methods of assigning phases to reflections:

(*a*) Random values between 0 and 360° are assigned to reflections. This is the most common method.

The random approach for phasing was derived from the observation that it is possible to solve crystal structures by starting with a large set of phases (more than 40–50) even if they are very inaccurate (Viterbo, 2002).

(*b*) Some strong reflections are chosen for fixing the origin and, if necessary, the enantiomorph [see Rogers (1980) for details of this procedure]. If the number of these reflections is not enough to seed the phasing process, it is necessary to choose a larger number, which then constitutes the 'starting set'. The starting set is selected by a convergence procedure. In this procedure (Germain *et al.*, 1970) the reflections most strongly embedded in triplets are selected. It is a cyclic process that, step by step, eliminates the reflection with minimum $\langle\alpha_{\mathbf{h}}\rangle$ (and all the triplets in which the discarded reflection is involved), where $\langle\alpha_{\mathbf{h}}\rangle = \sum_j G_j D_1(G_j)$ and the summation is over the current triplets. G_j is the reliability of the *j*th triplet (see Section 4.2.3.3), $D_1(G_j) = I_1(G_j)/I_0(G_j)$, and $I_1(x)$ and $I_0(x)$ are the modified Bessel functions of order one and zero, respectively. The reflection with minimum $\langle\alpha_{\mathbf{h}}\rangle$ is retained only if it is necessary for fixing the origin or if it has already been included in the starting set. Towards the end of the process, the reflection with the smallest $\langle\alpha_{\mathbf{h}}\rangle$, *i.e.*, one that is uncorrelated (or weakly correlated) with those left in the set, is included in the starting set because it represents the link to reflections that have already been discarded. The convergence procedure is iterated until an optimum starting set of reflections has been obtained.

Figure 4.2.1
Flow chart for the DM procedure.

The choice of the starting set is fundamental, because the estimates of the rest of phases depend on it. If random phases are used, this step may not be required.

Starting-set phases can be assigned according to one of the two following approaches: symbolic addition (Karle & Karle, 1966), which associates algebraic symbols with phases, and multisolution methods based on magic integers (White & Woolfson, 1975), which give approximate numerical values.

Phase refinement and extension: The fundamental equation for this process is the tangent formula (Karle & Hauptman, 1956), which both calculates the phases of strong reflections and refines them by exploiting triplet relationships as follows:

$$\tan\varphi_{\mathbf{h}}=\frac{\sum_{\mathbf{k}}|E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}|\sin(\varphi_{\mathbf{k}}+\varphi_{\mathbf{h}-\mathbf{k}})}{\sum_{\mathbf{k}}|E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}|\cos(\varphi_{\mathbf{k}}+\varphi_{\mathbf{h}-\mathbf{k}})}=\frac{T_{\mathbf{h}}}{B_{\mathbf{h}}}. \qquad (4.2.15)$$

The summations in (4.2.15) are over **k** reflections related to **h** and **h** − **k** *via* the triplet relationship. Equation (4.2.15) is probably the most widely used formula in direct methods; it derives the phase of **h**, *via* knowledge of the phases ($\varphi_{\mathbf{k}}$, $\varphi_{\mathbf{h}-\mathbf{k}}$) of (**k**, **h** − **k**) couples.

$\varphi_{\mathbf{h}}$ in (4.2.15) is the most probable value of the phase of **h**; the reliability of $\varphi_{\mathbf{h}}$ is assessed *via* the parameter $\alpha_{\mathbf{h}}$, given by

$$\alpha_{\mathbf{h}}=(T_{\mathbf{h}}^2+B_{\mathbf{h}}^2)^{1/2}. \qquad (4.2.16)$$

Many variants of the tangent formula have been proposed, *e.g.* by including suitable weights and quartet relationships in order to make it more stable or improve its radius of convergence.

In general, only those reflections having $|E|>1$ are phased.

(4) *Figures of merit:* The DM phasing process provides a large number of possible sets of phases. They are ranked by figures of merit (FOMs) aimed at evaluating their reliability. CFOM is a suitably weighted combination of different FOMs. Among the most widely used FOMs (Declercq *et al.*, 1979; Karle & Karle, 1966; Cochran & Douglas, 1957) are

$$\mathrm{ABSFOM}=\frac{\sum_{\mathbf{h}}\alpha_{\mathbf{h}}-\sum_{\mathbf{h}}(\alpha_{\mathbf{h}})_r}{\sum_{\mathbf{h}}\langle\alpha_{\mathbf{h}}\rangle-\sum_{\mathbf{h}}(\alpha_{\mathbf{h}})_r} \qquad (4.2.17)$$

and

$$R_\alpha=\frac{\sum_{\mathbf{h}}\left|\alpha_{\mathbf{h}}-\langle\alpha_{\mathbf{h}}\rangle\right|}{\sum_{\mathbf{h}}\langle\alpha_{\mathbf{h}}\rangle}, \qquad (4.2.18)$$

where $\alpha_{\mathbf{h}}$ is the parameter in equation (4.2.16) estimating the reliability of the most probable phase of reflection **h**; $\langle\alpha_{\mathbf{h}}\rangle$ is the expected value of $\alpha_{\mathbf{h}}$ and $(\alpha_{\mathbf{h}})_r$ is the expected value of $\alpha_{\mathbf{h}}$ when the phases are assumed to be randomly distributed. ABSFOM tends to be unity for phases giving $\langle\alpha_{\mathbf{h}}\rangle$ and zero for random phases. A good set of phases may give ABSFOM in the range 1.0–1.4. R_α should be a minimum for the correct set of phases.

$$\Psi_0 = \frac{\sum_{\mathbf{h}} \left| \sum_{\mathbf{k}} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}} \right|}{\sum_{\mathbf{h}} \left(\sum_{\mathbf{k}} \left| E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}} \right|^2 \right)^{1/2}}, \qquad (4.2.19)$$

where the outer summations are over $\mathbf{h}$ for which $E_{\mathbf{h}}$ is small, ideally zero; the inner summations include the large structure factors for which the phases are being determined. Ψ_0 is expected to be small for a correct set of phases and also for random phases. The individual FOMs can be combined into (Woolfson & Fan, 1995)

$$\begin{aligned} \mathrm{CFOM} = {} & w_1 \frac{\mathrm{ABSFOM} - \mathrm{ABSFOM}_{\min}}{\mathrm{ABSFOM}_{\max} - \mathrm{ABSFOM}_{\min}} \\ & + w_2 \frac{(\Psi_0)_{\max} - \Psi_0}{(\Psi_0)_{\max} - (\Psi_0)_{\min}} \\ & + w_3 \frac{(R_\alpha)_{\max} - R_\alpha}{(R_\alpha)_{\max} - (R_\alpha)_{\min}}, \end{aligned} \qquad (4.2.20)$$

where max and min refer to the value for the phase set with the greatest and least FOM, respectively and w_1, w_2, w_3 are empirical weights usually set to 0.6, 1.2 and 1.2, respectively.

Improved formulations of FOMs and CFOM have been proposed (Cascarano *et al.*, 1987, 1992). CFOM is expected to be 1.0 for a correct set of phases. In the case of powder data, the uncertainty on the integrated intensities makes CFOM statistically meaningless (*i.e.*, CFOM can be 1.0 for a wrong set and far from 1.0 for the set corresponding to the correct solution). Classical FOMs, which are functions of $\{|E|\}$, can be misleading for powder data and are less effective that those for single-crystal data. A new figure of merit, an atom-matching-based FOM (AMB FOM), has recently been proposed (Altomare *et al.*, 2011*a*), coupled with a special decomposition procedure (Altomare *et al.*, 2003; Altomare *et al.*, 2004) (see Section 4.2.4.3). The procedure, which is based on the generation of a huge number of phasing trials and of corresponding *E*-map [see step (5)] structure models, aims to select a subset of candidate models to be submitted to a refinement procedure. Adopting a similarity criterion (*i.e.*, two structure models are considered to be similar if they share a high percentage of atoms), the AMB FOM re-groups similar trial models in batches. Then the batch leader is identified as the representative model of the batch and finally the most reliable batch leaders are selected.

(5) *E-map calculation*: The best phase set is used for calculating an electron-density map $\rho(\mathbf{r})$ *via* a Fourier synthesis for which the coefficients are the $|E_{\mathbf{h}}|$ values (an *E*-map):

$$\rho(\mathbf{r}) \simeq (1/V) \sum_{\mathbf{h}} |E_{\mathbf{h}}| \exp(i\varphi_{\mathbf{h}}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{r}). \qquad (4.2.21)$$

The limited number of reflections used for the Fourier synthesis leads to truncation errors. The Fourier synthesis plays the role of a mathematical lens giving, *via* the *E*-map, the direct image of the electron-density distribution. The maxima in the map, located *via* a peak-search procedure, should correspond to positions of atoms in the unit cell. A chemical interpretation of the peak positions is performed by taking into account the cell content. In the case of powder-diffraction data, the poor significance of FOMs may lead to uninterpretable or unsatisfactory structure models. In this case, other phasing sets among those most highly ranked by figures of merit should be explored. Often more than one *E*-map is calculated.

Problems with direct methods using powder data are:

(1) Information about the presence or absence of an inversion centre in the crystal structure cannot be accurately derived *via* the statistical analysis of the normalized experimental structure-factor moduli.

(2) The *B* value can be meaningless, not only because of inaccuracy in the integrated intensities, but also because of truncation errors. Negative values are not uncommon and can be reset to a positive value.

(3) In the case of severely overlapping reflections, strong wrongly estimated reflections can be responsible for failure of the phasing process. In order to improve the phasing efficiency, a procedure based on the generation of numerous trials of pattern decomposition has been developed (Altomare *et al.*, 2003, 2004) (see Section 4.2.4.3).

(4) In the case of structures containing heavy atoms, non-negligible pseudotranslational effects often occur. The statistical analysis of $\{|E|\}$ can detect the presence of pseudotranslation and evaluate the mean fractional scattering power of atoms involved in pseudosymmetry (Cascarano *et al.*, 1985). The pseudotranslational symmetry information can be suitably exploited in the Le Bail decomposition process (see Chapter 3.5) in order to improve the estimates of the integrated intensities (Altomare, Foadi *et al.*, 1996) (see Section 4.2.4.1).

(5) Preferred-orientation (PO) effects are responsible for a distortion of the ratios of the integrated intensities. In order to avoid failures in phasing, correction functions for PO have been proposed (Dollase, 1986; Altomare *et al.*, 1994; Altomare, Burla *et al.*, 1996) (see Section 4.2.4.2).

Despite these limitations, DM are often able to provide the correct solution.

4.2.4. Improving data normalization

4.2.4.1. *Pseudotranslational symmetry*

Pseudotranslational symmetry effects occur when a non-negligible part of the electron density, say $\rho_p(\mathbf{r})$, satisfies a vector $\mathbf{u}$ that is not exactly equal to a crystallographic translation (Lipson & Woolfson, 1952; Rogers & Wilson, 1953; Buerger, 1956, 1959). In this case, the structure should be treated as the sum of a substructure $\rho_p(\mathbf{r})$ and of a superstructure $\rho(\mathbf{r}) - \rho_p(\mathbf{r})$. Pseudotranslational symmetry may be recognized by the statistical analysis of the normalized structure-factor moduli because, when present, a non-uniform value of the average normalized intensity is obtained, *i.e.*, equation (4.2.8) is violated. The fractional scattering power (FSP) of the atoms obeying pseudo-translational symmetry can be evaluated (Altomare, Foadi *et al.* 1996) *via*

$$\mathrm{FSP} = \left(\left\langle |E_{\mathbf{h}}|^2 \right\rangle - 1 \right) \Big/ (\beta_{\mathbf{h}} - 1), \qquad (4.2.22)$$

where $\beta_{\mathbf{h}}$ is proportional to the number of times that the algebraic congruence $\mathbf{h} \cdot \mathbf{R}_s \mathbf{u} \equiv 0 \,(\mathrm{mod}\ 1)$ is satisfied by varying s (where $\mathbf{R}_s$ is the sth rotational symmetry operator). $\beta_{\mathbf{h}}$ corresponds to a superstructure reflection if equal to 0, and to a substructure reflection if non-zero. The information gained from equation (4.2.22) may be used to correct the normalized structure factors, which can then be used as a starting point for programs based on the Le Bail algorithm to obtain more accurate extracted structure-factor moduli.

4.2.4.2. *Preferred orientation*

Preferred orientation (PO) occurs when crystallites are not completely randomly oriented in the specimen. It produces a distortion of the ratios of the integrated intensities and therefore weakens the power of DM. In order to avoid this problem, the integrated intensities corresponding to randomly oriented crystallites have to be retrieved. These values can be derived in different ways:

1. by exploiting the measurements of pole-density distributions (Bunge *et al.*, 1989);
2. by using the symmetrized harmonics method (Järvinen, 1993); or
3. by applying a mathematical correction to the structure-factor moduli (*e.g.*, Dollase, 1986; Altomare *et al.*, 1994; Altomare, Burla *et al.*, 1996).

Among several mathematical forms proposed for the correction of PO effects, the most widely used is the March–Dollase function (Dollase, 1986).

Using a statistical analysis of the normalized structure-factor moduli it is possible to detect the presence of preferred-orientation effects (under the hypothesis that the specimen has cylindrical symmetry) (Altomare *et al.*, 1994; Altomare, Burla *et al.*, 1996). In the case of PO, the condition (4.2.8) is violated and, in order to correct for it, the $O_{\mathbf{h}}$ function has been introduced for transforming the experimental $|E_{\mathbf{h}}|^2$ values into corrected $|E_{\mathbf{h}}|^2_{\rm corr}$ according to

$$|E_{\mathbf{h}}|^2_{\rm corr} = |E_{\mathbf{h}}|^2 O_{\mathbf{h}}^{-1}. \qquad (4.2.23)$$

$O_{\mathbf{h}}$ is given by a von Mises distribution:

$$O_{\mathbf{h}} = \exp(G_{\rm PO}\cos 2\gamma), \qquad (4.2.24)$$

where $G_{\rm PO}$, to be estimated, represents the strength of the PO effect and γ is the angle between reflection **h** and the preferred-orientation direction. This approach uses the following steps:

1. a full pattern decomposition capable of estimating the experimental $\{|F_{\mathbf{h}}|\}$;
2. the normalization of the structure-factor moduli; and
3. the selection of the first n strongest reflections ($10 \le n \le 30$) in the low $\sin\theta/\lambda$ range. For each reflection, **k**, selected, the following additional steps are performed:
    - (*a*) Reciprocal space is divided into cones having common vertices and axes (*i.e.* vertices at the origin of the reciprocal space and axes [**k**] = [*hkl*]). The regions between two cones (*i.e.* a shell) have approximately equal volumes in order to contain, on average, equal numbers of reflections. The reflections **h** belonging to a shell form an approximately constant γ angle with **k**.
    - (*b*) For each shell, the $\langle|E|^2\rangle$ value is calculated. In the case of PO, this value is expected to be strongly different from 1.0. The trend of $\langle|E|^2\rangle$ *versus* γ is considered.
    - (*c*) Least-squares methods are used for evaluating the von Mises distribution in (4.2.24) best fitting the experimental $|E_{\mathbf{h}}|^2$ values according to (4.2.23).
    - (*d*) The plane **k** characterized by the largest value of $G_{\rm PO}$ is selected as the PO direction.
    - (*e*) New values of $|E_{\mathbf{h}}|^2_{\rm corr}$ are obtained.

The presence of preferred orientation in a pattern is not always obvious to the eye and, if undetected, can prove fatal to any structure-solution process. Undetected preferred orientation tends to concentrate electron density in a plane (for plate-like crystals) or in a line (for needles). The above statistical analysis can rationalize the effects of such patterns in the electron density, and provide evidence that preferred orientation is present. It is generally better to re-prepare the specimen to eliminate or reduce preferred orientation, rather than to deal with a distorted data set.

4.2.4.3. *Systematic decomposition*

After normalization, the reflections are sorted according to their $|E|$ values and only those larger than a threshold are actively used in the phasing process. Procedures have been proposed that aim to improve the quality of the extracted integrated intensities when the standard decomposition step fails to provide the correct solution. They are based on systematic variation of the normalized structure-factor moduli of clusters of severely overlapping reflections (Altomare *et al.*, 2003). The clusters containing the reflections that are expected to play a minor role in DM applications, *i.e.*. those for which no constituent reflection falls among the largest reflections, are not considered. This approach uses the Le Bail decomposition and carries out a systematic partition of the overall intensity of each of *ndoub* doublets of reflections, in three different ways, giving rise to $N_{\rm trials} = 3^{ndoub}$ decompositions. A doublet consists of a cluster of two overlapped reflections (no other reflection overlaps them); two reflections **h** and **k** are considered to overlap if

$$|2\theta_{\mathbf{h}} - 2\theta_{\mathbf{k}}| < {\rm th}_{\rm ov}{\rm FWHM}_{\mathbf{h}}, \qquad (4.2.25)$$

where ${\rm th}_{\rm ov}$ is a suitable threshold (usually in the range 0.1–1.0) and ${\rm FWHM}_{\mathbf{h}}$ is the full width at half maximum of the peak associated with the reflection **h**. If *ndoub* is large, a huge number of decompositions are to be performed. A consistent reduction of this number can be obtained by using linear error-correcting codes (Altomare *et al.*, 2004). For each decomposition trial, DM phasing is carried out and, by using a suitable figure of merit, the correct solution is recognized among the large number of trials (Altomare *et al.*, 2011*a*).

4.2.5. Patterson methods

The Patterson function $P(\mathbf{u})$ is the self-convolution of the electron density $\rho(\mathbf{r})$ in the cell (Milanesio & Viterbo, 2011):

$$P(\mathbf{u}) = \rho(\mathbf{r}) * \rho(-\mathbf{r}) = \int_V \rho(\mathbf{r})\rho(\mathbf{r}+\mathbf{u})\,{\rm d}\mathbf{r}. \qquad (4.2.26)$$

Its name is due to Patterson (1934), who proposed a mathematical expression for $P(\mathbf{u})$ in terms of Fourier synthesis of the observed $|F_{\mathbf{h}}|^2$ values:

$$P(\mathbf{u}) = T^{-1}[|F_{\mathbf{h}}|^2] = (1/V)\sum_{\mathbf{h}} |F_{\mathbf{h}}|^2 \exp(-2\pi i\mathbf{h}\cdot\mathbf{u}). \qquad (4.2.27)$$

$P(\mathbf{u})$ has a great advantage with respect to $\rho(\mathbf{r})$: it is easily calculated from the available experimental structure-factor moduli, and no phase information is required. Maxima occur in $P(\mathbf{u})$ if both $\rho(\mathbf{r})$ and $\rho(\mathbf{r} + \mathbf{u})$ are different from zero. This happens if **u** is an interatomic vector. The heights of the $P(\mathbf{u})$ maxima are proportional to the products of the atomic numbers of atoms involved in **u** and to the multiplicity of **u** (the multiplicity tells us how many times **u** occurs). The $P(\mathbf{u})$ maxima consist of N^2 peaks; N of them overlap and give rise to a strong origin peak, corresponding to the vector from each atom to itself; the remaining $N(N-1)$ peaks are distributed in the unit cell.

The interpretation of $P(\mathbf{u})$ is clearly more difficult than $\rho(\mathbf{r})$: Patterson peaks are broader, more numerous and usually overlap. These problems occur in both single-crystal and powder data, but they are more critical in the case of powder X-ray diffraction data: errors in integrated intensity estimates and truncation effects are responsible for the presence of very broad peaks, some of them false or misplaced from correct positions, making the Patterson map less easily interpretable than one from single-crystal data. The removal of the origin peak (using $|E_{\mathbf{h}}|^2 - 1$ as a Fourier coefficient) as well as the use of alternative coefficients such as $|E_{\mathbf{h}}|^2$, $|E_{\mathbf{h}}||F_{\mathbf{h}}|$ or $(|E_{\mathbf{h}}|^3|F_{\mathbf{h}}|)^{1/2}$ aim to sharpen the Patterson map and improve its interpretability.

The most traditional approach for interpreting the Patterson map is based on the use of Harker sections (Harker, 1936), which contain interatomic vectors $\mathbf{u}_{\mathrm{H}i} = \mathbf{r} - C_i\mathbf{r}$ ($C_i\mathbf{r} = \mathbf{R}_i\mathbf{r} + \mathbf{T}_i$, $\mathbf{R}_i$ and $\mathbf{T}_i$ are the rotational and translational components, respectively, of the ith symmetry operator of the space group) between an atom and its symmetry equivalents. In the case of structures with only a few heavy atoms, the Patterson peaks involving heavy atoms are usually dominant in the map and easily identified. By inspection of the Harker sections, it is possible to determine the heavy-atom positions from which the remaining light atoms can be located by Fourier synthesis using the observed structure-factor moduli and the phases calculated from the heavy atoms.

The use of the symmetry minimum function (SMF) or image-seeking minimum function (IMF) (Buerger, 1959) is based on automatic analysis of the Patterson map (Sheldrick, 2008), and is more effective than the manual inspection of Harker sections (Estermann & David, 2002). An example of the successful application of the SMF to powder data is given by Burla *et al.* (2007).

A different approach has been developed by Rius (Rius, 2002, 2011; Rius *et al.*, 1999, 2000, 2007; Rius & Frontera, 2007). In this context, a major role is played by the direct-methods modulus sum function used as a target function for refining phases of structure factors (Rius, 2002):

$$S'(\Phi_S) = \int_V P'(\mathbf{u})P(\mathbf{u}, \Phi_S)\,\mathrm{d}\mathbf{u}, \qquad (4.2.28)$$

where $P'(\mathbf{u})$ is the Patterson map without the origin peak, $P(\mathbf{u}, \Phi_S)$ is the calculated Patterson map where Φ_S is the set of phases of the strong reflections (those with the largest $|E|$ values). $S'(\Phi_S)$ should be a maximum for the true phases. The subtraction of the origin peak in $P'(\mathbf{u})$ enables weak reflections (reflections with the smallest $|E|$ values) to play an active role in the $S'(\Phi_S)$ maximization. The phases refined by maximizing $S'(\Phi_S)$ are considered to be the most probable ones and they are used for calculating the electron-density map. The method for maximizing $S'(\Phi_S)$ has also been optimized to refine the intensities of severely overlapping reflections with accidental overlap (Rius *et al.*, 2000). Other approaches have been developed for refining phases by maximizing S': the S'-TF tangent formula (Rius, 2002); the S-FFT approach which applies, in parallel mode, the tangent formula, and the fast Fourier transform (FFT) algorithm (Rius *et al.*, 2007). For powder data the use of the S_c-FFT procedure (Rius & Frontera, 2007) combining the S-FFT procedure with real-space constraints is similar to the *Shake-and-Bake* approach (Weeks *et al.*, 1993). A new type of direct methods, called Patterson-function DM, have also been developed that use the Patterson function of the squared structure directly (Rius, 2011) instead of the modulus function. It is based on the maximization of the S_P Patterson-function sum function:

$$S_P = 2\sum_{\mathbf{h}} \frac{I_{\mathbf{h}} - \langle I\rangle}{N} G_{-\mathbf{h}}(\Phi_S), \qquad (4.2.29)$$

where the summation is over the number of experimentally available reflections (strong and weak), $I_{\mathbf{h}}$ is the intensity of reflection $\mathbf{h}$ which, in the case of overlap, is obtained by the equidistribution of the overall intensity of the overlap cluster to which $\mathbf{h}$ belongs, $\langle I\rangle$ is the average intensity taken over all non-systematically absent reflections and $G_{-\mathbf{h}}(\Phi_S)$ is the calculated structure-factor amplitude of the squared structure. S_P has been optimized with the Patterson-function tangent formula using a variant of the S-FFT algorithm.

4.2.5.1. *The use of the Patterson function for estimating integrated intensities*

Patterson-function information has been used to improve the estimates of the integrated intensities of reflections. David (1987) proposed two approaches based on:

(1) maximization of the entropy of the Patterson function, subject to the constraints of measured intensities, and

(2) squaring of Patterson map using the squaring method of Sayre (1952).

Alternatively, the FIPS (fast iterative Patterson squaring) procedure can be used (Estermann *et al.*, 1992; Estermann & Gramlich, 1993). This adopts the squaring method, and has the following steps:

(1) A $P(\mathbf{u})$ map is calculated. The intensities of the strongly overlapping reflections are derived by equipartitioning the cluster intensity.

(2) A modified Patterson map $P^M(\mathbf{u})$ is derived by setting to zero any negative values in $P(\mathbf{u})$ and squaring the positive ones.

(3) New integrated intensities are obtained *via* the inverse Fourier transform of $P^M(\mathbf{u})$.

(4) The new intensity values are shifted away from the originally equipartitioned ones. The shifts are usually in the right direction but, in the majority of cases, they are too small with respect to the true amounts. In an attempt to obtain a distribution of intensity containing both small and large values, the shifts are exponentially increased by an empirical extrapolation. The intensities of non-overlapping reflections remain unchanged.

The previous cycles are repeated until convergence is attained.

A similar procedure (Altomare, Foadi *et al.*, 1998) carries out the following steps:

(1) Reduction of the effects of the origin peak: The intensities of the points of the Patterson map corresponding to the origin peak and belonging to a sphere with radius 2 Å are multiplied by an empirical value set to 0.7.

(2) Modification of the $P(\mathbf{u})$ map *via* a truncation criterion: The intensities of the pixels in the map having a density less than $\langle P\rangle + \sigma/n$ are set to zero. $\langle P\rangle$ is the average value of the Patterson density, σ is the standard deviation of the map and n is the current cycle number [see step (5)]. In this way, in the first cycle only the main peaks in the Patterson map are taken into account, then weak peaks are also considered.

(3) Inversion of the modified Patterson map: New integrated intensity values are obtained under the constraint that the overall observed intensity of clusters of overlapping reflections must be unchanged.

(4) Restoration of the single reflection intensities and assignment of new intensities to overlapping reflections. These intensities are used as a starting point for a new full-pattern-decomposition process according to the Le Bail algorithm (Le Bail *et al.*, 1988; Chapter 3.5).

(5) The intensities extracted in the previous step are now used and steps (2)–(4) are repeated.

4.2.6. Charge flipping

The charge-flipping (CF) method was devised by Oszlányi & Sütő (2004) for single-crystal data and successively improved (Oszlányi & Sütő, 2005, 2007, 2008, 2011); it has also been adapted to powder-diffraction data (Wu *et al.*, 2006; Baerlocher *et al.*, 2007). In its many variants it has been applied to a wide range of crystallographic problems: structure solution from single-crystal data; powder-, neutron- and electron-diffraction data; periodic and aperiodic structures; quasicrystals; and protein heavy-atom substructures. It is a dual-space iterative method switching back and forth between real and reciprocal space. Charge flipping needs the unit-cell parameters and the set of the experimental structure-factor moduli; neither the chemical composition nor symmetry information is required. It is based on the following steps:

(1) Random phases (satisfying the Friedel's law: $\varphi_{-\mathbf{h}} = -\varphi_{\mathbf{h}}$) are assigned to the observed structure-factor moduli $|F_{\mathbf{h}}|$ expanded to space group $P1$. Unobserved moduli are set to zero, except for $F(\mathbf{0})$ which is initially set to zero and allowed to change freely in the phasing process. The inverse Fourier transform of the structure factors is calculated to provide the starting electron density $\rho(\mathbf{r})$.

(2) $\rho(\mathbf{r})$ is modified into $g(\mathbf{r})$ by reversing (flipping) the sign of the density of all pixels with densities below a given (small) threshold positive value δ. The value of δ is a fraction of a typical light-atom peak and is the only parameter of the algorithm. The optimal choice of δ is critical because it determines the computational cost and the quality of the solution. It depends on the grid size used for calculating the density, the data resolution, the displacement parameters, and the types of atoms present in the cell. Some procedures have been proposed for evaluating the proper value of δ. The *a priori* determination of δ is a problem that has not been completely solved.

(3) The Fourier transform of $g(\mathbf{r})$ is carried out and the corresponding structure factors $G_{\mathbf{h}}$ are calculated.

(4) The phases of $G_{\mathbf{h}}$ are combined with the experimental $|F_{\mathbf{h}}|$ amplitudes.

(5) The new structure factors $F_{\mathbf{h}}$ are inverted to calculate a new electron-density map.

(6) The process is repeated from step (1) until convergence, or the requisite number of iterations has been carried out, or the system converges.

Figures of merit have been chosen for recognizing, in an automatic way, that the solution has been found and the process can stop (Oszlányi & Sütő, 2008).

CF is extremely simple and easily implemented. It works well at atomic resolution (better than 1.2 Å in the case of organic compounds, 1.6 Å for heavy-atom structures). As it is a method based on Fourier transforms, it is sensitive to data completeness (removing strong reflections from the data set is particularly harmful). An important aspect of CF is the handling of symmetry. No symmetry information is required and the method solves the structure in space group $P1$. The symmetry, which is encoded in the experimental amplitudes, is estimated from the analysis of the full electron density. This is an important advantage, making the structure solution insensitive to possible ambiguities in the determination of the space group. On the other hand, the density produced by CF is randomly shifted and the origin of the space group must be located. However, small deviations from a higher symmetry cannot be always accurately detected (*i.e.*, when all the heavy atoms match a higher symmetry and only a few light atoms break the symmetry).

Improvements to CF have been developed in relation to the treatment of weak reflections (reflections with small observed moduli) (Oszlányi & Sütő, 2005). This is introduced as a variant involving step (3): the new procedure identifies the weak reflections, and for them the amplitudes of $G_{\mathbf{h}}$ (and not the observed moduli) are retained and the phases are shifted by $\pi/2$.

In order to overcome the requirement for complete high-resolution data, new approaches have been proposed based on:

(*a*) the combination of classical CF with a maximum-entropy-optimized Patterson map to assign intensities to missing reflections (Palatinus *et al.*, 2007);

(*b*) the incorporation of the tangent formula of classical direct methods to create a modified iteration scheme (Coelho, 2007); and

(*c*) a variant of the basic algorithm in which an extended shell of freely floating reflections is combined with the iterative scheme. (The amplitude of a freely floating reflection is unconstrained and can evolve freely as the algorithm progresses.) This is known as the 'averaged alternating reflections' (AAR) scheme (Bauschke *et al.*, 2002, 2004) and uses significantly fewer data than are normally required (Oszlányi & Sütő, 2011).

As in other methods, the application of CF to powder data suffers from the inaccuracy of the extracted reflection intensities. If the reflection overlap is not too severe, the experimental structure-factor moduli values are reliable and the success of structure solution by CF is comparable to the single-crystal case. However, as the reflection overlap increases, the quality of the extracted intensities decreases and electron-density maps obtained by CF become unreliable, although they are not always completely wrong. One modification of the standard CF procedure for powder data is based on the concept that the ratios of $|G_{\mathbf{h}}|$ can be used for repartitioning the overall intensities of groups of overlapping reflections. This approach was first applied by Wu and co-workers (Wu *et al.*, 2006). They equipartitioned the overall intensity of a group of overlapping reflections to obtain the observed structure-factor moduli $|F_{\mathbf{h}}|$ used in step (1). In order to overcome the dependence upon the equipartitioned $|F_{\mathbf{h}}|$ values, a histogram-matching and repartitioning-based method has been proposed (Baerlocher *et al.*, 2007). The approach starts from the basic idea that correct and incorrect solutions can often be distinguished by the shape of the histogram of the electron-density map. After a certain number of cycles (defined by the user), the histogram-matching procedure modifies the values of the current density $\rho^{n}(\mathbf{r})$ so that the histogram of the modified density matches the expected one. The Fourier transform of the new density $\rho^{n\mathrm{HM}}(\mathbf{r})$ produces the structure factors $F_{\mathbf{h}}^{\mathrm{HM}}$ corresponding to the modified $\rho^{n}(\mathbf{r})$. Since $\rho^{n\mathrm{HM}}(\mathbf{r})$ has been improved by histogram-matching, $F_{\mathbf{h}}^{\mathrm{HM}}$ should also be improved with respect to $F_{\mathbf{h}}$ and, in particular, the ratios of the new amplitudes should be closer to the true ones. The new ratios are used for repartitioning the overall intensity of a group of overlapping reflections and obtaining new structure factors $F_{\mathbf{h}}^{\mathrm{new}}$ according to

$$F_{\mathbf{h}}^{\mathrm{new}} = F_{\mathbf{h}}^{\mathrm{HM}} \left(\frac{\sum |F_{\mathbf{h}}|^2}{\sum |F_{\mathbf{h}}^{\mathrm{HM}}|^2} \right)^{1/2}, \qquad (4.2.30)$$

where the summations run over reflections within an overlapping group. In the case of an individual reflection

$$F_{\mathbf{h}}^{\rm new} = F_{\mathbf{h}}^{\rm HM} \frac{|F_{\mathbf{h}}|}{|F_{\mathbf{h}}^{\rm HM}|}, \qquad (4.2.31)$$

that is, $|F_{\mathbf{h}}^{\rm new}| = |F_{\mathbf{h}}|$ and the phase of $F_{\mathbf{h}}^{\rm HM}$ is combined with the experimental amplitude of $F_{\mathbf{h}}$. In the case of overlapping reflections, the overall intensity of the overlapping group corresponds to the total experimental intensity, but the individual amplitudes within the group are modified.

The $F_{\mathbf{h}}^{\rm new}$ values are used as input to the next iteration cycle; the algorithm continues and the sequence of n cycles followed by histogram matching is repeated until convergence has been reached.

The reference histogram, provided by the user according to the chemical composition of the compound to be studied, describes the expected distribution of the electron density but does not locate the density in the unit cell. This adaptation of CF to powders has been successfully applied to solving different kinds of structures (Baerlocher *et al.*, 2007).

CF can be used not only as a structure-solution method, but also as a structure-completion method. In this case, the starting phases are not random but correspond to the partial structure model (Oszlányi & Sütő, 2005).

4.2.7. Maximum-entropy methods

Bricogne (1984) gave the theoretical basis for using maximum entropy (ME) for solving the phase problem, first for single-crystal data (Bricogne & Gilmore, 1990; Gilmore *et al.*, 1990) and successively for electron, powder (Bricogne, 1991; Gilmore *et al.*, 1991) and macromolecular data [see Gilmore (1996) for a general review]. ME methods (MEM) were found to be more robust than traditional DM in the case of structure solution using incomplete data sets, low-resolution data or intensities affected by errors (Gilmore, 1996).

If a discrete probability distribution is considered, given by a set of M probabilities $P = \{p_1, p_2, \ldots, p_M\}$, the relative entropy H of the distribution is

$$H = -\sum_{j=1}^{M} p_j \log(p_j/m_j), \qquad (4.2.32)$$

where $\{m_j\}$ are probabilities corresponding to prior knowledge. The goal of MEM is the determination of P by the maximization of H, subject to constraints which are expressed as expectation values representing knowledge derived from experiments or hypotheses.

This can be placed in a crystallographic context by replacing the discrete probabilities in equation (4.2.32) by normalized pixels in a trial electron-density map; the map is then subjected to constrained entropy maximization in which the constraints are the structure factors used to generate that map. The ME approach is based on the following steps (Gilmore, 1996; Gilmore *et al.*, 1999):

(1) The structure factors $|F_{\mathbf{h}}|$ are normalized and the corresponding unitary structure-factor moduli $|U_{\mathbf{h}}|$ are calculated *via*

$$|U_{\mathbf{h}}| = k|F_{\mathbf{h}}| \Big/ \sum_{j=1}^{N} f_j \exp(-B \sin\theta/\lambda). \qquad (4.2.33)$$

(2) A basis set $\{H\}$ is selected; it consists of phased reflections (*i.e.*, defined by the rules on origin and enantiomorph, see Rogers, 1980); let $\{K\}$ be the disjoint set of unphased reflections. The basis reflections in $\{H\}$ define the root node of the MEM phasing tree; their amplitudes and phases are exploited as constraints at the entropy-maximization step.

(3) $\{H\}$ is enlarged *via* an algorithm of optimum second-neighbourhood extension (Gilmore *et al.*, 1990) involving some strong non-phased reflections to which permuted phase values are given. Each possible phase choice creates a node that is subjected to constrained entropy maximization; the addition of reflections to $\{H\}$ leads to a huge generation of tree nodes (*i.e.*, 2^{nc} in the case of nc centric reflections, with possible phase values 0 and π, or $\pm\pi/2$; 4^{na} in the case of na acentric reflections, if four possible values of phases are considered: $\pm\pi/4$ and $\pm3\pi/4$). The likelihood function (Bricogne, 1984) is used as a suitable figure of merit; the log-likelihood gain (LLG) is able to recognize and discard nodes corresponding to wrong phase assignments (Gilmore *et al.*, 2002). It is a measure of the reliability of the phase prediction performed *via* the entropy-maximization process. Since no estimate of LLG standard deviations is available, the criterion of the highest LLG value for the selection of the nodes could be inadequate. In order to avoid this drawback, an analysis of the LLG values using the Student *t* test is performed (Shankland *et al.*, 1993) for selecting the best 8–16 nodes.

(4) The permutation-likelihood analysis procedure described in step (3) is iterated until a plausible structure model is obtained or the likelihood values begin to decrease.

The main problems related to MEM are a non-negligible computing time, due to the large number of solution trials generated, and difficulties that may arise in interpreting the results. Let us consider n nodes, p reflections and m degrees of freedom for each reflection to which permuted phases are assigned; nm^p phase sets are generated and subjected to constrained entropy maximization. In order to reduce the number of nodes in the MEM tree, error-correcting codes are used that ensure both an efficient phase permutation and a great decrease of the number of sets of phases (Gilmore *et al.*, 1999, 2002).

MEM have been suitably adapted for solving structures from powder data. The LLG can be calculated by considering or excluding the contribution of overlapping reflections (the preferred choice considers them). Entropy maximization coupled with likelihood can also predict the best assignment of integrated intensities of overlapping reflections (Dong & Gilmore, 1998; Gilmore *et al.*, 2002). In addition to the conventional phases, the method uses some angles, called pseudophases, which are introduced for describing the integrated intensities of the overlapping reflections. Let a given overlap contain m_a acentric and m_c centric reflections. The net intensity, I, is

$$I = \sum_{i=1}^{m_a} p_i(A_i^2 + B_i^2) + \sum_{i=m_a+1}^{m_a+m_c} p_i C_i^2, \qquad (4.2.34)$$

where p_i is the multiplicity of reflection i, A and B are the real and imaginary parts of an acentric structure factor, and C is the structure-factor component for centric reflections. The problem is one of determining the A, B and C coefficients in equation (4.2.34). It is useful to re-phrase this problem in terms of hyperphases. To do this we define the overlap as a vector $\mathbf{F}$ in an n-dimensional space R^n (Bricogne, 1991) as

$$\mathbf{F} = \begin{bmatrix} p_1^{1/2}A_1 \\ p_1^{1/2}B_1 \\ p_2^{1/2}A_2 \\ p_2^{1/2}B_2 \\ \vdots \\ p_{m_a}^{1/2}A_{m_a} \\ p_{m_a}^{1/2}B_{m_a} \\ \vdots \\ p_m^{1/2}C_m \end{bmatrix}, \tag{4.2.35}$$

where $n = 2m_a + m_c$ is the number of degrees of freedom, and $m = m_a + m_c$ is the number of reflection moduli under the overlap. $\mathbf{F}$ can be visualized as a hypersphere in R^n. A total of $m - 1$ splitting angles $\psi_{j,j=1,m-1}$, $0 \le \psi \le \pi/2$, which are called *pseudophases*, define a point on the positive unit hypersphere.

This is best seen *via* an example: consider an overlap of net intensity $I^{1/2}$ comprising two acentric reflections and one centric reflection. The radius of the hypersphere is $R = ||\mathbf{F}|| = I^{1/2}$. Defining R_1, R_2 and R_3 as the individual intensities of these three reflections, then

$$\begin{aligned} R' &= R\sin\psi_1, \quad 0 \le \psi_1 \le \pi/2, \\ R_1 &= R'\cos\psi_2, \quad 0 \le \psi_2 \le \pi/2, \\ R_2 &= R'\sin\psi_2, \\ R_3 &= R\cos\psi_1. \end{aligned} \tag{4.2.36}$$

The angles ψ_1 and ψ_2 are the two *pseudophases*; once they are known the individual intensities of the reflections are determined. It is then necessary to derive the associated phase angles to fully characterize the overlap, and this is the process of determining *hyperphases*. The whole partitioning of the overlap problem is now defined exclusively in terms of angles.

If m reflections overlap in a cluster, $m - 1$ pseudophases are considered. Permuted values belonging to the range $[0, \pi/2]$ are assigned to them. The phasing process aims to determine both the pseudophases and the conventional phases (this is known as hyperphases determination). Each possible choice of pseudophases and conventional phases defines a node in the MEM tree, subjected to constrained entropy maximization [see point (3)]. LLG analysis is performed in two steps by considering firstly the pseudophases and then the conventional phases. Statistical criteria are adopted for the selection of the pseudophases followed by the analysis of conventional phases.

4.2.8. Optimization of the structure model

In the case of powder data, the model derived from $\rho(\mathbf{r})$ calculated after the phasing process is often far from being a chemically reasonable one: some peaks are isolated, false peaks occur, some other positions are misplaced from the true ones, the chemical labels associated with peaks according to their intensities in the map may be roughly estimated, and atoms are missing. In serious cases the very approximate model cannot be refined by the Rietveld method (Rietveld, 1969; McCusker *et al.*, 1999) which, because of its modest convergence rate, needs a good starting model in order to provide a reliable refined structure. However, in many cases, despite the approximate starting point, the application of structure-optimization techniques leads to the correct model, or more generally to a reliable model appropriate for the final Rietveld refinement. Therefore, optimization of the model of the structure is sometimes a necessary step in the solution process (Altomare *et al.*, 2011*b*). We will now analyse the main tools for improving the model quality. Their efficiency often increases if they are suitably combined.

4.2.8.1. *Fourier recycling (FR)*

Starting from the available model supplied by RS methods, the structure factors $F_{\mathbf{h}c}$ can be calculated:

$$F_{\mathbf{h}_c} = \sum_{j=1}^{N} f_j^o \exp\left(-B_j \frac{\sin^2\theta_{\mathbf{h}}}{\lambda^2}\right) \exp(2\pi i \mathbf{h}\cdot\mathbf{r}_j) = |F_{\mathbf{h}}|_c \exp(i\varphi_{\mathbf{h}_c}), \tag{4.2.37}$$

where the overall isotropic displacement factor derived from the Wilson plot is associated with each atom. A Fourier synthesis is computed by using the $\varphi_{\mathbf{h}_c}$ phase values and the coefficients $|F_{\mathbf{h}}|_o$ (observed Fourier) or $(|F_{\mathbf{h}}|_o - |F_{\mathbf{h}}|_c)$ (difference Fourier) or $(2|F_{\mathbf{h}}|_o - |F_{\mathbf{h}}|_c)$ (summation of observed and difference Fouriers). The use of Fourier-map calculations is common and effective with single-crystal data for locating missing atoms (*e.g.*, the difference Fourier map is used for locating hydrogen atoms). A weighting scheme in the Fourier synthesis is usually used for two main reasons: minimizing the mean-square error in the electron density due to the errors in phases, and reducing the extent to which the electron-density map calculated using partial structure phases is biased towards the partial structure itself. In particular, Sim weights (Sim, 1960), which require that a well localized fraction of the structure is known, can also be applied when the number of missing atoms is not exactly determined (Altomare *et al.*, 2006).

In case of powders, we cannot expect the same behaviour because of the uncertainties in the $|F_{\mathbf{h}}|_o$ values. However, the Fourier-map techniques work quite well in many cases, especially if the following strategies are adopted:

1. $(2|F_{\mathbf{h}}|_o - |F_{\mathbf{h}}|_c)$ Fourier-map coefficients are used.
2. In order to improve the $|F_{\mathbf{h}}|_o$ estimates for overlapping reflections, the overall observed intensity of each cluster of overlapping reflections is partitioned in proportion to the calculated intensity of each reflection according to

   $$|F_{\mathbf{h}}|_n^2 = \frac{\sum_{\mathbf{k}} I_{\mathbf{k}o}}{\sum_{\mathbf{k}} I_{\mathbf{k}c}} |F_{\mathbf{h}}|_c^2, \tag{4.2.38}$$

   where $|F_{\mathbf{h}}|_n$ is the new modified $|F_{\mathbf{h}}|_o$, the summation is over the reflections belonging to the cluster, and $I_{\mathbf{k}o}$ and $I_{\mathbf{k}c}$ are the individual observed and calculated integrated intensities, respectively:

   $$I_{\mathbf{k}o} = m_{\mathbf{k}} LP_{\mathbf{k}} |F_{\mathbf{k}}|_o^2, \quad I_{\mathbf{k}c} = m_{\mathbf{k}} LP_{\mathbf{k}} |F_{\mathbf{k}}|_c^2, \tag{4.2.39}$$

   where $m_{\mathbf{k}}$ is the reflection multiplicity and $LP_{\mathbf{k}}$ is the Lorentz–polarization factor.
3. $|F_{\mathbf{h}}|_n$ is a better estimate of the partition than the original $|F_{\mathbf{h}}|_o$ value (although not much better if the model is very approximate), but it is biased by the current model and its use can sometimes prevent the complete recovery of the missing atoms.
4. The Fourier recycling technique is combined with weighted least-squares refinement (Altomare *et al.*, 2006) and with electron-density-map modification for resolution bias (Altomare, Cuocci, Giacovazzo, Kamel *et al.*, 2008; Altomare, Cuocci, Giacovazzo, Moliterni & Rizzi, 2008; Altomare, Cuocci *et al.*, 2009; Altomare *et al.*, 2010*a*,*b*).

4.2.8.2. *Weighted least-squares (WLSQ) refinement*

A least-squares refinement procedure using the integrated intensities can be used for refining an approximate structural model in order to make it more suitable for the final Rietveld refinement. It is based on the minimization of the residual

$$\sum_{\mathbf{h}} w_{\mathbf{h}}(I_{\mathbf{h}o} - I_{\mathbf{h}c})^2, \tag{4.2.40}$$

where the summation is over the number of reflections and $w_{\mathbf{h}}$ is a suitable weight, which is now described. It is important to realize that the optimization approach described here is preliminary, and not an alternative to the Rietveld method, which remains the most appropriate technique for refining a structural model from powder data. David (2004) has demonstrated a substantial equivalence between the results obtained from the Rietveld method and those from properly correlated integrated intensities extracted using the Pawley refinement (Pawley, 1981; Chapter 3.5). If the observed intensity estimates are reliable, the Rietveld method and the minimization procedure *via* (4.2.40) are comparable (Prince, 1981). Unfortunately, the $I_{\mathbf{h}o}$ values are not very well determined. This problem can be bypassed by using the overall intensities of clusters of overlapping reflections (in addition to the single intensities of non-overlapping reflections) in (4.2.40) instead of the individual observed intensities, because the cluster intensity is less affected by errors than the individual intensities within that cluster (Giacovazzo, 1998). This approach has the advantage that the observations are more reliable, but the disadvantage that the summation is over the number of overlapping clusters. This last number is smaller (sometimes much smaller, depending on the degree of overlap) than the number of reflections and, consequently, the ratio of the number of observations to the number of parameters for refinement decreases. The number of parameters to be refined is often large (*e.g.* when the crystallographic fractional coordinates and the isotropic displacement factors are varied). The use of the cluster intensity is more suitable for small structures.

If all the reflections are considered in (4.2.40), it is helpful to weight them in a suitable way. The following weighting scheme is able to take into account the lack of accuracy of the single reflection intensities (Altomare *et al.*, 2006):

$$w_{\mathbf{h}} = w_{1\mathbf{h}} w_{2\mathbf{h}}, \tag{4.2.41}$$

where

$$w_{1\mathbf{h}} = 1/[1 + 4(m_{\mathbf{h}} LP_{\mathbf{h}} |F_{\mathbf{h}}|_o)^2] \tag{4.2.42}$$

$$w_{2\mathbf{h}} = w_{a\mathbf{h}} w_{b\mathbf{h}} \tag{4.2.43}$$

$$w_{a\mathbf{h}} = \exp[-0.5(\sin\theta_{\mathbf{h}}/\lambda)^2] \tag{4.2.44}$$

$$w_{b\mathbf{h}} = (\mathrm{I}_{\mathbf{h}o}/\mathrm{I}'_{\mathbf{h}o})^{1/2} \tag{4.2.45}$$

$$I'_{\mathbf{h}o} = \sum_{\mathbf{k}} (1 - q^2_{\mathbf{kh}}) I_{\mathbf{k}o}, \tag{4.2.46}$$

where the summation is over the number of reflections $\mathbf{k}$ that overlap with $\mathbf{h}$ [see equation (4.2.25) for the numerical definition of overlap], including $\mathbf{h}$ itself:

$$q_{\mathbf{kh}} = |2\theta_{\mathbf{k}} - 2\theta_{\mathbf{h}}|/\mathrm{FWHM}_{\mathbf{h}}. \tag{4.2.47}$$

$w_{1\mathbf{h}}$ is used in order to avoid the least-squares calculation being dominated by the largest intensities. $w_{2\mathbf{h}}$ decreases with: (*a*) increasing $\theta_{\mathbf{h}}$ (it is more difficult to model overlaps and background in the high-angle regions of the experimental pattern), and (*b*) an increasing number of reflections overlapping with $\mathbf{h}$ ($I'_{\mathbf{h}o}$ increases, on average, when the number of overlapping reflections in a cluster increases). If the reflection is single, then $w_{2\mathbf{h}} = 1$, if it overlaps with other reflections the value of $w_{2\mathbf{h}}$ depends on the intensities of the neighbouring reflections: *i.e.*, if $I_{\mathbf{h}o}$ is large and the intensities of the reflections that overlap with $\mathbf{h}$, $I_{\mathbf{k}o}$, are small, then $w_{2\mathbf{h}} \simeq 1$; on the other hand $w_{2\mathbf{h}} \simeq 0$ if $I_{\mathbf{h}o}$ is small and the $I_{\mathbf{k}o}$ intensities are large.

The use of $w_{\mathbf{h}}$ in (4.2.40) is able to drive refinements towards an effective convergence. $w_{2\mathbf{h}}$ can also be used in (4.2.38) in order to reduce the model dependence on the data partition equation. Equation (4.2.38) is changed accordingly:

$$|F_{\mathbf{h}}|_n^2 = w_{2\mathbf{h}} |F_{\mathbf{h}}|_o^2 + \frac{\sum_{\mathbf{k}} (1 - w_{2\mathbf{k}}) I_{\mathbf{k}o}}{\sum_{\mathbf{k}} (1 - w_{2\mathbf{k}}) I_{\mathbf{k}c}} (1 - w_{2\mathbf{h}}) |F_{\mathbf{h}}|_c^2. \tag{4.2.48}$$

The partition in (4.2.48) is based on the following rationale: if $|F_{\mathbf{h}}|_o$ is well estimated (*i.e.*, $w_{2\mathbf{h}}$ is ~1), $|F_{\mathbf{h}}|_n$ differs only slightly from $|F_{\mathbf{h}}|_o$; on the contrary, if $w_{2\mathbf{h}} \simeq 0$, $|F_{\mathbf{h}}|_n$ is proportional to $|F_{\mathbf{h}}|_c$.

Cycles of least-squares minimization followed by $(2|F_{\mathbf{h}}|_o - |F_{\mathbf{h}}|_c)$ Fourier-map calculations are able to refine the current model towards the correct solution by discarding false positions and moving misplaced atoms towards their true positions (see the example in Section 4.2.9.4). A good strategy for balancing partition improvement and model dependence is to move from (4.2.48) to (4.2.38) ($w_{2\mathbf{h}} \simeq 0$) in the last cycles of the procedure, when the model is approaching the correct solution and the partitioning according to $|F_{\mathbf{h}}|_c$ is more effective.

4.2.8.3. *Resolution bias modification (RBM)*

After the phasing process, the electron-density map is obtained by Fourier synthesis. Ideally, this summation is over an infinite data set. In practice, the summation is finite because the measured experimental domain of the reciprocal space is finite. As a consequence, series-truncation errors can distort the map: negative values occur, peak intensities are distorted, peaks are broadened and surrounded by positive and negative ripples, and the combination of peaks and ripples moves peaks away from their true positions. Resolution bias effects, which are negligible at atomic resolution and critical when the resolution is >1 Å, are an additional source of error which combines with uncertainties in the intensities and phases.

The problem is particularly severe in case of organic compounds for which the data are usually far from atomic resolution. In fact, the rapid decay of the scattering factors of light atoms makes the high-2θ-angle region of the experimental pattern poorly informative. The resolution bias modification (RBM) method modifies the electron-density map in order to reduce the resolution bias effects and better locate peaks. This new approach works in direct space (Altomare, Cuocci, Giacovazzo, Kamel *et al.*, 2008; Altomare, Cuocci, Giacovazzo, Moliterni & Rizzi, 2008), reciprocal space (Altomare, Cuocci *et al.*, 2009) and with an appropriate combination of the two (Altomare *et al.*, 2010*a*). We will describe the *RBM* direct-space method. The procedure is based on two main steps:

(1) Determining a resolution bias correction function and applying it to the electron-density map (which we will call MAP). The correction function is evaluated as follows:
   (*a*) One single atom (*i.e.*, an atom belonging to the most frequent species in the unit cell) is located at the unit-cell origin and the displacement factor provided by the Wilson method is associated with it.

(*b*) The corresponding structure factors are calculated (up to the current resolution) and then used as coefficients in a Fourier synthesis.

(*c*) The resulting map consists of a main peak domain (MD) and a ripples domain (RD).

(*d*) The intensities $I_{\rm RD}$ of pixels belonging to the RD are normalized to $I_{\rm RDN}$ values in order to avoid dependence on chemical species:

$$I_{\rm RDN} = I_{\rm RD}/I_{\rm MD0},$$

where $I_{\rm MD0}$ is the maximum intensity of the main peak.

(*e*) For each peak in the electron-density map MAP, $I_{\rm RDN}$ is multiplied by the maximum value of the peak and then subtracted from the intensities of pixels not belonging to the main peak domain.

(2) Each main peak is described by the best-fit Gaussian function.

The new modified map, consisting of a summation of Gaussian-like peaks, has improved features: it is well resolved with better positioned peaks and reduced ripple contributions.

RBM, combined with the WLSQ-FR procedure, is able to optimize partial and poor models even at resolutions >1 Å (see the example in Section 4.2.9.5). The RBM strategy strongly increases the probability of a successful solution of organic compounds by RS methods.

More recently, the COVMAP approach has been proposed (Altomare *et al.*, 2012*a*) for completing and adjusting an approximate structure model. It was inspired by a mathematical technique for the evaluation of the covariance and/or the correlation between two points of an electron-density map (Altomare *et al.*, 2012*b*). COVMAP modifies the electron-density map corresponding to the imperfect model by considering some basic connectivity rules in order to pick up the missing atomic positions. Combined with RBM and WLSQ-FR procedures, it is able to provide the correct solution even when starting from a very rough model with few well-located atom positions and a large number of misplaced ones. These results encouraged the authors to propose the RAMM method (Altomare, Cuocci, Moliterni & Rizzi, 2013), which skips the phasing process by direct methods and starts from a fully random structure model. Cycles of combined RBM–COVMAP–WLSQ-FR procedures drive the random model to the correct solution. The RAMM method opens the way for a new RS solution approach, which avoids the direct phasing step and has a central role in structure-model optimization tools working in reciprocal and direct space.

4.2.9. Software packages for powder solution

One of the reasons for the increasing interest and progress in solving crystal structures from powder-diffraction data is the availability of sophisticated software packages in which constantly evolving theories are implemented. Computer programs based on RS methods include:

(1) *POWSIM* (Peschar *et al.*, 2002), which is a traditional DM package, properly modified for treating overlapping reflections.

(2) *XLENS* (Rius, 2013) uses the S-FFT phasing procedure (Rius *et al.*, 2007; Rius & Frontera, 2007). This has been recently optimized by an innovative Patterson-function DM approach (Rius, 2011) and is able to solve powder structures from good-quality diffraction patterns.

(3) *MICE* (Gilmore & Bricogne, 1997; Gilmore & Nicholson, 1994) is a maximum-entropy likelihood program, strengthened by the use of error-correcting codes for phase permutation (Gilmore *et al.*, 1999), and is able to solve structures resistant to traditional DM.

(4) *SUPERFLIP* (Palatinus & Chapuis, 2007) is able to solve crystal structures (including aperiodic structures, incommensurately modulated structures and quasicrystals from X-ray and neutron diffraction data) by application of the charge-flipping algorithm. Structure solution from powder-diffraction data is supported by combining the methodology with a histogram-matching procedure.

(5) *EXPO* (Altomare, Camalli *et al.*, 2009; Altomare, Cuocci, Giacovazzo *et al.*, 2013) is a software package for solving structures by DM. In addition, *EXPO* is uniquely able to carry out the complete structure-solution process: indexing, determination of the space group, *ab initio* structure solution or, alternatively, solving the structure by direct-space techniques, and finally refining by the Rietveld method.

The remainder of this section will focus on examples using *XLENS*, *SUPERFLIP* and *EXPO*. Extensive and detailed descriptions are given for the examples using *EXPO*. Full details on the use of the software can be found in the *EXPO* manual.

4.2.9.1. *Example of structure solution by XLENS*

The Patterson-function DM approach implemented in the *XLENS* program (Rius, 2013) was successfully applied to the crystal structure of (*S*)-(+)-ibuprofen (Freer *et al.*, 1993; Rius, 2011) (see Fig. 4.2.2). It consists of two symmetry-independent molecules in the asymmetric unit forming a cyclic hydrogen-bonded dimer with the chemical formula $C_{26}H_{16}O_4$. The structure is monoclinic (a = 12.4627, b = 8.0251, c = 13.5293 Å, β = 112.9509°) with space group $P2_1$, $2\theta_{\max} \simeq 54^\circ$, 1009 reflections, with a resolution of 1.10 Å. Data were collected at the Swiss Light Source using the Mythen-II microstrip one-dimensional detector at λ = 1.00097 (3) Å. There are 26 C and 4 O atoms in the asymmetric unit.

XLENS processed the integrated intensities, estimated by the program *DAJUST* (Vallcorba *et al.*, 2012) *via* whole-pattern least-squares refinement, and provided atomic distances accurate enough to enable the molecule to be identified in Fourier maps. Twenty-five different trials were attempted, of which 7 were

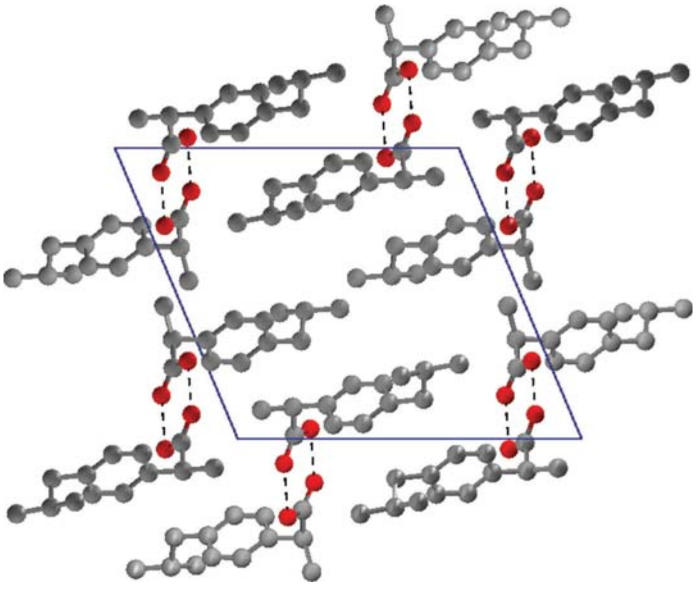

Figure 4.2.2

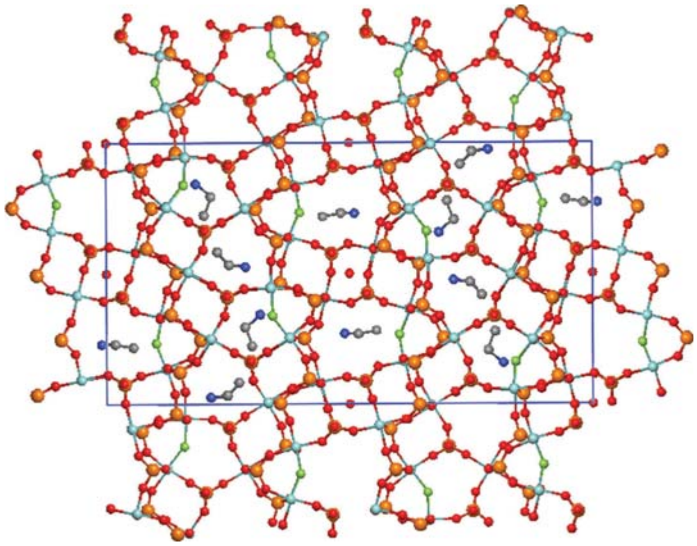

Figure 4.2.3
Crystal structure of the zeolite ZrPOF-EA solved by *SUPERFLIP*.

successful. All correct solutions led to the complete structural model.

4.2.9.2. *Example of structure solution by SUPERFLIP*

As an example of structure solution by the powder charge-flipping (pCF) algorithm (Oszlányi & Sütő, 2004; Baerlocher *et al.*, 2007) as implemented in the program *SUPERFLIP*, we consider the open-framework zirconium phosphate, $[(C_2H_7NH)_8(H_2O)_8][Zr_{32}P_{48}O_{176}F_8(OH)_{16}]$ (denoted ZrPOF-EA). Details of the experimental conditions and crystallographic information are given by Liu *et al.* (2011): orthorhombic (a = 6.165, b = 19.955, c = 37.062 Å), space group *Pbam*, 2θ experimental range 2–40°, with 6681 reflections measured to a resolution of 0.73 Å. The data were collected on the Swiss–Norwegian Beam line at the ESRF in Grenoble, France with λ = 0.50095 Å. There are 8 Zr, 12 P, 2F, 3N, 6 C and 42 O atoms in the asymmetric unit (some of them on special positions and/or with fractional occupancy).

Zirconium phosphate materials have been extensively investigated because they have important applications in the fields of ion exchange, catalysis, photochemistry and biotechnology. The structure of ZrPOF-EA is complicated (see Fig. 4.2.3): there are 3-, 4-, 5-, 6-, 7-, and 8-ring units in the structure, and these form small one-dimensional channels parallel to the c (7-ring) and a (8-ring) axes. Open-framework structures with 7- and 8-ring channels appear to be relatively rare.

The pattern was decomposed into single integrated intensities assuming first the space group $Pmc2_1$ and then the pCF algorithm in *SUPERFLIP* was applied. The interpretation of the resulting electron-density map yielded the positions of 16 zirconium, 23 phosphorus and 55 oxygen atoms. This model, with the missing bridging oxygen atoms inserted, was subjected to Rietveld refinement using the program *XRS-82* (Baerlocher, 1982).

A series of difference-electron-density maps led to the location of the missing P atom, the terminal O atoms and the non-framework species. Atoms bridging between two Zr atoms were assigned as F. The refinement was completed in the space group *Pbam*.

4.2.9.3. *The input file for a default run of EXPO*

To run *EXPO*, an input file containing minimal crystallographic information must be prepared. A typical example is shown in Fig. 4.2.4 for the solution of the structure of clomipramine hydrochloride, $C_{19}H_{23}ClN_2{\cdot}HCl$ (Florence *et al.*, 2005). The input file name is `clomipramine.exp`; `.exp` represents the default extension of the *EXPO* input file, which is an ASCII file created by the user by using the *EXPO* graphical interface or *via* a standard editor. The input file contains *commands*, which are identified by the % character preceding the command name, and *directives*, which are used as subcommands with no special character preceding them. Looking at the `clomipramine.exp` file, we have:

```
%structure clomipramine
%job laboratory X-ray data
%data
pattern clomipramine.xy
wavelength 1.54056
cell 15.514 8.610 14.035 90 96.93 90
spacegroup P 21/c
content (C19H23ClN2·HCl)4
%continue
```

Figure 4.2.4
Default input file for *EXPO* for the structure of clomipramine.

The command `%structure` followed by *name* (clomipramine), which specifies the output file names, where the program stores its main results.

The command `%job` is an optional character string to specify the job title.

The command `%data` is the most important one and contains the directives that provide the required minimal information for *EXPO*:

(1) The directive `pattern` is followed by the name of the file containing the observed diffraction pattern; different file formats are allowed. In case of clomipramine, the profile file is an ASCII text file containing values of 2θ and intensities in separate columns;
(2) The directive `wavelength` specifies the wavelength used in ångstroms. Laboratory X-ray data are the default choice, as in case of clomipramine; if synchrotron or neutron data are used, an additional directive `synchrotron` or `neutron` has to be introduced, respectively;
(3) The directives `cell` and `spacegroup` provide the obvious information. Because *EXPO* is able to determine the cell parameters and the space group, these directives can contain the information derived by *EXPO*;
(4) The directive `content` gives the atomic content of the unit cell.

The last command, `%continue`, allows the program to continue in a default way through the *ab initio* structure-solution process, performing in sequence normalization, structure-invariant estimation, the phasing process, E-map calculation and optimization of the structure model.

4.2.9.4. *An example of model optimization by EXPO for an inorganic compound*

In the case of heavy-atom inorganic structures, RS methods are usually able to locate the heavy atoms quite well, but the positions of the light atoms are more difficult to find. Some light atoms are often missing or misplaced from their true positions. The use of difference Fourier maps may be convenient, but is often insufficient to provide the complete model. We consider here the example of chromium chromate tetrachromate, Cr_8O_{21} (Norby *et al.*, 1991). The relevant data are: triclinic (a = 5.433, b =

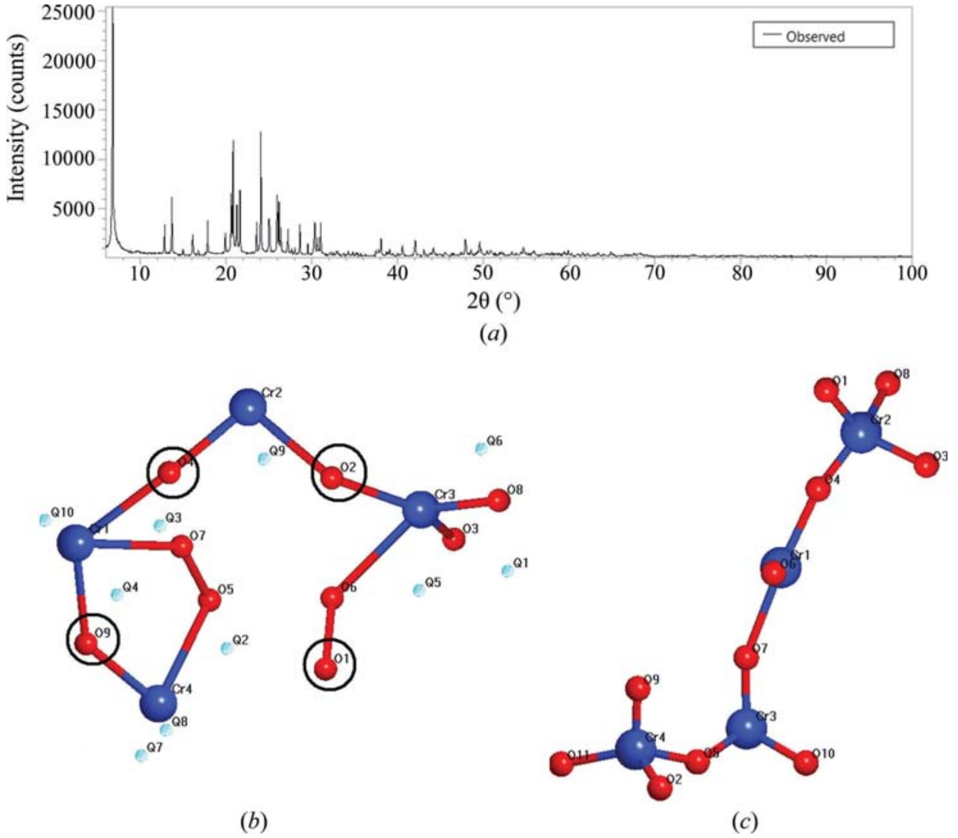

Figure 4.2.5

Structure solution for chromium chromate tetrachromate, Cr_8O_{21}: (*a*) the powder pattern; (*b*) the DM structure model; (*c*) the model optimized by the automatic *EXPO* WLSQ-FR procedure.

6.557, c = 12.117 Å, α = 106.36, β = 95.73, γ = 77.96°), $P\bar{1}$, 2θ experimental range 6–100°, 1130 reflections, resolution 0.91 Å; good-quality laboratory X-ray data (λ = 1.39222 Å); 39% of independent observations in the pattern calculated using the algorithm of Altomare *et al.* (1995); 4 Cr and 11 O atoms in the asymmetric unit. Starting *EXPO* with the experimental pattern (shown in Fig. 4.2.5*a*), the cell parameters, the space group and the unit-cell content information, DM are able to phase the structure. The solution with the first ranked CFOM phases the 293 largest reflections with a 9.8° average phase error. The DM Fourier map supplies the structure model for the asymmetric unit shown in Fig. 4.2.5(*b*), where, in addition to positions labelled as chromium (blue) and oxygen (red), those labelled Q (light blue) correspond to ghost atoms whose intensities in the electron-density map do not allow reasonable chemical label assignment. The structure appears not to be completely solved. In fact, a comparison with the true model indicates that, neglecting the 10 uninterpretable Q peaks, the 4 Cr peaks are all well positioned. However, only 4 of the 9 O peaks (circled in Fig. 4.2.5*b*) are reasonably located, with distances from the true positions less than 0.6 Å. The WLSQ-FR procedure described in Section 4.2.8.2 and implemented in *EXPO* for the automatic solution of inorganic structures is successful in this case: its application provides the model shown in Fig. 4.2.5(*c*) corresponding to the complete structure with an average distance of Cr and O peaks from the true atom positions of 0.16 Å.

It is worth highlighting that the Cr atoms are polyhedrally coordinated: Cr1 is octahedrally coordinated, and Cr2, Cr3 and Cr4 are tetrahedrally coordinated. If the polyhedral coordination information is available *a priori*, the POLPO method (Altomare *et al.*, 2000; Giacovazzo *et al.*, 2002) can be used as an alternative to the WLSQ-FR procedure for completing the model. The POLPO method is a hybrid approach – a reciprocal- and direct-space method, which exploits the DM solution and requires additional information (the polyhedral coordination type and expected atom–atom distances). It starts only with the reliable cation positions obtained by DM and generates several complete structure models according to a Monte Carlo scheme, all of which are compatible with the available polyhedral information. The model corresponding to the best figure of merit (the agreement between the observed and calculated diffraction profile is calculated here) is then selected. POLPO is able to successfully solve the Cr_8O_{21} structure by starting only from the four Cr positions of Fig. 4.2.5(*b*).

4.2.9.5. *Example of model optimization by EXPO for an organic compound*

As previously discussed, organic structures are usually resistant to attempts at solution by RS methods. In the case of organic compounds, *EXPO* automatically applies the RBM procedure to correct the electron-density map. We now examine the *EXPO ab initio* solution of clomipramine hydrochloride, $C_{19}H_{23}ClN_2{\cdot}HCl$ (Florence *et al.*, 2005), the input file for which is described in Section 4.2.9.3. Details are: monoclinic, $P2_1/c$ (a = 15.514, b = 8.610, c = 14.035 Å, β = 96.93°), 2θ experimental range 5–65°, 659 reflections, data resolution 1.43 Å, medium-quality laboratory X-ray data (λ = 1.5456 Å; see Fig. 4.2.6*a*), 43% of independent observations in the pattern (Altomare *et al.*, 1995), 2 Cl, 2 N and 19 C atoms in the asymmetric unit. The complete solution was not obtained in the first phasing set (ranked according to CFOM). The second set, however, provides the full model. An *a posteriori* analysis revealed that 209 reflections were phased with an average phase error of 29° in the first set, while 189 reflections were phased with an average phase error of 23° in the second set. It is very interesting to evaluate how the RBM optimization

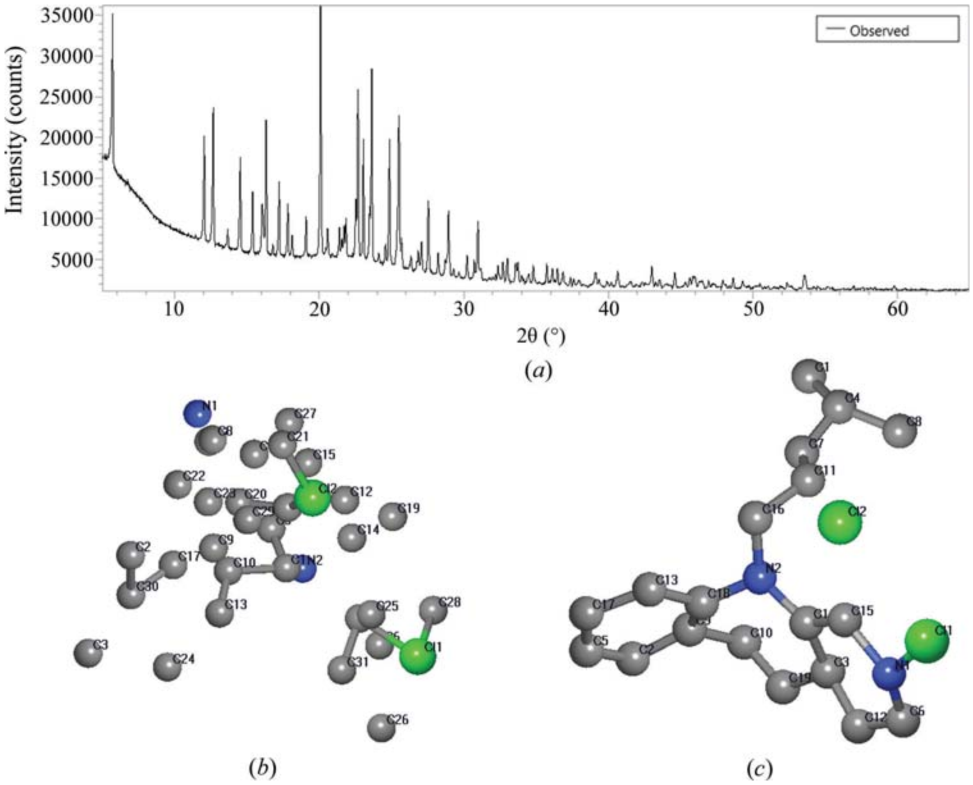

Figure 4.2.6
Structure solution for clomipramine hydrochloride, $C_{19}H_{23}ClN_2{\cdot}HCl$: (*a*) the powder pattern; (*b*) the DM structure model; (*c*) the model optimized by the automatic *EXPO* RBM procedure.

procedure worked: the DM Fourier map (*E*-map) is shown in Fig. 4.2.6(*b*) and the final model generated by RBM is shown in Fig. 4.2.6(*c*). The results are surprising:

(1) The uninterpretable model of Fig. 4.2.6(*b*) consists of 2 Cl, 2 N and 31 C peaks. (The number of peaks taken from the Fourier map is usually larger than the expected number of atoms in the asymmetric unit.) Only the 2 Cl peaks and 9 C peaks are close to the true positions at distances less than 0.6 Å. The average distance from the true coordinates is 0.33 Å and one of the quite well located C atoms has been labelled as N.

(2) The model of Fig. 4.2.6(*c*) is much improved and provides the solution. The incorrect assignments of atom type for C4 and N1 can be immediately corrected by using the user-friendly

The ALLTRIALS procedure in *EXPO* for solving 1,4-bis-(2-phenethyloxy-ethanesulfonyl)-piperazine, $C_{24}H_{34}N_2O_6S_2$: (*a*) the phasing sets ranked according to CFOM; (*b*) the phasing sets ranked according to R_F; (*c*) the correct solution is automatically detected as set No. 17.

graphical tools of *EXPO*. The correct structure is suitable for Rietveld refinement.

4.2.9.6. *The ALLTRIALS tool in EXPO: exploring all the phase sets*

Once the data decomposition process has been carried out, the DM phasing process generates several trials which are ranked according to the combined figure of merit CFOM. The first 20 phasing trials are retained by *EXPO*; the one corresponding to the best CFOM is considered the most promising and the corresponding structure model is automatically submitted to the next optimization procedure. However, ranking the possible trials by CFOM quite often fails to find a solution in the case of powder-diffraction data, so all the available phasing sets have to be explored. The ALLTRIALS tool in *EXPO* does this automatically. For each of the 20 top-ranked trials by CFOM it carries out the solution process up to the final structure model, optimized according to the procedures described above, and shows the results graphically. For each final model, a reliability factor R_F is calculated, where

$$R_F = \frac{\sum \left| |F_{\mathbf{h}}|_o - |F_{\mathbf{h}}|_c \right|}{\sum |F_{\mathbf{h}}|_o}. \tag{4.2.49}$$

The model corresponding to the smallest R_F is automatically selected and displayed. As an example of an application of ALLTRIALS, the case of the 1,4-bis-(2-phenethyloxy-ethanesulfonyl)-piperazine $C_{24}H_{34}N_2O_6S_2$ structure (Florence *et al.*, 2005) is shown in Fig. 4.2.7. Details are: monoclinic, $P2_1/a$ (a = 13.442, b = 5.182, c = 19.796 Å, β = 108.74°) 2θ experimental range 4–65°, 464 reflections, with a resolution of 1.4 Å; medium-quality laboratory X-ray data (λ = 1.54056 Å); 48% of independent observations in the pattern (Altomare *et al.*, 1995); 1 S, 1 N, 3 O and 12 C atoms in the asymmetric unit. Fig. 4.2.7 shows the graphical display that supports the use of ALLTRIALS. In Fig. 4.2.7(*a*) the 20 stored sets of phases are listed and ranked according to CFOM; in this case, CFOM does not discriminate well between them, as none of the sets are significantly different from the best statistically expected value of unity. The top-ranked set of phases, which is automatically selected by the program to calculate the trial electron-density map, is not able to give the correct solution, so the use of CFOM alone has failed. Therefore, all the 20 phasing trials are processed and the solution process is carried out for each of them. *EXPO* automatically displays the view shown in Fig. 4.2.7(*b*), in which the sets are now ranked according to R_F. The lowest R_F trial here was ranked 17th by CFOM in Fig. 4.2.7(*a*). The corresponding complete structure solution is shown in Fig. 4.2.7(*c*). The wrong chemical assignments for O3 and C6 can be easily recognized and corrected using graphical options in *EXPO*. The structure models corresponding to the other phasing sets can be checked, and it can be verified that the best solution corresponds to the model shown in Fig. 4.2.7(*c*).

4.2.9.7. *Graphical tools in EXPO*

A user-friendly graphical interface supports all the principal procedures of the *EXPO* program, and can be used to visualize and to check the various steps of the solution process and to modify the default choices performed by the program. Some graphical tools are particularly useful for completing and validating the final model supplied by the program:

(1) Displaying crystal packing.
(2) Locating hydrogen atoms (these are ignored in the structure-solution process): *EXPO* can use geometrical criteria to add hydrogen atoms to the final structural model in an automatic way or by selecting the carbon type (tertiary C—H, secondary CH_2, primary CH_3, ethylenic $=CH_2$, acetylenic $\equiv CH$, aromatic C—H).
(3) Searching for hydrogen bonds and short non-bonded contacts: these are particularly useful for validating organic structures, and can be automatically found and displayed.
(4) Building coordination polyhedra: if polyhedrally coordinated atoms are present in the structure, the polyhedra can be automatically built and their drawing options modified.

4.2.10. Conclusions

RS methods, the best choice for the solution of small- and medium-sized crystal structures from single-crystal diffraction data, can be modified to solve structures from powder data as well. In particular, the phasing process and procedures for optimization of the structural model are key in dealing with the problems arising from peak overlap. RS methods also have the great advantage of requiring little starting information: the experimental pattern, the cell parameters, the space group and the chemical formula. They do not need a structural model. Their dependence on the quality of experimental pattern, in particular on the peak resolution, is a serious limitation, which can be overcome in many cases. Of course, the use of synchrotron radiation is always advantageous and is preferable. Progress to date enables us to state that, in general, medium-quality conventional laboratory diffractometer X-ray data with a resolution better than 1.4 Å can be successfully used for solving inorganic as well organic compounds by RS methods. Structures with around 30 non-hydrogen atoms in the asymmetric unit can be solved *ab initio*. The development of new sophisticated methodologies and software packages is ongoing.

4.3. Real-space methods for structure solution from powder-diffraction data: application to molecular structures

W. I. F. David

4.3.1. Introduction

Structure determination from powder-diffraction data (SDPD) is a significant crystallographic challenge. Determining the complete three-dimensional structure of a material from the single dimension of a powder-diffraction pattern is, *prima facie*, an uphill endeavour against a significant loss of information. Since 1990, however, considerable progress has been made in addressing this issue through the development of new algorithms, the availability of powerful structure-solution software and advances in powder-diffraction instrumentation. Prior to 1990, the recognized strength of powder diffraction was in the final refinement of a crystallographic model using the Rietveld method (Rietveld, 1969), in which a calculated diffraction pattern is compared with observed powder-diffraction data. However, the success of the Rietveld method depends on having an accurate starting model that is close to the correct structure, which can subsequently be obtained by standard least-squares minimization. For many materials, particularly organic molecular structures, this is often not the case and, in the absence of single crystals and with the availability only of powder samples, SDPD is the only method for directly obtaining the correct crystal structure.

The complexity of structures that can be refined from powder-diffraction data indicates the potential for the structure determination of equally complex systems. However, prior to 1990 attempts to solve structures from first principles would typically be limited to the stage of accurate lattice-parameter determination. Further progress towards structure solution was generally approached by searching structure databases for similar structures or by intuitive model building. Both approaches have been, and still are, successfully used for SDPD. The structural analyses of numerous high-temperature superconductor structures in the 1980s exemplified the strength of intuitive chemical crystallography combined with Rietveld analysis and established the power of powder diffraction to the chemistry, physics and materials-science communities. However, no automated procedure existed to move beyond unit-cell determination to space-group assignment and subsequent structure solution. Bricogne (1991) detailed the extent of the structure-factor information loss associated with the compression of the three-dimensional reciprocal lattice on to the one dimension of a powder-diffraction pattern. This loss is mathematically similar to the loss of phase information in a single-crystal experiment. However, while the phase loss associated with an individual single-crystal intensity is a single parameter, the hyper-phase permutations of N overlapping non-centrosymmetric powder-diffraction reflections runs to $2N - 1$ dimensions. Consequently, a modified direct-methods approach to solving crystal structures from powder-diffraction data appears to be a vast combinatorial challenge for all but the simplest structures. Despite this complexity, various maximum-entropy approaches have been developed and show significant promise (Gilmore *et al.*, 1991, 1993; David & Sivia, 2002). Direct-methods programs (Altomare *et al.*, 2009) have also been successfully developed for powder-diffraction data and are extensively discussed in Chapter 4.2.

Perhaps unsurprisingly, given the complexities of hyper-phase permutations, the breakthrough in SDPD followed a different route and generalized the intuitive model-building approach used previously in conjunction with the Rietveld method. While the work of Semenovskaya *et al.* (1985) indicated a putative algorithmic approach, it was the work of Lightfoot *et al.* (1993) and Harris *et al.* (1994) that paved the way for the development of SDPD. The successful solution of a molecular pharmaceutical crystal structure, the first structure determination from the powder-diffraction round-robin challenge in 1998 (Le Bail & Cranswick, 2001), along with an associated paper on the structure determination of three moderately complex pharmaceutical compounds (David *et al.*, 1998), established the potential of real-space methods for SDPD.

The process of SDPD has been compared with the challenge of walking through a maze; see Fig. 4.3.1(*a*). It is not always straightforward to complete the journey; how to reach the centre of the maze is never obvious at the beginning and multiple decisions must be taken sequentially to determine the most effective route to the solution. The decision to select real-space global-optimization methods as the structure-solution technique does reduce the number of decision points and complexity in the maze but also introduces additional prerequisites associated with the development of an initial structural model. This is illustrated in Fig. 4.3.1(*b*), which has two entrances to the structure-solution maze.

The first entrance involves the decisions associated with the sequential processes of sample preparation, experiment and initial analysis of the diffraction data. Introducing the second entrance highlights the fact that building the structural model can be undertaken in parallel and, indeed, independently of the initial diffraction experiment and analysis.

Preparation of the structural model is a sequence of processes that starts with determining the chemical formula. Generally, for molecular structures, this is already known, as for a new pharmaceutical polymorph. If the structure is only partly known (for example, the degree of hydration of a material) then additional physical measurements such as thermogravimetric analysis or more sophisticated minimization approaches such as maximum-likelihood methods (see Section 4.3.6) can be used to overcome this information loss. The molecular topology (connectivity) is again generally known beforehand. If there are uncertainties, then the best approach is to determine all the possible molecular topologies (which will usually be a small number) and test each topology in the structure-solution process. Molecular geometries, such as bond lengths, angles and dihedral angles, can be determined heuristically, but are best assessed by consulting a structural database such as the Cambridge Structural Database (Groom *et al.*, 2016).

Structure parameterization, both parameter selection and parameter range, can also be determined by chemical intuition or database screening (Bruno *et al.*, 2004). The parameterization itself is usually expressed in terms of molecular connectivity.

(*a*) The maze of strategies associated with the determination of crystal structures from powder-diffraction data (after Baerlocher & McCusker, 2002) and (*b*) the modified 'global-optimization' maze showing the double start point and simplification of the principal maze.

Early structure determinations used the procedure outlined by Arnott & Wonacott (1966). More recently, the *Z*-matrix approach has been adopted and programs such as *OpenBabel* (O'Boyle *et al.*, 2011) exist for converting molecular structures from common formats, such as CIF, to the *Z*-matrix formalism. The development of molecular models for the global-optimization methods of SDPD is discussed further in Section 4.3.3.2.

Returning to the experimental component of the structure-solution process, it is important to emphasise that careful sample preparation is essential for maximizing the success of a structure solution and for obtaining the best and most accurate crystal structure. For X-rays, capillary geometry is the geometry of choice as preferred-orientation effects are minimized. Careful measurements on laboratory X-ray diffractometers are quite sufficient for a significant proportion of molecular crystal structures (Florence *et al.*, 2005), but the improved resolution afforded by synchrotron X-ray diffractometers can help with the determination of more complex structures. Additionally, the rapid counting times available with synchrotron instrumentation mean that intermediate and transient phases may be observed during *in situ* experiments. Care, however, must be taken with synchrotron measurements, as the high fluxes can lead to radiation damage and sample degradation in organic materials. Molecular structures generally contain a significant amount of hydrogen and this, historically, has been an issue for neutron powder-diffraction measurements because of the concomitant high backgrounds associated with incoherent scattering from hydrogen. Deuteration is an option but introduces additional expense and synthesis complexity. This impasse has been significantly ameliorated by a new generation of instruments that include WISH (ISIS, http://www.isis.stfc.ac.uk/instruments/wish/wish-6465.html), POWGEN (SNS, http://neutrons.ornl.gov/powgen/), SuperHRPD (J-PARC, http://www.kek.jp/en/Facility/IMSS/MLF/KENS/BL08/) and D2b (ILL, https://www.ill.eu/instruments-support/instruments-groups/instruments/d2b/description/instrument-layout/). The visibility of hydrogen atoms in a neutron powder-diffraction experiment is an important benefit for determining the most accurate final structure, but also introduces the necessity of additional torsion angles, which further complicates the structure-solution process. Generally, if neutron powder-diffraction data are available, it is best to use X-rays in the first instance and, once the structure is solved, perform a combined structure refinement using the X-ray and neutron powder-diffraction data. The contrasting scattering factors in an X-ray and neutron powder-diffraction experiment mean that the successful fitting of both data sets may remove ambiguity and bring a higher degree of confidence to the accuracy of the final crystal structure.

After successful data collection, the next step is the determination of the unit cell of the unknown crystal structure. There are a number of different approaches that have been developed for autoindexing and these are extensively discussed in Chapter 3.4. The step following autoindexing is the fitting of the diffraction data. This not only further validates the correctness of the unit-cell assignment but also enables peak-shape and background parameters to be accurately determined. In the absence of a crystal structure, the intensities of the Bragg peaks must be treated as parameters to be refined. Two techniques, the Pawley and Le Bail methods (see Chapter 3.5), have been developed for this atom-coordinate-free profile refinement. It is at this point that the greatest care should be taken in fitting the diffraction pattern, as these methods will yield a better fit to the data than the final Rietveld refinement. Ideally, the unit-cell parameters, peak-width values and background polynomial coefficients should be fixed for all subsequent real-space structure determination attempts as well as the final Rietveld refinement.

Real-space structure-determination methods involve moving an atom or a set of atoms around a unit cell, determining whether the resulting fit to the diffraction data improves or worsens, and then deciding on whether to accept or reject the move.

Some real-space structure-determination programs, such as *DASH* (David *et al.*, 2006), use the extracted integrated intensities in addition to the diffraction profile for accelerated comparison between observed and calculated profiles (see Section 4.3.4.1); this requires evaluation of the integrated intensities covariance matrix, which is readily accessible using the Pawley method. Space-group determination is generally undertaken at the same time as initial profile fitting. The first space-group choice for profile refinement should be a space group of the appropriate Laue class having no systematic absences; these are $P\bar{1}$ (triclinic), $P2/m$ (monoclinic), $Pmmm$ (orthorhombic), $P4/m$ and $P4/mmm$ (tetragonal), $P\bar{3}$, $P\bar{3}1m$ and $P\bar{3}m1$ (trigonal), $P6/m$ and $P6/mmm$ (hexagonal), and $Pm\bar{3}$ and $Pm\bar{3}m$ (cubic).

Space-group determination is often undertaken by visual assessment of the systematically absent reflections and consultation of *International Tables for Crystallography* Volume A, Chapter 1.6. Automated space-group determination programs are also available, *e.g. ExtSym* (Markvardsen *et al.*, 2001, 2012), *DASH* (David *et al.*, 2006), *EXPO* (Altomare *et al.*, 2009) and *FOX* (Favre-Nicolin & Černý, 2004*a*,*b*), and give an accurate probabilistic ranking of the various extinction symbols using both present and absent reflections. Each extinction symbol is generally associated with more than one space group and chemical reasoning such as the presence or absence of a centre of symmetry from chirality considerations or an estimation of the number of molecules in a unit cell from volume considerations can reduce the number of potential options. If more than one space group is a plausible candidate, then multiple global-optimization runs with each potential space group should be performed. Space-group determination from powder-diffraction data is discussed more extensively in Chapter 3.4. The final Pawley or Le Bail fitting of the diffraction data should be performed using the final selection of space group(s). All the necessary diffraction information is then in place to proceed to the real-space structure-determination stage of the structure-solution process.

4.3.2. Real-space structure determination: a global-optimization extension of the Rietveld method

Real-space SDPD may be accurately described as a global Rietveld method. In both cases, a preliminary model is essential and the optimal structure is determined by minimizing the difference between the observed and calculated powder-diffraction patterns. The goodness of fit in real-space structure determination is the same as in standard Rietveld analysis, where the function that is minimized is either the least-squares function [with N, P and C, respectively, representing the number of observations, parameters and parameter constraints, and $w(i)$ is the statistical weight associated with observation i]

$$\chi^2 = S^2/(N-P+C),$$

where

$$S^2 = \sum_{i=0}^{N} w(i)\big[y_{\rm obs}(i) - y_{\rm calc}(i)\big]^2,$$

or the essentially equivalent weighted profile R factor, $R_{\rm wp}$,

$$R_{\rm wp} = \left(\frac{S^2}{\sum_{i=0}^{N} w(i) y_{\rm obs}(i)^2}\right)^{1/2}.$$

The ideal targets for χ^2 and $R_{\rm wp}$, for both real-space structure determination and Rietveld analysis, are, respectively, $\chi^2 = 1$ and the expected R factor, $R_{\rm exp}$,

$$R_{\rm exp} = \left(\frac{N-P+C}{\sum_{i=0}^{N} w(i) y_{\rm obs}(i)^2}\right)^{1/2}.$$

The equivalence between minimizing χ^2 and $R_{\rm wp}$ can be seen by noting that

$$\chi^2 = \left(R_{\rm wp}/R_{\rm exp}\right)^2.$$

The essential difference between real-space structure determination and the standard use of the Rietveld method is the range of convergence of the two techniques. The Rietveld method has been developed as a refinement procedure where the parameters chosen for the initial starting model are sufficiently close to the correct answer for a standard steepest-descents or equivalent minimization method to be adequate to obtain the structural parameters that correspond to an optimal fit between observed and calculated diffraction profiles. In other words, the initial starting parameters must be in the global minimum basin of the χ^2 hypersurface. Real-space structure determination, on the other hand, sets out to solve crystal structures from any randomly chosen set of structural parameters. As such, it is an optimization method that requires global-optimization algorithms. As stated previously, this implies that real-space structure determination is essentially a global parameter exploration version of the Rietveld method. The nature of the χ^2 hypersurface, which is discussed further in Section 4.3.4.2, is, however, extremely complex with multiple local minima. Given this complexity, the principal challenge in the development of real-space structure determination is the implementation of global-optimization techniques that efficiently and comprehensively explore the full structural parameter space that completely describes all chemically possible crystal structures. This goal requires the resolution of two distinct and significant issues. The first of these, the most efficient and compact description of the full structural parameter space, is discussed in Section 4.3.3.2. The second challenge, the optimal exploration of the full structural parameter space combined with the effective minimization of the goodness of fit between observed and calculated diffraction patterns, is discussed in Section 4.3.5.

4.3.3. Optimizing the process of real-space structure determination from powder-diffraction data

4.3.3.1. *Introduction*

Global optimization is a comprehensive and time-consuming procedure, and all possibilities for accelerating the search process should be explored. The choice of cost function and the metric for the comparison of observed and calculated diffraction data should be chosen to make the process as fast as possible without loss of accuracy. In the case of SDPD, the fastest, accurately representative cost function is the correlated integrated intensities goodness of fit, which is discussed in Section 4.3.4.1. Full-profile fitting is also commonly used and is (if fully optimized) less than an order of magnitude slower. Importantly, if full-profile fitting is being used, the refinement of parameters other than the essential structural parameters should be avoided. The inclusion in the real-space structure-determination process of the variation of lattice parameters, peak widths and background coefficients substantially reduces performance and convergence.

A number of different global-optimization algorithms have been developed and used for real-space structure determination. The majority of these algorithms are stochastic in nature and include simulated annealing, parallel tempering and genetic and evolutionary algorithms. Deterministic approaches have been explored to a lesser extent, but techniques such as the hybrid Monte Carlo method show significant promise. Other techniques, such as swarm and diffusion equation methods, have been discussed but not extensively explored. These methods have been summarized by David & Shankland (2008) and are discussed in more detail in Section 4.3.5.

The final significant factor in determining the performance of a global-optimization approach to real-space structure determination of molecular materials is the parameterization of the molecular structure. The shape, geometry and conformation of most molecules that can be tractably solved from powder-diffraction data are well known or can be constructed from structural databases. This can reduce the number of degrees of freedom from the maximum values of the 3*N* atomic coordinates of a molecule with *N* atoms to the six external degrees of translational and rotational freedom of the molecule and the often small number of internal torsional degrees of freedom. Although the building blocks of molecular structures are generally much more complicated than for many inorganic structures, the absence of an extended, connected framework for molecular structures (with the exception of polymeric materials) means that each independent molecule can be treated as an isolated entity. Molecules may be moved at random around the unit cell in the search for the correct crystal structure while maintaining the intramolecular connectivity and exploring the intramolecular geometry without any concern for all the possible permutations of extended framework connectivity.

4.3.3.2. *Parameterization of the molecular structure*

After the pioneering work of Arnott & Wonacott (1966), a number of formats have been developed to describe molecular structure. One common format for expressing molecular connectivity is the *Z*-matrix formalism developed for the *Gaussian* computer program (https://www.gaussian.com). The benefits of using a connectivity representation for molecular atomic coordinates are best illustrated by an example.

Consider the diuretic drug hydrochlorothiazide (Leech *et al.*, 2008), $C_7H_8ClN_3O_4S_2$, illustrated in Fig. 4.3.2(*a*). An atom in the molecule is selected to define the origin of the molecular coordinate system.

In hydrochlorothiazide, the best origin choice is the Cl atom. There are two criteria that are significant in this choice; firstly, the atom should ideally be part of a substantial inflexible component of the molecule that is close to the centre of the molecule, and second, the atom should be one of the stronger scatterers (for X-rays, this equates to one of the heavier atoms in the molecule). The reasons for these selection criteria will be discussed in Section 4.3.4.2.

The molecular coordinate system is described in terms of Cartesian coordinates. The *z* axis is chosen to align along the first molecular bond, Cl(1)—C(2); the *x* axis is defined to lie in the plane of the first three selected atoms, Cl(1), C(2) and C(3), and the *y* axis is perpendicular to both the *x* and *z* axes forming an orthogonal right-handed coordinate system. Full details of the molecular connectivity of the first five atoms are illustrated in Fig. 4.3.2(*b*) and shown symbolically in Table 4.3.1, where b_1, b_2, b_3 and b_4 denote the Cl(1)—C(2), C(2)—C(3), C(3)—S(4) and S(4)—O(5) bond lengths, respectively, φ_1, φ_2 and φ_3 are the bond angles Cl(1)—C(2)—C(3), C(2)—C(3)—S(4) and C(3)—S(4)—O(5), and τ_1, and τ_2 are the dihedral angles associated with the atom quartets Cl(1)—C(2)—C(3)—S(4) and C(2)—C(3)—S(4)—O(5).

Table 4.3.2 lists the full *Z*-matrix for hydrochlorothiazide using a slightly modified definition developed for *DASH* (David *et al.*, 2006) that illustrates generically all the required information to define the molecule confirmation.

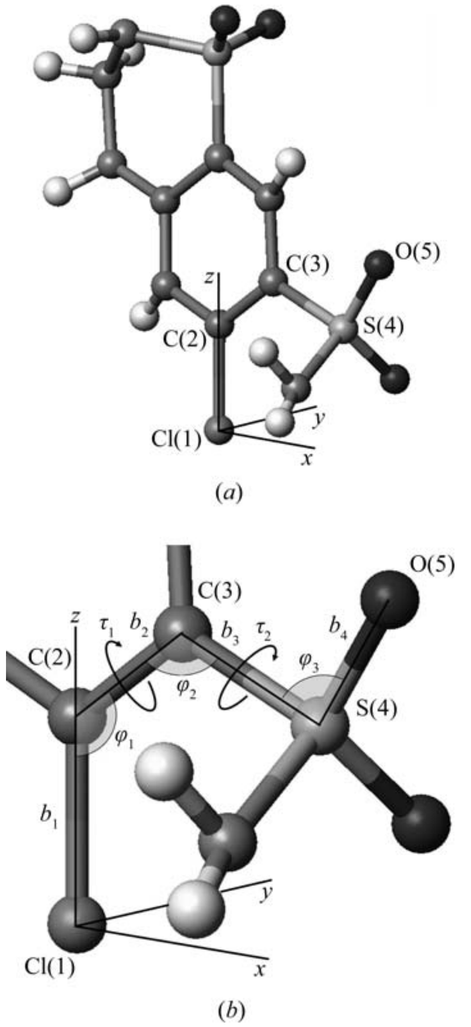

Figure 4.3.2
(*a*) The Cartesian molecular coordinate system for hydrochlorothiazide. The origin is located at the chlorine atom. (*b*) An expanded view around the origin of the molecular coordinate system highlighting the initial bond lengths, angles and dihedral angles in the *Z*-matrix of hydrochlorothiazide.

The rows shown in Table 4.3.2 define the full molecular connectivity. Each row has ten columns. The first denotes the atom type and columns 8, 9 and 10 indicate the atoms to which this atom is connected. Consider the first sulfur atom, which is atom number 4 in the list. It is 1.754 Å from atom 3, C(3), forms an angle with atom 3 and atom 2 [*i.e.* C(2)—C(3)—S(4)] of 124° and a dihedral angle of 1.07° involving the atom quartet Cl(1)—C(2)—C(3)—S(4). The remaining three columns, columns 3, 5 and 7, are flags indicating whether the bond length, angle or dihedral angle should be fixed (flag = 0) or varied (flag = 1). Inspection shows that all these flags are zero except for one, the dihedral angle listed in the fifth atom row. This corresponds to the dihedral angle, τ_2, and is the only dihedral angle in hydrochlorothiazide that can vary over a significant range of angles and is thus the only true torsion angle in the molecule (Fig. 4.3.2). All other dihedral angles and bond lengths and angles are chemically reasonable and close enough to their correct values to be fixed in the structure-solution process. This means that the global-optimization search only spans a seven-dimensional space corresponding to the six external degrees of freedom (three translational and three rotational) and one internal degree of torsional freedom, τ_2. This is the minimal number of degrees of freedom that fully describes the molecular flexibility. Other

approaches, such as that of the computer program *FOX* (Favre-Nicolin & Černý, 2004*b*), favour rather more flexible *Z*-matrices. Without this explicit connectivity obtained from an accurate knowledge of all intramolecular bonds and angles and the majority of intramolecular dihedral angles, all atoms would need to be moved independently of one another. Ignoring hydrogen atoms and noting that there would be three positional degrees of freedom associated with each non-hydrogen atom results in a 51-dimensional space. An indication of the probability of being able to tackle a global optimization in such a large parameter space is discussed in Section 4.3.4 and the probabilities of success are very low. Anti-bump and neighbour-avoiding random walks substantially reduce the search volume of this large hyperspace, but given that optimization complexity and time to solution increase exponentially with search-space dimensionality, it is evident that the *Z*-matrix and similar connectivity formalisms not only will lead to a massively improved rate of success but also represent the optimal parameterization of the molecular structure because they span the minimum number of parameter dimensions that contain all the chemically reasonable molecular locations and conformations.

4.3.4. The nature and magnitude of the global-optimization challenge

This section explores the nature and scale of the global-optimization challenge for real-space SDPD and highlights the efficiency of the bond-connectivity (*e.g.* the *Z*-matrix algorithm) approach for the solution of molecular crystal structures. Global optimization, by definition, involves full evaluation and a comprehensive exploration of the structure parameter space under investigation. In order to emphasize the effectiveness of the *Z*-matrix approach, it is worth stepping back and assessing the magnitude of the challenge if the chosen route were to move individual atoms independently around the unit cell.

Consider an organic molecular structure with N_A atoms (ignoring hydrogens) in each molecule. An estimate of the volume, V_c, of the unit cell is $V_c \simeq ZV_AN_A$ Å^3 (where Z is the number of molecules in the unit cell and $V_A \simeq 17$ Å^3 is a commonly considered approximate volume associated with a non-hydrogen atom in an organic crystal structure). Assuming that all the atoms are located on general positions (and this is often the case), the parameter space to be searched spans $3N_A$ dimensions. If an adequate solution is obtained when every atom is within a generous $r \simeq 1$ Å of a correct position, then the probability of finding an acceptable solution at random can be shown to be

$$\text{prob}_{\text{sol}} \simeq N_A!\left[r^3/N_A\left(V_A - V_{\text{EXC}}\right)\right]^{N_A}, \qquad (4.3.1)$$

where V_{EXC} is the excluded volume where atoms are forbidden to overlap. If atoms are placed randomly in the unit cell, then $V_{\text{EXC}} = 0$, whereas if solutions with overlapping atoms are forbidden then $V_{\text{EXC}} \simeq (1.4)^3$ Å^3, where 1.4 Å represents a typical interatomic distance. The $N_A!$ contribution in equation (4.3.1) allows permutation between all non-hydrogen atoms; in other words, each non-hydrogen atom must be at a non-hydrogen position, but not necessarily its correct position. This is a reasonable, common assumption and greatly increases (by a factor of $N_A!$) the probability of selecting $3N_A$ coordinates and obtaining a good solution at random. Equation (4.3.1) may be modified and simplified to give

$$\log_{10}(\text{prob}_{\text{sol}}) \simeq -N_A\left\{\log_{10}\left[\left(V_A - V_{\text{EXC}}\right)/r^3\right] + 0.43\right\}. \qquad (4.3.2)$$

For a molecule containing N_A = 5, 10 and 20 atoms, the solution probability values, with $V_{\text{EXC}} = (1.4)^3$ Å^3, are $10^{-7.9}$, $10^{-15.8}$ and $10^{-31.7}$, respectively. The likelihood of being within 1 Å of a correct solution is roughly 1 in 10^8 for the 5-atom molecule and vanishingly small for the 10- and 20-atom molecules. This correct solution can, however, be found if each random atom selection is within the radius of convergence of the global minimum in the $3N_A$-dimensional structural hyperspace. In Section 4.3.4.1, this radius of convergence, the extent of the global minimum basin, is shown to be similar to the spatial extent of an average interatomic vector peak in the Patterson function. Invoking the convolution theorem, this will be $r \simeq 2.0$ Å, which is about $2^{1/2}$ times larger than a typical atomic scattering-factor distribution. This doubling of the value of r leads to a very different set of probabilities when neighbour-avoiding solutions are considered. This is essentially the procedure adopted by Semenovskaya *et al.* (1985) in one of the earliest attempts at global optimization of real-space SDPD. For N_A = 5, 10 and 20 atoms with non-overlapping $V_{\text{EXC}} \simeq 2.7$ Å^3, the solution probability values are now 1 in ∼2500, 1 in $\sim 6 \times 10^6$ and 1 in $\sim 4 \times 10^{13}$. With 5- and 10-atom structures, it is feasible to consider the least-squares minimization of multiple neighbour-avoiding, semi-random atom configurations as a method of structure solution from powder-diffraction data. However, for larger structures this procedure is evidently not practical.

It is clear from equation (4.3.2) that the crucial factors in determining the probability of a successful structure determination are the number of atoms, N_A, and the excluded volume, $V_{\rm EXC}$, as both the typical radius of convergence, $r \simeq 2.0$ Å, and the approximate atom volume, $V_A \simeq 17$ Å^3, are essentially fixed quantities. The optimal approach to the issue of the excluded volume is (as discussed in Section 4.3.3.2) the use of molecular connectivity. Atoms within a molecule are not only forced to be apart but are optimally located apart by the use of chemically sensible and accurate bond lengths, angles and dihedral angles.

Moving from an individual-atom approach to a fully connected molecule also substantially reduces the dimensionality of the search space, as discussed in Section 4.3.3.2 where the selected example, hydrochlorothiazide, shows a lowering of search space dimensionality from $3N_A = 51$ to 7 dimensions. While it is straightforward to estimate the exponentially increased probability of structure-solution success from this reduction in dimensionality, it is less clear about the impact of the optimal excluded volume from the use of a *Z*-matrix or equivalent formalism. The discussion in Section 4.3.4.2 of success in the structure solution of the histamine H2-receptor antagonist, famotidine, $C_8H_{15}N_7O_2S_3$, (Shankland *et al.*, 2002) suggests that there is a very significant advantage. With 6 external and 7 internal torsional degrees of freedom ($N_{\rm DOF} = 13$), multiple random starts followed by direct least-squares minimization leads to a success rate of order 1 in 5000. Substituting this value into an appropriately modified version of equation (4.3.2),

$$\log_{10}({\rm prob}_{\rm sol}) \simeq -\tfrac{1}{3}N_{\rm DOF}\log_{10}\left[N_A\left(V_A - V_{\rm EXC}\right)/r^3\right], \qquad (4.3.3)$$

gives an estimated value of $V_{\rm EXC} \simeq 13.6$ Å^3 of the available 17 Å^3 compared with $V_{\rm EXC} \simeq 2.7$ Å^3 for the independent-atom search. Not only is the dimensionality of each search space substantially smaller when using a *Z*-matrix or equivalent molecular-connectivity formalism but the required fraction of the search space that must be explored is also greatly reduced.

Given the observed success rate for famotidine, the convergence hypersurface must only be ~5000 times smaller than the total 13-dimensional hypersurface. This corresponds, on average, to a fraction of around $0.5 \simeq (1/5000)^{1/13}$ for each degree of freedom. Remarkably, using molecular connectivity to reduce the size of the parameter space means that finding the hypersurface basin that contains the global minimum is essentially equivalent to tossing a coin for each external and internal degree of freedom. Correspondingly, increasing the number of degrees of freedom only increases the number of trials by a factor of around two. While this is a surprisingly small penalty to pay for increasing molecular complexity, it nevertheless means that the addition, for example, of ten more internal torsional degrees of freedom will lead to about a 1000-fold increase in minimization complexity. Increases in computer speed go some way to addressing this issue, but the principal gain can be had by parallelizing multiple structure-solution attempts. This strategy has been used for computer programs such as *DASH*, where *MDASH* (for multi-processors use on a single machine; Griffin *et al.*, 2009*a*) and the fully grid-enabled version *GDASH* (for very large calculations involving hundreds of processor cores; Griffin *et al.*, 2009*b*) have enabled complex structures to be solved on manageable timescales (Fernandes *et al.*, 2007). *FOXGrid*, a parallel version of the structure-solution program *FOX* (https://fox.vincefn.net/Manual/Fox.Grid) is also available.

In addition to the direct approach of utilizing multiple processors, additional stratagems for tackling more complex organic structures include the development of new global-optimization algorithms (see Section 4.3.5) and the reduction of the parameter exploration space. The latter strategy can be tackled using three different approaches: firstly, by restricting parameter ranges such as limiting torsion-angle values to those observed in structural databases, secondly, by limiting torsion angles and, more generally, molecular conformations by using additional structural information from other experimental data (such as NMR) and, thirdly, by completely removing parameters from the structural-solution process using maximum-likelihood methods; see Section 4.3.6.

4.3.4.1. *Interpretation of the least-squares cost function*

There is a close relationship between the best goodness-of-fit values obtained from a Pawley and a Rietveld refinement of a powder-diffraction pattern (David, 2004). The unnormalized goodness of fits

$$S^2_{\rm PAW} = \sum_{i=0}^{N} w(i)\left[y_{\rm obs}(i) - y_{\rm PAW}(i)\right]^2$$

and

$$S^2_{\rm RIET} = \sum_{i=0}^{N} w(i)\left[y_{\rm obs}(i) - y_{\rm RIET}(i)\right]^2$$

are related by the equation

$$S^2_{\rm RIET} = S^2_{\rm PAW} + S^2_{\rm CI}, \qquad (4.3.4)$$

where the correlated integrated intensities goodness of fit, $S^2_{\rm CI}$, is given by

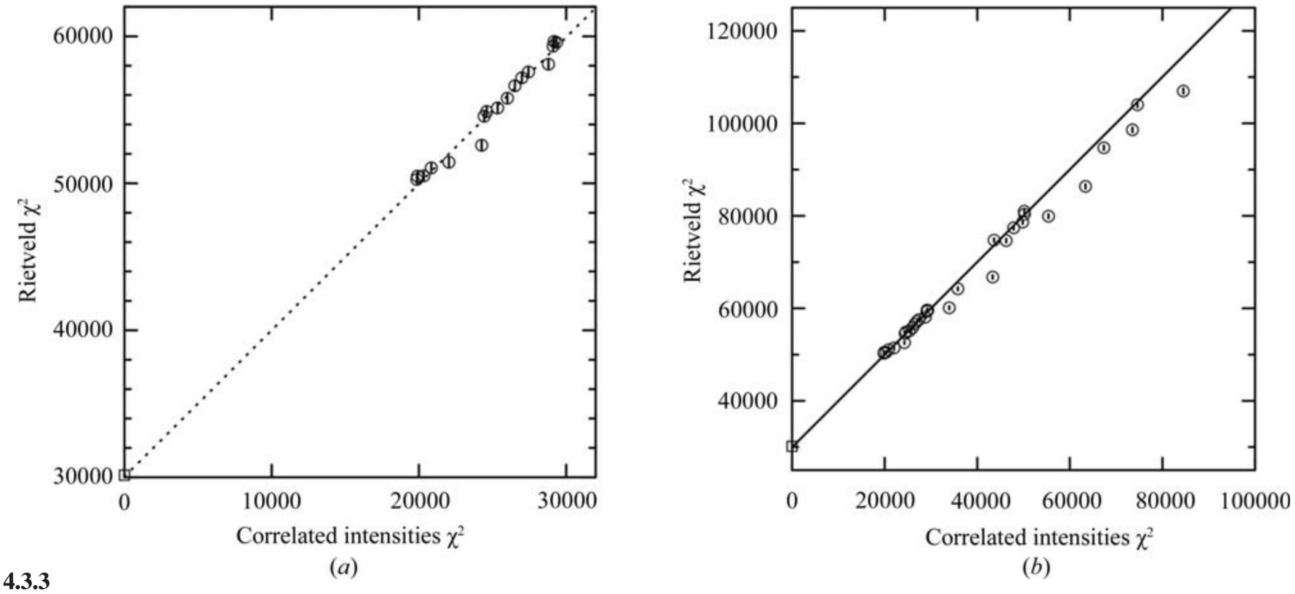
$$S^2_{\rm CI} = \sum_{j}^{N_R}\sum_{k}^{N_R}\left(V^{-1}_{\rm PAW}\right)_{jk}\left[I_{\rm obs}(j) - I_{\rm calc}(j)\right]\left[I_{\rm obs}(k) - I_{\rm calc}(k)\right]. \qquad (4.3.5)$$

N_R is the number of statistically independent reflection peaks and $I_{\rm calc}(j)$ is the sum of the intensities contributing to each clump given by $I_{\rm calc}(j) = c\sum_{\{\mathbf{h}_j\}} m_{\mathbf{h}_j}\left|F(\mathbf{h}_j)\right|^2$, where c is a scale factor. This sum is over metrically exact (such as the 511 and 333 reflections) and accidentally very close reflections. The equivalence expressed in equation (4.3.4) has been discussed extensively by David (2004) and is illustrated in Fig. 4.3.3 by an analysis of the various goodness of fits obtained in the structure solution of the antipsychotic drug promazine hydrochloride. The associated normalized $\chi^2_{\rm CI}$ goodness of fit is given by

$$\chi^2_{\rm CI} = S^2_{\rm CI}/\left(N_R - P_S + C_S\right), \qquad (4.3.6)$$

where P_S and C_S are, respectively, the number of the structural parameters that are varied and the number of structural constraints.

The degree of overlap for adjacent reflections in equation (4.3.5) is evaluated statistically from the inverse of the integrated-intensity component of the correlation matrix, $V^{-1}_{\rm PAW}$, obtained from a Pawley analysis. The number of off-diagonal terms in this matrix is typically between one and two times the number of diagonal terms and thus the number of terms that must be evaluated for $S^2_{\rm CI}$ is roughly twice the number of reflections. Use of $S^2_{\rm CI}$ in the early days of real-space SDPD provided a substantial speed advantage. With increases in computer power, the advantages of an accelerated goodness-of-fit evaluation have become less necessary and many real-space global-optimization programs now use the weighted profile *R* factor, $R_{\rm wp}$, or the equivalent $\chi^2_{\rm Riet}$. With the appropriate storage of peak-shape and background functions, this typically results in only a factor of 3–4 decrease in the rate of goodness-of-fit evaluation.



(*a*) (*b*)

Figure 4.3.3
The reported values for both $S^2_{\rm CI}$ and $S^2_{\rm RIET}$ in (*a*) the final stages of the structure-solution process for promazine hydrochloride. The dotted line is an intercept-only fit to these data (with a gradient of unity) and extrapolates to $S^2_{\rm PAW}$ to within statistical error. This provides experimental evidence of the equivalence $S^2_{\rm RIET} = S^2_{\rm PAW} + S^2_{\rm CI}$. (*b*) An extended plot of (*a*) showing that equivalence also holds well at earlier stages in the structure-solution process when the fit to the data is relatively poor.

The formal equivalence between minimizing either $\chi^2_{\rm Riet}$ or $S^2_{\rm CI}$ also sheds light on the nature of the real-space global-optimization process. The Patterson function is defined as the Fourier transform of the square of the structure-factor modulus:

$$P(\mathbf{u}) = \sum_{\mathbf{h}} \left|F(\mathbf{h})\right|^2 \exp(2\pi i\mathbf{h}\cdot\mathbf{u}) = \sum_{\mathbf{h}} F(\mathbf{h})F(\mathbf{h})^* \exp(2\pi i\mathbf{h}\cdot\mathbf{u})$$

(see Chapter 1.1). The Patterson function is the self convolution of the scattering density, $\rho(\mathbf{r})$; *i.e.* $P(\mathbf{u}) = \int_{V_c} \rho(\mathbf{r})\rho(\mathbf{u}+\mathbf{r})\,{\rm d}^3\mathbf{r}$. A more accessible and relevant understanding of this self-convolution is that the Patterson function is the set of interatomic vectors blurred by Debye–Waller factors and the atomic scattering distribution.

An important relationship in the theory of real-space structure determination may be obtained by invoking Parseval's theorem, which states that the scalar product of two functions in reciprocal space is exactly equivalent to the scalar product of the Fourier transforms of these two functions in real space.

If $P_1(\mathbf{u}) = \sum_{\{\mathbf{h}\}} |F_1(\mathbf{h})|^2 \exp(2\pi i\mathbf{h}\cdot\mathbf{u})$ and $P_2(\mathbf{u}) = \sum_{\{\mathbf{h}\}} |F_2(\mathbf{h})|^2 \exp(2\pi i\mathbf{h}\cdot\mathbf{u})$ then

$$\sum_{\{\mathbf{h}\}} \left|F_1(\mathbf{h})\right|^2 \left|F_2(\mathbf{h})\right|^2 = \int_V P_1(\mathbf{u})P_2(\mathbf{u})\,{\rm d}^3\mathbf{u}.$$

This may be extended to obtain the following equivalence for the unnormalized, unweighted integrated-intensity goodness of fit,

$$\begin{aligned} S^2_{\rm UWI} &= \sum_{\{\mathbf{h}\}} \left(\left|F_{\rm obs}(\mathbf{h})\right|^2 - \left|F_{\rm calc}(\mathbf{h})\right|^2\right)^2 \\ &= \int_V \left[P_{\rm obs}(\mathbf{u}) - P_{\rm calc}(\mathbf{u})\right]^2 {\rm d}^3\mathbf{u}. \qquad (4.3.7) \end{aligned}$$

In addition to $S^2_{\rm UWI}$ being the sum of the unweighted squares of the difference between the observed and calculated integrated intensities, it is also the integral over the difference between the observed and calculated interatomic vector maps (Patterson functions). This function is very similar to the function $S^2_{\rm CI}$, which accurately represents the minimization metric in the real-space structure-determination process. The only difference is the presence of the weight matrix, $(V^{-1}_{\rm PAW})$, in $S^2_{\rm CI}$. This has two consequences. The first concerns the on-diagonal terms, which are proportional to the inverse of the associated integrated intensity. This has the equivalent effect of sharpening the interatomic vector map features in the Patterson function by a factor of $\sim 2^{1/2}$. The second impact is from the off-diagonal terms. This is generally small for long *d*-spacing reflections but can be substantial at short *d*-spacings, where reflection overlap may become severe. In the limit of overlap, all reflections at a particular *d*-spacing will be completely overlapped. This is equivalent to forming a time-averaged pair distribution function where distance information is preserved but all directional information is lost. The goodness-of-fit functions in real-space structure determination will thus be smoother, and both inter- and intramolecular orientational information will be lost.

As a corollary, this real-space interpretation of severe overlap gives a clear rationale for the minimum *d*-spacing reflections to be used in the structure-solution process. A useful working criterion is to truncate the data at a point where the average separation between reflections is less than a fifth of the peak full width at half maximum. Assuming that the peak extent will be principally determined by strain broadening at short *d*-spacings leads to a $d_{\rm min}$ criterion of $\sim 2.7(\varepsilon N_{\rm AU})^{1/3}$, where $\varepsilon = \Delta d/d$ is the combined extent of the instrument resolution and strain broadening and $N_{\rm AU}$ is the number of non-hydrogen atoms in the asymmetric unit. ε will range from around 2×10^{-4} for sharply diffracting samples on synchrotron powder diffractometers to around 5×10^{-3} for samples with broader peaks on laboratory machines. The corresponding values for $d_{\rm min}$ for $N_{\rm AU}$ values of 20, 50, 100 and 500 are listed in Table 4.3.3 along with values of $\varepsilon = 2 \times 10^{-3}$ for good laboratory X-ray diffraction data.

Experience indicates that molecular structures may be solved using real-space SDPD alone if good diffraction data are available to a minimum *d*-spacing of ∼1.7 Å. This suggests that molecular structures with up to 50 atoms in the asymmetric unit may be solved from relatively poor diffraction data and up to 100 atoms for excellent laboratory data. This is a fair assessment of the potential of real-space structure determination from laboratory data alone, although the availability of additional informa-

Table 4.3.3
Estimated minimum *d*-spacing range extent (in Å) for structure solution for different complexities of molecular structures using low (5×10^{-3}), medium (2×10^{-3}) and high (2×10^{-4}) resolution instrumentation

	N_{AU}			
ε	20	50	100	500
5×10^{-3}	1.4	1.8	2.3	4.0
2×10^{-3}	0.9	1.3	1.6	2.7
2×10^{-4}	0.5	0.7	0.9	1.6

tion from, for example, NMR may extend these limits. The numbers for the very highest resolutions available with a combination of excellent sample and synchrotron powder diffraction suggest that very large structures may be successfully tackled, and this is indicated by the success of protein powder-diffraction measurements. However, the concomitant increase in structure complexity and, in particular, the combinatorial increase in torsion-angle conformations make real-space structure determination a difficult task without involving either new algorithm development or the use of ancillary information about inter- and intramolecular geometries from structural databases or additional experimental measurements.

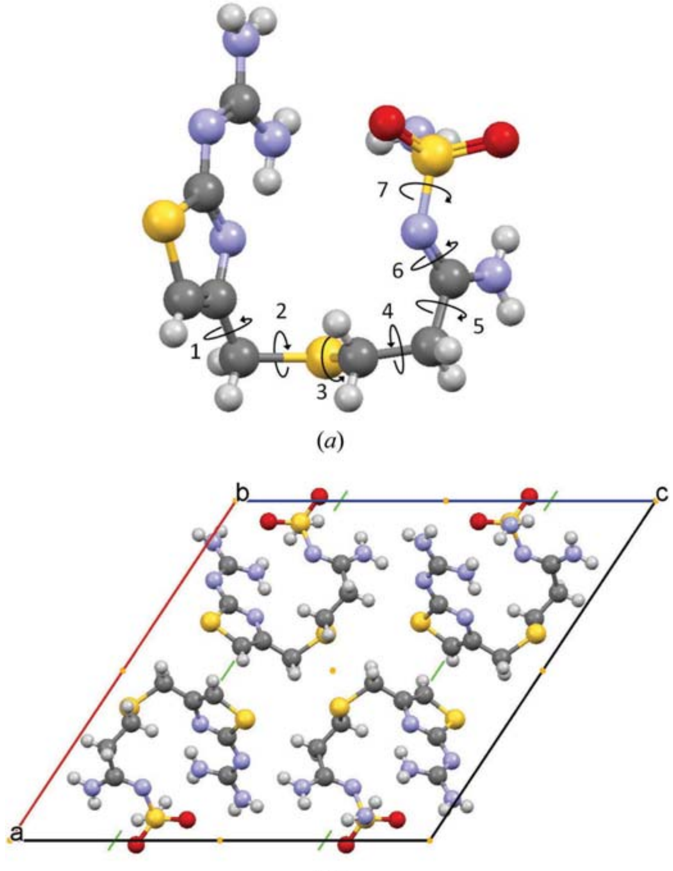
Equation (4.3.7), with consideration of the impact of $(V_{\rm PAW}^{-1})$, gives a numerical assessment and clear picture of the impact of moving atoms around the unit cell in the process of real-space structure determination. This will be discussed further in Section 4.3.4.2.

4.3.4.2. *The chi-squared hypersurface*

In the remaining sections of this chapter, all references to structural parameters will be considered within the context of molecular-connectivity algorithms. The *Z*-matrix algorithm will be explicitly used and it will mostly be assumed that only the external rotational and translational and the internal torsional degrees of freedom will be adjusted. External orientation degrees of freedom may be described by either Euler angles or quaternions. For a comparison of the use of Euler angles and quaternions in crystallography, see Skone *et al.* (2013). The quaternion method (see Mackay, 1984) will be used in the remaining sections of this chapter.

Unsurprisingly, the initial selection of structural parameters in a real-space structure determination essentially never results in a structure that is close to the correct answer and the cost function (designated as χ^2 for convenience) is always much higher than the final value associated with the correct structure. In this section, the nature of the χ^2 hypersurface as a function of the various structural parameters is considered. The discussion principally focuses on the real-space structure determination of the histamine H2-receptor antagonist famotidine (Shankland *et al.*, 2002), $C_8H_{15}N_7O_2S_3$, using high-resolution synchrotron X-ray powder-diffraction data at 130 K at a wavelength of 0.85075 Å on the diffractometer ID31 at the ESRF, Grenoble. Famotidine adopts the space group $P2_1/c$ with lattice parameters $a = 17.652$, $b = 5.293$, $c = 18.256$ Å, $\beta = 123.56°$ and $V = 1421.6$ Å^3. The diffraction data were truncated at a minimum *d*-spacing of 1.75 Å. The molecule and crystal structure of famotidine are shown in Fig. 4.3.4. The seven internal torsion angles are shown in Fig. 4.3.4(*a*).

Fig. 4.3.5 shows the frequency distribution of $\chi^2_{\rm CI}$ values [equation (4.3.6)] of 10^6 randomly selected sets of structural parameters (six external and seven internal torsional degrees of freedom). Over 98% of $\chi^2_{\rm CI}$ values are very high.



(*a*)

(*b*)

Figure 4.3.4
(*a*) The molecular structure and (*b*) the *b*-axis projection of the crystal structure of the polymorphic form B of famotidine. The seven internal torsion angles are enumerated in (*a*).

Fig. 4.3.6 gives an insight into this distribution of $\chi^2_{\rm CI}$ values. The two-dimensional section of the $\chi^2_{\rm CI}$ hypersurface shows $\chi^2_{\rm CI}$ as a function of *x* and *z* translational external degrees of freedom; all other parameters are set at the best refined values. Two sets of four deep minima are observed. The minima come in quartets because four different enantiomers are represented in this figure; all four deepest minima represent correct equivalent solutions that are illustrated in Fig. 4.3.6. There are a number of further significant features in this two-dimensional section of the $\chi^2_{\rm CI}$ hypersurface that merit further discussion.

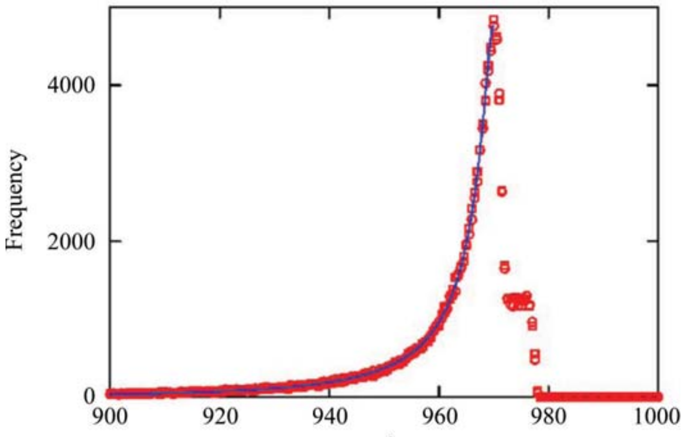


Figure 4.3.5
The $\chi^2_{\rm CI}$ frequency distribution for famotidine (form B).

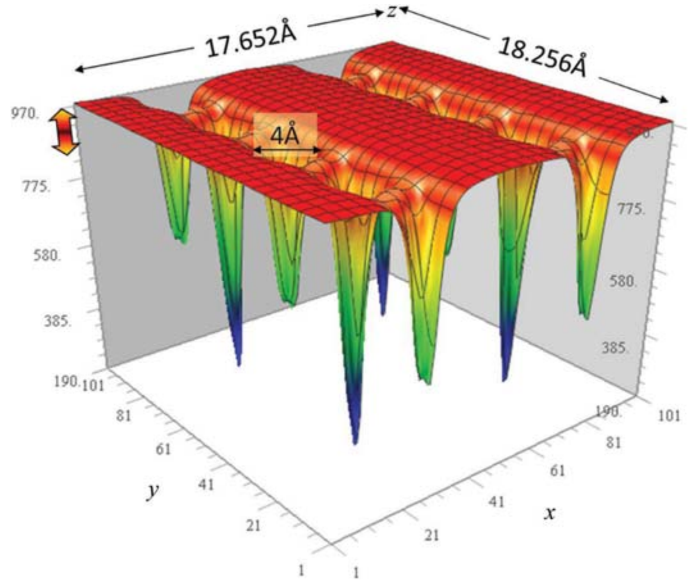

Figure 4.3.6

(*a*)

(*b*)

Figure 4.3.7
Comparison of the crystal structure shifted by z = 1/4 with the correct crystal structure of famotidine (form B). (*a*) The *b*-axis projections of the two structures are identical, implying that all $h0l$ reflections will be identical, and (*b*) an off-axis projection indicating the small differences in the crystal structure associated with the two deep fourfold-degenerate minima in Fig. 4.3.6.

Firstly, despite the fact that all the other 11 structural parameters are at their correct values, the majority of this surface is at high $\chi^2_{\rm CI}$ values equivalent to the highest observed with the random generated structures; see Fig. 4.3.5. The correct structure is never far away from a wrong solution that fits the diffraction data very badly. However, this top plateau is not reached for all the structural parameters. Later in this section it will be shown that the biggest $\chi^2_{\rm CI}$ changes are associated with the external rotational and translational parameters that involve the movement of the largest number of atoms and the greatest change in the number of interatomic vectors.

A second important point illustrated in Fig. 4.3.6 concerns the probability of choosing an x, z pair of coordinates at random and directly minimizing to the correct solution. The areas of each minimum are at least 4×4 Å^2 = 16 Å^2 out of a possible ~320 Å^2. With four degenerate correct and incorrect solutions, the probability of dropping into any of these minima will be greater than 0.4. Indeed, the flatness of the plateau suggests that there may be a 50:50 chance of obtaining the correct solution and that no other minima exist. This observation agrees with the discussion in Section 4.3.3 that the use of molecular connectivity in real-space structure determination costs an unexpectedly small factor of around two for each degree of freedom.

The third point of note in Fig. 4.3.6 is that the $\chi^2_{\rm CI}$ surface shows different behaviour as a function of the x and z translational coordinates. There is a substantially larger plateau region between solutions along the x coordinate, whereas the plateau is not reached along the z coordinate because of the presence of deep local minima between the global minima. Indeed, the four degenerate local minima are sufficiently deep to appear to be a relatively good fit to the data. The reason for this is illustrated in Fig. 4.3.7.

The local minima correspond to all the structural parameters being correct except for the z coordinate, which is shifted by 1/4. The corresponding incorrect structure (capped sticks in the figure) is superposed upon the correct structure (ball-and-stick model). The *b*-axis projection shown in Fig. 4.3.7(*a*) indicates an exact overlap in projection between the two structures, implying that all $h0l$ reflection intensities are the same for both. Given the short b axis, the $h0l$ reflections dominate the powder diffraction from long to intermediate d-spacings and, for low angles in particular, the calculated diffraction pattern for both correct and incorrect structures will be identical. Differences will only be seen at intermediate angles and even then these will be subtle as, from Fig. 4.3.7(*b*), it can be seen that half of the molecules (upper row) are coincident with one another and the other half (lower row) only differ by a mirror plane at y = 3/4. These pseudosymmetry features are commonly found in good but not correct solutions and, in molecular structures with two long axes, the optimal fitting of all low-angle reflections can lead to an unwarranted confidence in the crystal structure. All reflections up to the limit of data resolution should fit well before there can be confidence in the correctness of the structure. Checking this should be the final arbiter in determining the correctness of the structure, but even here, as illustrated in the example of famotidine, this may not be straightforward as the intramolecular geometry is correct in both cases and it is only a small number of interatomic distances (those between the upper and lower rows) that are wrong. Fortunately, these correct and incorrect solutions must occur with essentially equal probability and the best approach is to perform a sufficient number of structure-solution attempts to find the correct one. This has been discussed by Shankland *et al.* (2010), who successfully obtained the correct structure through multiple local minimizations.

Fig. 4.3.8 shows the distribution of $\chi^2_{\rm CI}$ obtained after minimizing 20 000 randomly chosen sets of parameters. This distribution is well-fitted to a log-normal distribution. When compared with the distribution of $\chi^2_{\rm CI}$ associated with randomly chosen structures (see Fig. 4.3.8*b*), the log–log scale reveals a number of significant details about the nature of the $\chi^2_{\rm CI}$ hypersurface. The log-normal distribution of minima (which appears as a quadratic function on a log–log scale) is shifted to significantly lower values than the $\chi^2_{\rm CI}$ values of the randomly selected structures. Indeed, the extrapolation of the latter distribution indicates that the

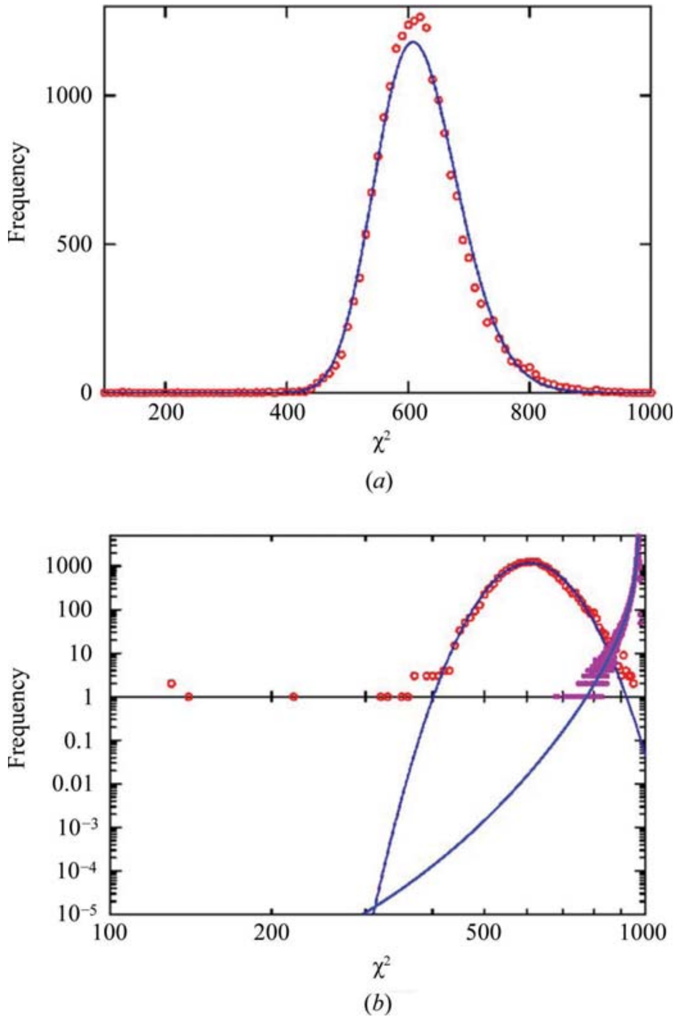

Figure 4.3.8

(*a*) The log-normal distribution of local minima obtained from steepest-descents minimization of 20 000 randomly selected famotidine form B crystal structures. (*b*) A log–log representation of the $\chi^2_{\rm CI}$ distributions of (i) random selected structures (purple points – fitted to an exponential distribution) and (ii) local minima (red points – fitted to a log-normal distribution). Note the small number of good and excellent $\chi^2_{\rm CI}$ values that depart from the log-normal distribution.

direct location of any of the many local minima is extremely improbable. As a consequence, efficient minimization is an essential component of any real-space structure-determination program. This, however, must be balanced with the requirement of escaping local minima, of which there are clearly a very large number that are substantially deeper than their immediate neighbourhood in the $\chi^2_{\rm CI}$ hypersurface. This conflict between efficient minimization and the need to escape local minima is the principal challenge facing a real-space global-optimization method. Many different approaches to this problem have been developed and are discussed in detail in Section 4.3.5.

The log–log scale in Fig. 4.3.8(*b*) also reveals that the tails of the frequency spectrum of the $\chi^2_{\rm CI}$ minima deviate from the log-normal distribution. There are deep minima that are distinct from the very large number of local minima that have $\chi^2_{\rm CI}$ values above 400. As discussed previously, all these minima are found to have some aspect of the correct solution either by translational pseudosymmetry or by correlated torsional mistakes that enable the strongly scattering components of the molecule (these are the sulfur atoms and rigid planar components in famotidine) to be located in approximately the correct position, while the weaker scattering components are not.

This is illustrated in Fig. 4.3.9, which shows three solutions that are correctly located with respect to both the translational and orientational external degrees of freedom. The structure corresponding to $\chi^2_{\rm CI}$ = 135 is the correct solution with the lowest goodness of fit. The structure with $\chi^2_{\rm CI}$ = 224 has only two carbon atoms that are substantially misplaced because of two correlated mistakes associated with neighbouring torsion angles. Again, the chemical differences between these two structures are small, as all the bond lengths and angles and the majority of torsion angles are correct. Given that both these structures look chemically sensible, care must be taken in ensuring that the correct structure has been found. The third solution ($\chi^2_{\rm CI}$ = 325) shown in Fig. 4.3.9 contains more incorrect torsion angles. Nevertheless, all the strongly scattering components of the molecule are correctly located, which, of course, must be the case for the $\chi^2_{\rm CI}$ value to be so low. It is interesting to conjecture that some of these solutions may represent metastable polymorphs; this could be tested using computational modelling techniques such as dispersion-force-corrected density-functional-theory geometry optimization.

Earlier in this section, it was noted that the global minimum was closely surrounded by regions of very high $\chi^2_{\rm CI}$. With all other parameters at their correct values, displacement of only the *x* coordinate by any value between 0.15 and 0.35 resulted in a $\chi^2_{\rm CI}$ value that was amongst the highest observed in the 10^6 random structure evaluations.

The *x*-coordinate shifted structure for $\Delta x = 1/4$ is shown in Fig. 4.3.10 and it is immediately clear why the agreement between the observed and calculated diffraction data is poor, as pairs of famotidine molecules are completely overlapped, leaving half the unit cell entirely devoid of any atoms and consequently totally absent of any scattering density.

Changing any of the translational or rotational external degrees of freedom has a significant impact on the $\chi^2_{\rm CI}$ goodness of fit because all the atoms are moved away from their correct positions. This impact may be quantified by investigating the changes in $\chi^2_{\rm CI}$ associated with different structural parameters during a real-space structure determination. Unsurprisingly, the effect of changing the other structural parameters (torsion angles, bond angles and bond lengths) is generally smaller, as fewer atom positions are altered in the process. This is illustrated in Fig. 4.3.11, which shows the r.m.s. fluctuation of $\chi^2_{\rm CI}$ in the initial stages of the structure solution of famotidine using *DASH* (David *et al.*, 2006). In addition to the six external and seven torsional degrees of freedom, four bond angles and six bond lengths are also allowed to vary. The logarithmic scale in Fig. 4.3.11 highlights

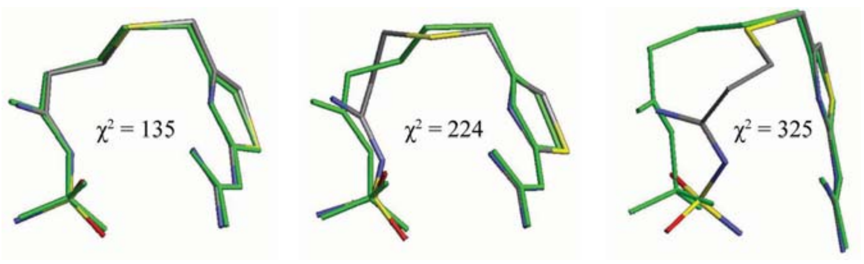

Figure 4.3.9

Three good solutions for the crystal structure determination of famotidine form B. All three solutions are correctly located with respect to both the translational and orientational degrees of freedom. The structure with $\chi^2_{\rm CI} = 135$ represents the correct solution. All the heavier atoms are essentially correctly located in the other two structures.

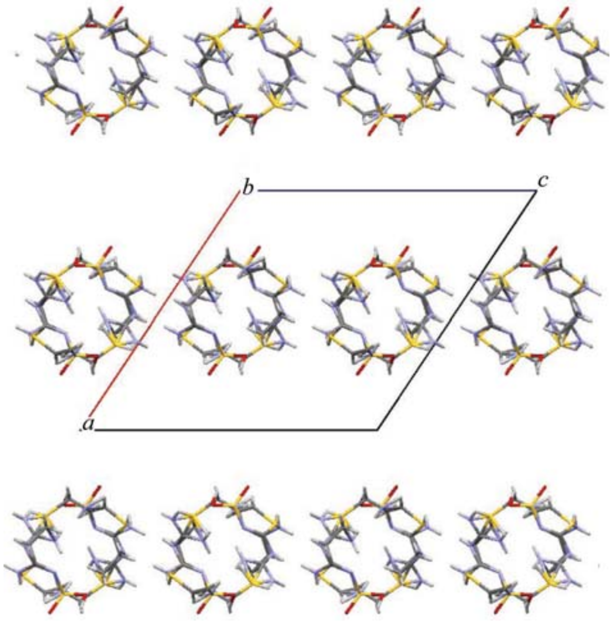

Figure 4.3.10
The crystal structure of famotidine form B associated with a $\Delta x = 1/4$ shift from the correct solution.

the substantial differences in the impact of the various structural parameters. The $\chi^2_{\rm CI}$ variations associated with bond-length variations are always small. This can be understood by recollecting the essential equivalence between $\chi^2_{\rm CI}$ and the volume integral of the square of the difference between observed and calculated interatomic vector maps; see Section 4.3.4.1. A single bond-length alteration only changes the interatomic vectors associated with two atoms, which is only a small fraction (approximately $1/N_A$) of the Patterson function. Moreover, the $\sim$2 Å blur associated with the real-space interpretation of $\chi^2_{\rm CI}$ [equation (4.3.6)] implies that small distance changes in interatomic vectors will have little impact on $\chi^2_{\rm CI}$ values. Indeed, fluctuations in $\chi^2_{\rm CI}$ from bond-length variations are never observed to be greater than 10 in Fig. 4.3.11 and therefore there is no advantage in including bond lengths as structural parameters in a structure solution, as they simply slow down the structure-solution process by introducing unnecessary additional $\chi^2_{\rm CI}$ evaluations.

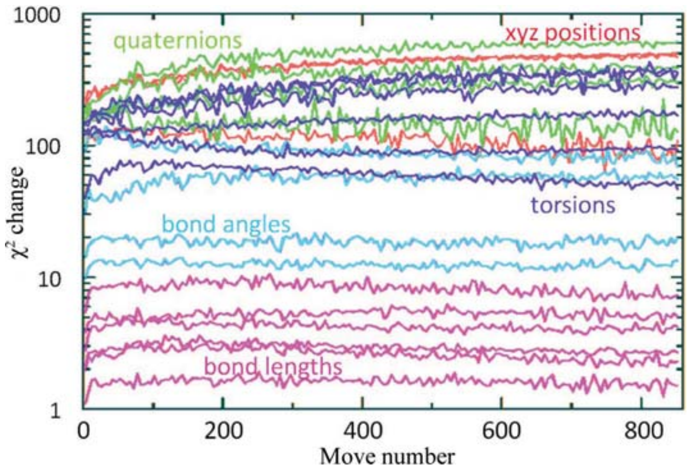

Figure 4.3.11
The move-by-move change in $\chi^2_{\rm CI}$ observed during a real-space structure-solution run for famotidine form B. Changes in orientation (quaternions) and location of the molecule have the largest effect on $\chi^2_{\rm CI}$. The effects of torsion angles, bond angles and bond lengths are progressively smaller.

It can be seen from Fig. 4.3.11 that bond angles produce greater $\chi^2_{\rm CI}$ changes than bond lengths, with values ranging from about 10 to about 100. Variations in key angles, such as the central C—S—C angle, will result in major alterations in the interatomic distances between opposite ends of the molecule and should be allowed to vary over the range of expected values if there is any significant bond-angle uncertainty. Most angles, however, are either adequately known or do not significantly alter the interatomic distances within a molecule and therefore need not be varied.

The remaining structural parameters, *i.e.* the translational and orientational external coordinates and internal torsion angles, can all have a major impact on the $\chi^2_{\rm CI}$ goodness of fit. Translational degrees of freedom change all the intermolecular interatomic vectors, while the orientational degrees of freedom alter both inter- and intramolecular interatomic vectors. It is thus to be expected (and is observed in the case of famotidine) that the orientational degrees of freedom, expressed in terms of quaternions, exhibit a slightly larger effect than the translational degrees of freedom. Key torsion angles, particularly those involving the central sulfur atoms, have an impact that is almost equivalent to the external degrees of freedom. Again, this can be understood in terms of the number of interatomic vectors that are changed. Torsion angles affect a subset of intra- and intermolecular interatomic vectors and, for this reason, generally have less impact than the orientational and translational coordinates. Indeed, the larger the fragment that is rotated on altering a torsion angle, the larger will be the change in $\chi^2_{\rm CI}$.

Parameters that should be included in a real-space global-optimization structure solution are those that have the potential to move a significant proportion of the crystal structure resulting in a change of a substantial fraction of the interatomic vectors by more than about 2 Å. These parameters are the external orientational and translational coordinates and the internal flexible torsion angles. The only significant addition to this set may be a key angle which possesses a range of possible values; it is important for the success of the structure solution that the angular range is limited to the range of possible values. Finally, varying known bond lengths and angles in a structure solution should be avoided, as including this only slows down the structure-solution process.

4.3.5. Global-optimization algorithms

The important issues for global optimization for real-space SDPD may be summarized as follows:

(1) Real-space structure determination may be regarded as a global Rietveld analysis where an initial, generally poorly fitting, structural model is proposed. With multiple iterations, the fit between observed and calculated diffraction data improves until excellent agreement is obtained and the resulting structure may be finally refined to obtain the correct crystal structure.

(2) For molecular crystal structures, the molecular connectivity (using the *Z*-matrix or equivalent formalism) provides an optimal method for defining the structural parameters that should be used in the global-optimization process.

(3) There are numerous local minima (greater than about 2^{N_P}) on the N_P-dimensional goodness-of-fit hypersurface. Any global-optimization program must be able not only to explore these minima but also escape false minima, some of which

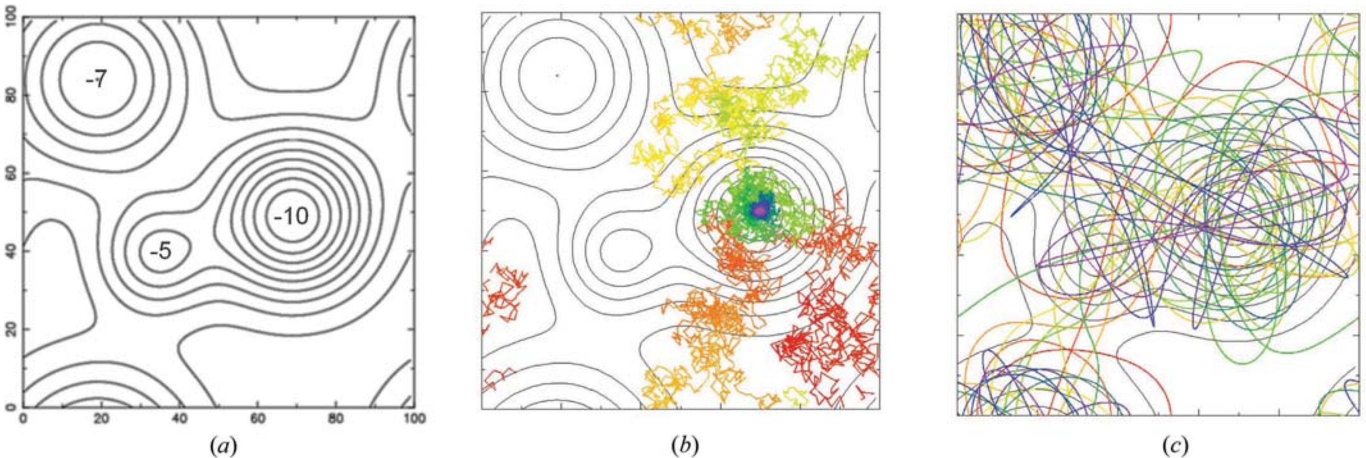

Figure 4.3.12
(*a*) A simple periodic potential-energy function constructed over a square cell. The maximum value of the potential energy is 0, with uniform contour levels shown. The function has three minima with values of −10, −7 and −5 at positions (70, 50), (20, 83) and (35, 40), respectively. (*b*) A simulated-annealing (SA) solution for the test function shown in (*a*). The SA run consists of 1000 moves and locates the global minimum. The figure highlights the random-walk nature of the SA algorithm. (*c*) A molecular-dynamics (MD) solution for the test function shown in (*a*). The MD run consists of 1000 steps and, significantly, all three minima are visited many times. The smooth trajectory is a consequence of the deterministic nature of MD equations of motion.

may appear to be excellent solutions and yet do not correspond to the correct crystal structure.

An effective global-optimization program for the real-space determination of molecular crystal structures must have properties that address all three of these issues. A wide range of programs and algorithms have been developed and these are discussed here.

Global-optimization programs can be broadly characterized as either stochastic (involving a substantial component of randomness in structural-parameter selection) or deterministic (involving a directed path from iteration to iteration for the structural parameters). The generic aspects of these conceptually very distinct algorithms are illustrated in Fig. 4.3.12, which shows the different search characteristics over a simple periodic function constructed over a square cell. (This could correspond to probing the full-range goodness-of-fit surface with two degrees of freedom.) In terms of understanding global-optimization algorithms, it is easier to consider the figure as representing a conceptually equivalent gravitational-potential-energy surface with the contours indicating depth rather than the goodness of fit.

Fig. 4.3.12(*b*) shows the trajectory followed by a simulated-annealing algorithm. This trajectory, which begins with red and follows the colours of the rainbow through to indigo, reaches the basin of the deepest minimum very quickly after around 100 moves. Direct downhill minimization at this point would lead to the correct solution. However, the algorithm can also enable the trajectory to leave the global minimum basin. It is this balance between the requirements of escaping false minima and efficiently reaching the global minimum that makes global optimization a difficult and often computationally expensive process. The trajectory in Fig. 4.3.12(*b*) essentially performs a random walk over a large area of high potential-energy values before finally settling into the global minimum. This search over high values is necessary if other deep minima are to be found. Of concern, however, is that this particular trajectory only samples a single minimum and this highlights the necessity of multiple attempts to reach the global minimum. Other stochastic processes such as genetic algorithms show a different behaviour from iteration to iteration. However, the time-averaged population of the energy landscape is similar, with a random distribution of attempts that are biased towards the best solutions and, as a consequence, the general issues discussed in this section also apply to these and other stochastic global-optimization algorithms.

The trajectory in Fig. 4.3.12(*c*), which is determined by a hybrid Monte Carlo (HMC) molecular-dynamics algorithm, shows an altogether different behaviour. Here, it is best to consider the trajectory in terms of the movement of a particle over the potential-energy surface. A position is selected at random and the particle is given an initial velocity vector and associated kinetic energy that is sufficient for it to move over the highest point on the surface. The particle trajectory is required to obey Hamilton's equations of motion for the combined kinetic and potential energies. The resulting trajectory must preferentially sample areas of lower potential energy, but also has sufficient total energy to escape these minima and explore the complete range of the potential-energy surface. Fig. 4.3.12(*c*) shows that the trajectory sampling is highly optimal, with the maximum amount of time spent within all the minima and with significant areas of high potential energy completely unexplored. The first observation means that there is a high probability that a significant fraction of deep minima will be visited in an HMC optimization, while the latter suggests that the particle dynamics introduce aspects of the search where high-potential-energy locations are not only not revisited but are never visited. These aspects of the deterministic trajectory and the stochastic trajectory are illustrated in Figs. 4.3.12(*c*) and (*b*), respectively, and are comparable with the difference between a downhill skier who can ski down into valleys and, without friction, ski straight back out again with a view to heading down the next valley, and a random walk that has the tendency to head in the right direction but can also waste time exploring unprofitable features. Unsurprisingly, the few studies of deterministic algorithms (Johnson *et al.*, 2002) all report a significantly improved performance. However, the implementation of stochastic algorithms such as simulated annealing and genetic algorithms is simpler, and they have been found to be effective in a wide range of structure solutions.

In the remainder of this section, the basic properties of the various search algorithms for real-space structure determination are presented along with a comprehensive list of references and examples of successful structure solutions.

4.3.5.1. *Stochastic search algorithms*

4.3.5.1.1. *Introduction*

The most widely used real-space global-optimization methods for the structure determination of organic compounds are stochastic in nature and can be colloquially described as a 'random walk through the good solutions'. Many different stochastic methods have been explored that include: simple Monte Carlo (Harris *et al.*, 1994), genetic algorithms (Shankland *et al.*, 1997*a*,*b*; Kariuki *et al.*, 1997; Harris *et al.*, 2004; Feng & Dong, 2007), evolutionary strategies (Chong & Tremayne, 2006) and particle swarm (Csoka & David, 1999), but it is simulated annealing (Andreev *et al.*, 1997; David *et al.*, 1998, Engel *et al.*, 1999; Putz *et al.*, 1999; Pagola & Stephens, 2010; Coelho, 2000; Favre-Nicolin & Černý, 2004*b*; David *et al.*, 2006) that is most widely used and that has had the largest impact. Its high level of success may be attributed to the fact that it is an effective, easy-to-use algorithm with relatively few control variables that can all be set automatically. Various modifications to the basic annealing scheme, such as parallel tempering (Earl & Deem, 2005), have been implemented (Favre-Nicolin & Černý, 2004*b*). Of the other stochastic algorithms, genetic algorithms in particular have been shown to be capable of delivering solutions of considerable complexity (Albesa-Jove *et al.*, 2004; Feng & Dong, 2007).

4.3.5.1.2. *Monte Carlo methods*

The Monte Carlo method (Metropolis, 1987) is an algorithm that involves repeated random sampling to simulate systems with many degrees of freedom – systems that are difficult to solve analytically. The first significant success (Harris *et al.*, 1994) in real-space SDPD implemented a random-walk Monte Carlo approach regulated by an acceptance criterion, originally proposed by Metropolis *et al.* (1953), that provides a statistical balance between downhill moves (χ^2 improvement) and uphill moves that can escape local minima. Specifically, the Metropolis criterion states that all downhill moves should be accepted, while uphill moves are accepted with a Boltzmann probability given by $\exp[-(\chi^2_{(k+1)} - \chi^2_{(k)})/T]$, where $\chi^2_{(k+1)}$ and $\chi^2_{(k)}$ are the goodness-of-fit values for iterations $(k+1)$ and (k), respectively, and the pseudo-temperature (denoted subsequently simply as temperature), T, is on a χ^2 scale. Harris *et al.* chose the temperature, T, so that around 40% of the uphill moves were accepted. The method was tested on the known crystal structure of p-$CH_3C_6H_8O_2NHNH_2$ and successfully used to solve the unknown crystal structure of p-$BrC_6H_4CH_2CO_2H$.

4.3.5.1.3. *Simulated-annealing methods*

Simulated annealing extends the Monte Carlo method by recognizing that in the early stages of global optimization it is important to accept worse solutions so that an extensive search may be made over parameter space, and that towards the end of the solution process there is little necessity for uphill moves as the targeted (hopefully global) minimum is approached. This change in the acceptance of uphill moves is effected by a slow lowering of the temperature, T, as the global-optimization process progresses. The method is called simulated annealing because the similarity with the physical process of annealing is a strong one with a number of important correspondences. The rate of cooling in a simulated-annealing optimization must, as with physical annealing, be considered with care to avoid quenching to a sub-optimal state. For annealing, this would be a kinetically stabilized state that is not thermodynamically stable; for simulated annealing, the corresponding state is a deep local (but not the global) minimum. Both the physical and computational processes generally have a phase transition that is marked by significant energy or χ^2 fluctuations and this stage in the annealing process must be treated with the greatest care. The earliest structure solutions using simulated annealing indicated the extended scope of the technique with the successful solutions of the crystal structure of the polymer electrolyte $LiN(SO_2CF_3)_2$ (Andreev *et al.*, 1996) and the molecular crystal structures of capsaicin, promazine hydrochloride and thiothixene (David *et al.*, 1998). The latter paper introduced a fast, automated simulated-annealing computer program that was the progenitor to *DASH* (David *et al.*, 2006). A significant number of simulated-annealing programs are available for use including *DASH* (David *et al.*, 2006), *FOX* (Favre-Nicolin & Černý, 2004*a*,*b*), *PowderSolve* (Engel *et al.*, 1999), *TOPAS* (Coelho, 2000), *WinPSSP* (Pagola *et al.*, 2017) and *Endeavour* (Putz *et al.*, 1999). The range of complexity of molecular structures that can be solved from powder-diffraction data alone using real-space SDPD techniques has been estimated to extend to around half of the molecular structures in the Cambridge Structural Database. A representative sample of solved structures has been reported by Florence *et al.* (2005), who determined 35 new structures. Three of the more complex structures are illustrated in Fig. 4.3.13. Perhaps the most impressive example to be solved to date using real-space SDPD is the simulated-annealing structure of the malaria pigment beta-haematin by Pagola *et al.* (2000); see Fig. 4.3.14.

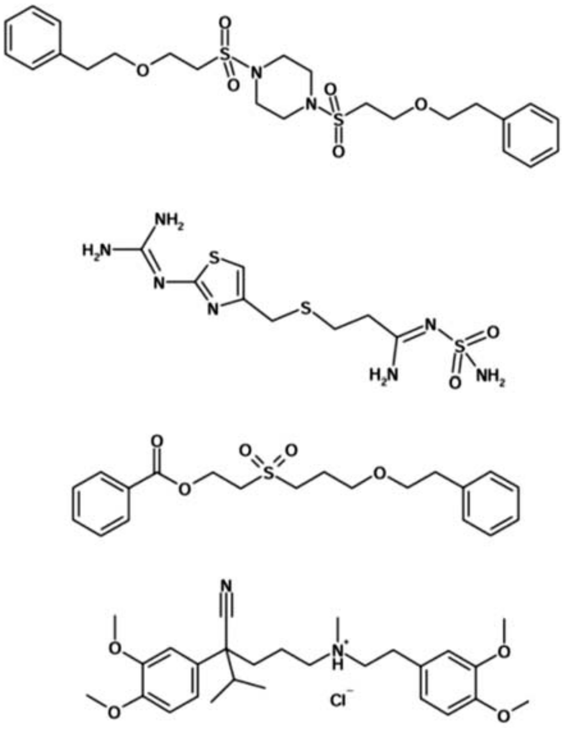

Figure 4.3.13
Molecular structures of 1,4-bis(2-phenethyloxyethanesulfonyl)piperazine, famotidine, 2-{[3-(2-phenylethoxy)propyl]sulfonyl}ethyl benzoate and verapamil hydrochloride.

The first step in a simulated-annealing procedure is the generation of an initial structure using a random set of parameters for both the external translational and orientational degrees of freedom and the internal torsion angles. One of the structural parameters, $p(i)$, is adjusted to a new value, $p'(i) = p(i) + \Delta p(i)$, and the diffraction pattern is recalculated. $\Delta p(i) = \mathrm{RAND}(-0.5{:}0.5)\Delta p_{\max}(i)$, where $\mathrm{RAND}(\ldots)$ is a random number between -0.5 and 0.5 and $\Delta p_{\max}(i)$ is the

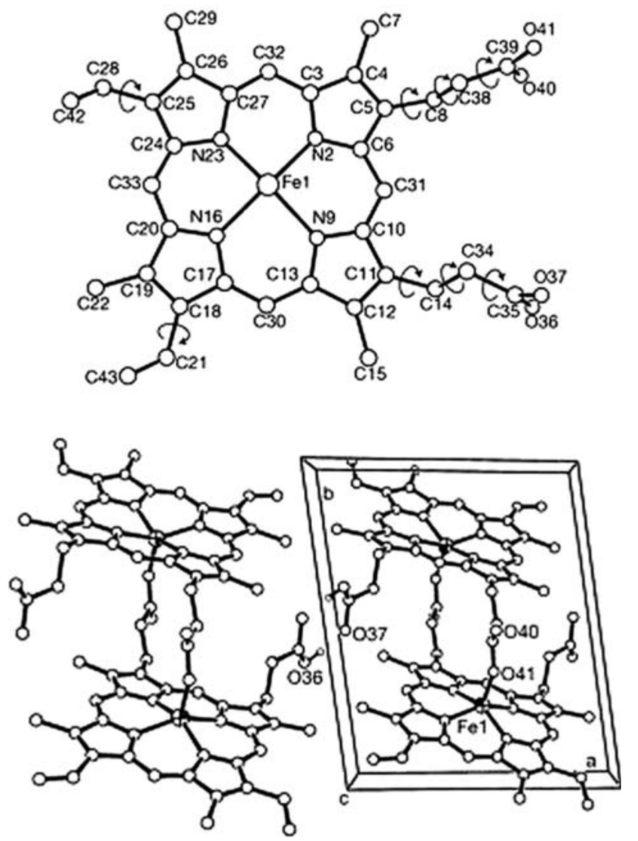

Figure 4.3.14

The molecular structure and crystal structure of the malaria pigment B-haematin. Reprinted by permission from Springer Nature (Pagola *et al.*, 2000).

magnitude of the maximum shift. This should initially represent the full extent of the range of the associated structural parameter. If the move represents an improvement, then the new structure is accepted. If the fit is poorer, then the new parameterization is not automatically rejected but is accepted with a Boltzmann probability of $\exp[-(\chi_1^2 - \chi_0^2)/T_0]$, where T_0 is the χ^2 'temperature', which is chosen so that a reasonable number of uphill moves are accepted. Consider the distribution of χ^2 values for famotidine illustrated in Fig. 4.3.5. In this case, it is highly probable that both χ_0^2 and χ_1^2 will be between ∼920 and ∼970. To ensure that there is an even probability of accepting an uphill move $\exp[-(\chi_1^2 - \chi_0^2)/T_0] \simeq \exp(-100/T_0) \simeq 0.5$, and so a good value for the initial temperature, T_0, would be ∼70. In other words, the initial temperature should approximate the χ^2 values of the initially randomly chosen structures. This effective temperature is maintained for $\sim 100N_p$ moves (where N_p is the number of parameters) with each parameter adjusted sequentially. The temperature is then lowered, which results in slightly fewer accepted uphill moves, and the procedure is repeated. A simple annealing schedule involves lowering the temperature by ∼2–5% each time.

In each simulated-annealing run, there is a transition from the sampling of only poor (high-χ^2) solutions to the sampling of both poor and good (low-χ^2) solutions. In the case of famotidine, the χ^2 values range from 990 to ∼750, corresponding to the onset of local minima; see Fig. 4.3.8(*a*). With a temperature of ∼70, the chance of a direct escape from the minimum is ∼1:30. Fortunately, there are intermediate plateaux and higher minima in the χ^2 hypersurface that permit escape from deep local minima. However, the observation of large χ^2 fluctuations is a signal to anneal more slowly. In general, a slow reduction in temperature through the high χ^2 fluctuation region of a simulated-annealing calculation generally leads to a much higher probability of reaching the global minimum and the resulting correct crystal structure.

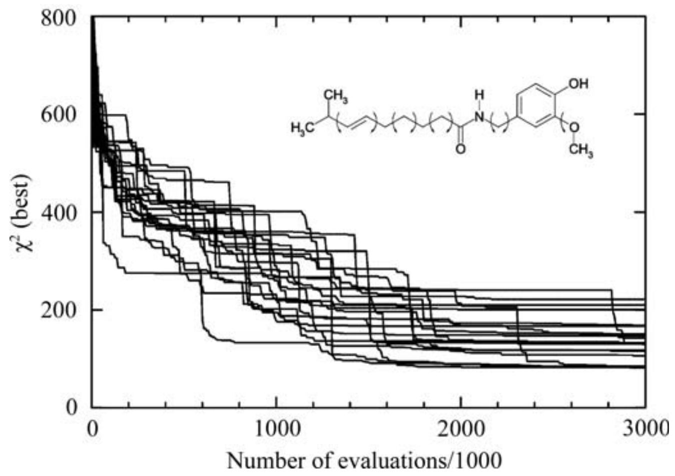

Figure 4.3.15

A plot of the best χ^2 values *versus* the number of χ^2 evaluations for the 20 simulated-annealing structure-solution attempts for capsaicin (after Shankland *et al.*, 2002). For comparison, see also Fig. 4.3.18.

A final consideration in the annealing protocol is the extent of the range, $\Delta p_{\max}(i)$, explored by each parameter shift. Initially, this range should explore the full parameter space. However, as the simulated-annealing process proceeds and good solutions are explored, this is inefficient. The best protocol is to ensure that the success rate for uphill moves remains around 0.5 as the temperature reduces. This reduction in parameter range is parameter dependent. For external translational and orientational parameters and significant torsion angles the reduction can be significant, while for torsion angles that do not change χ^2 significantly $\Delta p_{\max}(i)$ may not reduce at all. Additionally, when good solutions are obtained, there should be the option of direct downhill minimization. This can substantially speed up the final minimization and can be triggered automatically when χ^2 reaches a threshold; a good choice is when the ratio of Rietveld to Pawley χ^2 values is less than 5–10.

Despite these protocols, the stochastic nature of the simulated-annealing process means that structure solution is not guaranteed. Multiple runs are required. As shown in Fig. 4.3.15, if the observed success rate is low then the number of structure-solution attempts should be sufficiently high that at least 5–10 similarly low-χ^2 solutions are obtained, all corresponding to an excellent fit to the data. For a more general crystallographic discussion, see, for example, Brünger (1991).

4.3.5.1.4. *Parallel tempering*

While the underlying paradigm of simulated annealing is straightforward and readily understood, concerns about the choice of initial temperature and annealing schedule have led to the development and use of a closely related algorithm: parallel tempering. Here, as the name suggests, multiple constant-temperature runs are performed in parallel. Commonly, there are 5–10 temperatures, $T_1 < T_2 < \ldots < T_N$, where T_N is similar to the initial simulated-annealing temperature, T_0, and T_1 is a low temperature similar to the final expected χ^2 value. Few uphill moves are allowed for T_1 even when low-χ^2 values are obtained, while for T_N there is a relatively high probability of uphill moves even at the beginning of the structure-solution process. Thus the

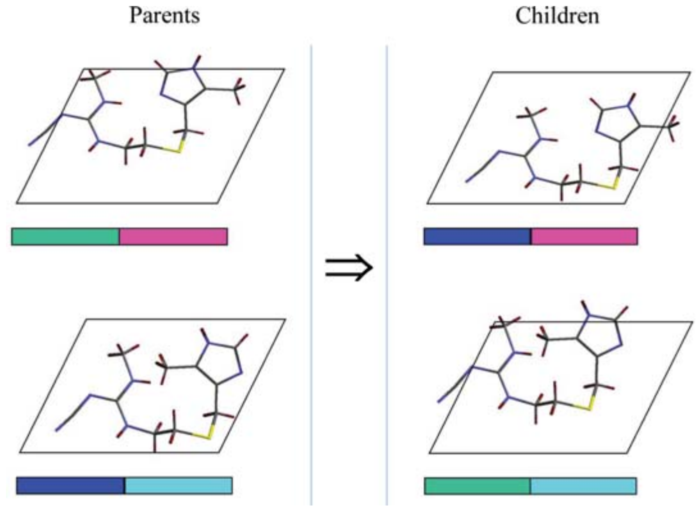

Figure 4.3.16
A single-point molecular crossover for cimetidine. In this simple example, each molecule is coded by only two genes, the leftmost one denoting the location of the central sulfur atom within the unit cell, the rightmost one denoting the torsion angle of the bond connecting the five-membered ring to the main chain. Note that after the crossover operation both children have inherited a position from one parent and a torsion angle from the other.

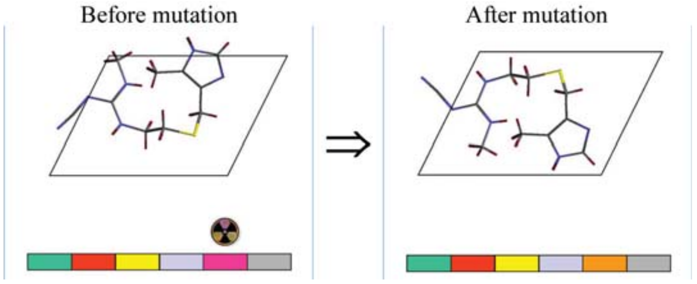

Figure 4.3.17
Mutation of a single gene influencing the orientation of a cimetidine molecule within the unit cell. A chance event (denoted by the mutation symbol) results in the value of a single gene changing to some new, random value. The result of this mutation is to turn the molecule upside down within the unit cell. In this way, new regions of space can be explored.

N temperatures together span the full range of criteria for accepting and rejecting moves.

The N parallel-tempering runs follow the same procedure as outlined in the previous section for a single temperature segment of a simulated-annealing run. Moves are always accepted if they lead to an improvement in the goodness of fit and are accepted with a probability $\exp\{-[\chi^2(k+1) - \chi^2(k)]/T_n\}$ for move $(k+1)$ at temperature T_n when the fit decreases. The temperatures T_n are chosen to follow a relationship of the form $T_{n+1} = \alpha T_n$ where $\alpha^N = T_N/T_1$.

The most significant aspect of parallel tempering is that moves may be swapped between different, normally adjacent, temperatures. After a set number of moves, which may be random, an exchange between the moves associated with T_n and T_{n+1} is performed with a probability given by $\min[1, \exp\{[\chi^2_n(k) - \chi^2_{n+1}(k)](T_n^{-1} - T_{n+1}^{-1})\}]$. This circumvents the need for an annealing protocol and is thus insensitive to the existence of high χ^2 fluctuations near the equivalent transition to the liquid–solid transition in a real annealing experiment. Parallel tempering was introduced in a crystallographic context by Falcioni & Deem (1999) and Earl & Deem (2005), and has been extensively and successfully utilized in the *FOX* program (Favre-Nicolin & Černý, 2004*b*).

4.3.5.1.5. *Genetic algorithms*

Genetic algorithms are the most familiar of a class of methods that imitate the process of natural evolution in order to find the global optimum of a given function (Goldberg, 1989). The algorithm relies on the collective learning over many generations of an initial population or set of populations of individuals. Each individual has a particular set of attributes, which in the optimization process correspond to various values of the structural parameters to be determined. The individuals, therefore, represent points in the space of potential solutions of the function under evaluation. The function values at the respective points represent the fitness of each individual within the population. With an initial random choice of individuals, adaptation then proceeds by means of selection, crossover and mutation. The selection process allows those individuals with a better fitness (lower χ^2 goodness of fit) to have more of an opportunity to reproduce compared with those individuals with a worse fitness (higher χ^2). The subsequent reproduction results from information exchange between individuals (crossover) combined with mutation of the resulting offspring. These offspring then replace the initial population and the process repeats until a high level of fitness is found for an individual in the population. Reaching the global minimum in the optimization process equates to finding the optimal individual (with parameters that describe the correct structure) for a particular ecological niche (fitting the calculated diffraction pattern to the observed powder-diffraction data).

The genetic-algorithm approach for SDPD may be explicitly described as follows: the molecular crystal structure is determined in terms of the N_τ internal torsional $\left(\tau_1, \tau_2, \ldots, \tau_{N_\tau}\right)$ and external translational (x, y, z) and orientational (q_1, q_2, q_3, q_4) quaternion coordinates. In genetic-algorithm terminology, this sequence $\left(x, y, z, q_1, q_2, q_3, q_4, \tau_1, \tau_2, \ldots, \tau_{N_\tau}\right)$ is a chromosome with genetic information that describes the molecular crystal structures; the individual parameters are the genes. Crossover and mutation processes are illustrated in a simple manner in Figs. 4.3.16 and 4.3.17 for the example of cimetidine.

In the first implementation of genetic algorithms for SDPD (Shankland *et al.*, 1997*a*,*b*; Csoka & David, 1999), crossover rates were typically in the range 80–90% (*i.e.* 80–90% of the parent population were selected for participation in crossovers) with an overall mutation rate of typically 5% (*i.e.* 5% of genes in the children were mutated). These children become the new generation and, after their fitnesses have been evaluated, the processes of selection, crossover and mutation are repeated. For complex structural-solution problems, populations can evolve over many thousands of generations before finally converging to the global minimum χ^2 value. As with simulated annealing and parallel tempering, good but false solutions may be obtained and therefore multiple attempts should be performed to ensure that the best structure has been obtained and that the correct structure may then be obtained after Rietveld analysis.

Unsurprisingly, given the complexities of evolution, there are many different opportunities for the optimization of genetic algorithms for real-space structure solution. Of particular note are the programs *EAGER* [Harris *et al.*, 1998, 2004; this program is based upon initial work (Kariuki *et al.*, 1997) that is contemporaneous with the work of Shankland *et al.* (1997*a*,*b*) and Csoka & David (1999)] and *GEST* (Feng & Dong, 2007). The latter paper gives a detailed description of algorithms and effective protocols for real-space SDPD using genetic algorithms. There are also a number of reviews of the subject (*e.g.* Harris, 2012).

4.3.5.1.6. *Differential evolution*

Differential evolution (Chong & Tremayne, 2006) can be regarded as a variant of genetic algorithms which self-regulates the region of the χ^2 hypersurface searched during each generation according to the extent of convergence of the population. In contrast to genetic algorithms in which the parameter values (chromosomes) of selected individuals are combined to create child structures, differential evolution uses the differences between individual chromosomes to create a child. Consequently, as the population converges and the genetic differences between individuals decrease, the region of the χ^2 hypersurface in which children are created also decreases. The evolution of a population of individuals is performed using a small number of operations, which makes differential evolution more straightforward to optimize and control than genetic algorithms. With differential evolution, child parameterizations are created from the parent using two main operations: mutation and recombination (which are analogous to the crossover operation in genetic algorithms). The two operations are controlled by separate control parameters designated K and F for recombination and mutation, respectively. These are independently assigned a value between 0 and 1 and thus differential evolution can be adapted to suit different types of optimization by using different combinations of K and F.

In common with genetic algorithms, the first step in differential evolution is the generation of a population of crystal structures using the usual random parameters. The population size is determined by the number of parameters and experience. Tremayne *et al.* (2009) have shown that, for a successful structure solution, the number of individuals in a population should be at least ten times the number of parameters. Similarly, it has been shown that setting $K = 1$ results in a rapid convergence, which generally will lead to a local minimum. However, setting $K = 0.99$ has been found to maintain a fast rate of convergence while reducing the probability of being trapped in a local minimum. The mutation constant, F, is usually set to a value between 0.4 and 0.7. Higher values reduce the probability of being trapped in a local minimum but increase the number of generations required to determine the correct crystal structure.

The search proceeds in a series of generations in which each parent, P, produces one child, C. To maintain genetic diversity, three new random individuals, R_1, R_2 and R_3, are selected to assist each new parent in the creation of a child which includes both recombination, $K(R_1 - P)$, to ensure the transferral of good parameter values and mutation, $F(R_2 - R_3)$, to avoid premature convergence. Specifically,

$$C = P + K(R_1 - P) + F(R_2 - R_3).$$

χ^2 is calculated for the child, C. If $\chi^2(C) < \chi^2(P)$, then the child replaces the parent as an active member of the population; otherwise the parent is retained. The lengths of the recombination and mutation vectors are determined by the distance between P, R_1, R_2 and R_3, As models cluster together, these distances decrease. During the initial generations, there is a high probability that P, R_1, R_2 and R_3 will range over a considerable region of the χ^2 hypersurface. Consequently, at the initial stages of global optimization, a child is likely to be created at a considerable distance from the parent. If the child is fitter than the parent, then the search rapidly moves to a distinctly different part of the χ^2 hypersurface, which means that it will be comprehensively explored in the initial stages of structure solution. Towards the end of the structure solution, when many models are clustered around what is hopefully the global minimum, there is a high probability that P, R_1, R_2 and R_3 will be clustered together near the minimum. The recombination and mutation vectors will be significantly shorter, increasing the probability that a child is created near the parent, thus allowing a controlled convergence towards the (global) minimum. As with all global-optimization strategies, it is essential to repeat many differential evolution runs to check for local minima and confirm that the global minimum has been reached.

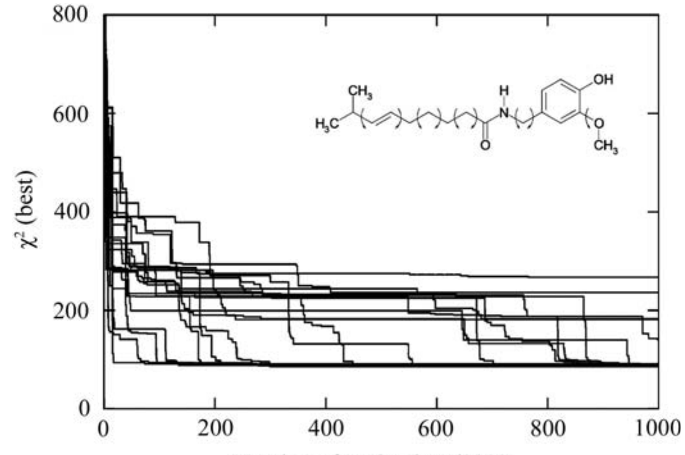

Figure 4.3.18
A plot of the best χ^2 values *versus* the number of χ^2 evaluations for the 20 hybrid Monte Carlo structure-solution attempts for capsaicin (after Shankland *et al.*, 2002). For comparison, see Fig. 4.3.15.

4.3.5.2. *Deterministic search algorithms*

4.3.5.2.1. *Introduction*

While stochastic techniques have been shown to be effective global-optimization methods, many other algorithms remain to be evaluated for SDPD and it is likely some of these will be more efficient and successful than the current techniques. One example is the hybrid Monte Carlo (HMC) algorithm that combines the key components of Monte Carlo (MC) and molecular dynamics (MD) approaches into a single algorithm.

4.3.5.2.2. *The hybrid Monte Carlo algorithm*

An extensive discussion of the HMC algorithm in the context of SDPD may be found in Johnston *et al.* (2002). HMC may be considered in terms of a particle that follows a trajectory determined by Hamilton's equations of motion in a hyperspace defined by a set of structural variables. The total energy of the particle at any point is equal to the sum of the kinetic energy and potential energy given by the goodness-of-fit target function. In theory, the total energy is conserved, but the use of finite time-step sizes in the numerical evaluation of the equations of motion means that this is not the case. To control this, a Metropolis acceptance criterion is used to determine whether to accept or reject the configuration at the end of a given molecular-dynamics trajectory. The trajectory either continues from the end point if it is accepted or returns to the previous start point if it is rejected. The effectiveness of the HMC algorithm has been convincingly demonstrated with the structure determination of capsaicin which, with a total of 15 degrees of freedom, represents a moderate challenge for SDPD. When compared with the default

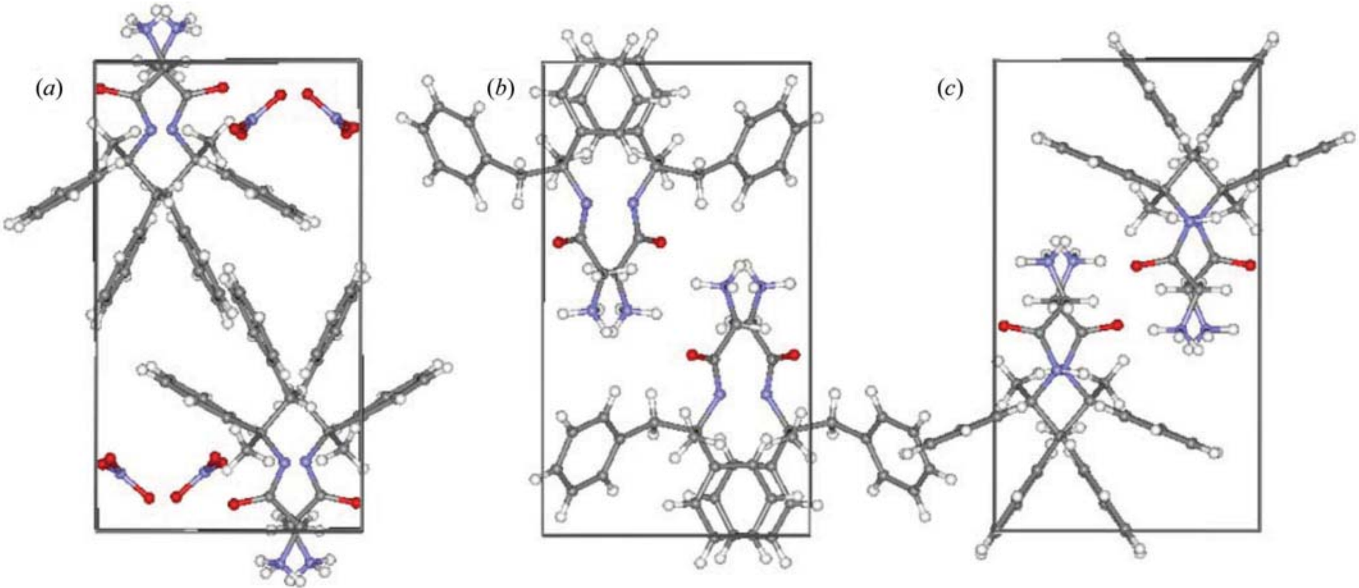

Figure 4.3.19
(*a*) The correct crystal structure of remacemide nitrate. (*b*) The best structure determination using a least-squares analysis to compare observed and calculated diffraction data with only the remacemide ion used in the structural model. Note that although the structural arrangement is completely incorrect, it is clear that the solution has resulted in an optimal correlation of observed and calculated electron density. Note in particular that the phenyl group maps closely onto the scattering density associated with the nitrate ion. (*c*) The best structure determination using a maximum-likelihood analysis to compare observed and calculated diffraction data with only the remacemide ion used in the structural model. The structure illustrated in (*c*) is enantioimetrically related to correct solution shown in (*a*). The agreement between the remacemide molecular position, orientation and conformation in (*a*) and (*c*) is as close as obtained in a standard least-squares analysis with the nitrate ion included.

implementation of simulated annealing in *DASH*, the HMC approach is a factor of 2 more successful in locating the global minimum over a series of 20 repeat runs. From a comparison of Figs. 4.3.15 and 4.3.18, it is evident that the hybrid Monte Carlo algorithm is also significantly more efficient, requiring on average an order of magnitude fewer χ^2 evaluations.

4.3.6. Using maximum-likelihood techniques to tackle incomplete structural models

4.3.6.1. *Introduction*

Solving crystal structures from powder-diffraction data is a significantly more difficult and less straightforward procedure than its single-crystal counterpart because of the loss of information associated with compressing the three-dimensional reciprocal lattice on to the one dimension of a powder-diffraction pattern with the corresponding inevitable overlap of Bragg reflections. The situation can be ameliorated and Bragg-peak intensities more easily extracted by explicitly using texture or methods such as differential thermal expansion (Brunelli *et al.*, 2003). However, discussion of these experimental methods is beyond the scope of this chapter. The incorporation of additional chemical information directly into the structure-solution process using both databases and complementary experimental techniques is discussed in Chapter 4.4. This section discusses the reverse situation, where there is a lack of chemical information, and highlights the effectiveness of maximum-likelihood methods.

4.3.6.2. *Working with incomplete structural models: maximum-likelihood methods*

In the previous section, the use of additional information to facilitate real-space structure solution was discussed. Specifically, constraining molecular conformation, through the active use of torsion-angle distributions derived from the Cambridge Structural Database and the intramolecular distance restraints derived from solid-state NMR measurements, was shown to accelerate structure solution and extend the range of complexity of structures that may be solved using real-space structure-determination techniques (Middleton *et al.*, 2002).

In this section, a complementary strategy is discussed where not all the structure is initially determined. Consider the case of a co-crystal or salt compound where there is more than one type of molecule in the crystal structure. It is possible, through the use of maximum-likelihood techniques, to account for and effectively ignore a significant structural component and yet determine precisely the location of all of the rest of the crystal structure. Take the specific case of the anti-convulsant agent remacemide nitrate ($C_{17}H_{21}N_2O^+ \cdot NO_3^-$). Markvardsen *et al.* (2002) showed that, although the nitrate group accounts for ~18% of the X-ray scattering, a real-space structure solution, based not on a conventional least-squares but on a maximum-likelihood optimization between observed and calculated diffraction data, yielded the correct location, orientation and torsion angles of the remacemide ion without any attempt to locate the nitrate ion; see Fig. 4.3.19.

The maximum-likelihood method is perhaps best explained by specific reference to this crystal structure. The remacemide and nitrate ions will be denoted as the fragment and blur, respectively, for the purposes of the discussion. Given that the objective of the maximum-likelihood approach is to determine only the remacemide fragment, the *a priori* presumption is that the scattering contribution of the blur is randomly distributed throughout the unit cell. In reciprocal-space terms, this means that the calculated structure factors are no longer a set of numbers but are instead represented by a multidimensional Gaussian distribution with a width that is determined by the magnitude of the random scattering associated with the blur. As a consequence, the scattering density of the nitrate ion is actively considered in structure-factor representation, even though its position is explicitly unknown. With a large unknown component, the Gaussian broadening will be large and the maximum-likelihood approach will lead to significantly different results than an equivalent least-squares analysis. As the blur scattering decreases, then the maximum-likelihood analysis becomes equivalent to least-squares analysis.

For further references on the use of maximum likelihood in crystallography, see, for example, McCoy (2004) and references therein. A full mathematical description of the maximum-likelihood formulation of powder-diffraction analysis, and particularly the discussion of overlapped and partially overlapped reflections, is beyond the scope of this article. A full discussion can be found in the paper by Markvardsen *et al.* (2002). Significantly, the analysis presented in the paper applies not only to structure determination but generally to structure refinement and Rietveld analysis.

4.4. The use of supplementary information to solve crystal structures from powder diffraction

A. J. Florence

4.4.1. General remarks

Structure determination by powder diffraction (SDPD) is an increasingly important element of structural investigations of a wide range of novel polycrystalline molecular materials including polymorphs (Chan *et al.*, 1999; Dinnebier *et al.*, 2000*a*; Florence *et al.*, 2008), salts (Stephenson, 2000; Lewis *et al.*, 2005; Antoniadis *et al.*, 2010), solvates (Pan *et al.*, 2005; Fernandes *et al.*, 2007; Chernyshev *et al.*, 2010) and co-crystals (Tremayne & Glidewell, 2000; Trask & Jones, 2005). This has been facilitated by access to high-quality synchrotron data and particularly the wide availability of modern laboratory powder diffractometers. Importantly, there is a wide range of powerful and user-friendly free and commercial software tools available for all stages of data analysis required for a successful SDPD study (Fig. 4.4.1).

Traditional direct-methods approaches used in single-crystal diffraction typically draw on thousands of individually measured reflection intensities in order to identify the positions of individual atoms within the unit cell. However, a high-resolution laboratory powder diffraction pattern may yield only a few hundred reliable reflection intensities as a result of peak overlap. Global-optimization methods accommodate the relative lack of diffraction intensity information by enabling additional non-diffraction data to be easily introduced into the structure-determination process. This supplementary information is typically in the form of chemical structure details, such as molecular geometry (bond lengths, angles) describing the atomic connectivity within the molecular fragments, or conformational constraints that have been derived from knowledge bases, calculation or measurement. This is of particular importance given the relative complexity of many molecular solids, including pharmaceuticals, in terms of the number of degrees of freedom that need to be resolved during the global-optimization process. Such structures may comprise large, flexible molecules and may have multiple fragments and/or $Z' > 1$ and/or disorder.

The fundamentals of global-optimization strategies for structure determination have been described elsewhere (Shankland & David, 2002) and a range of effective search methods has been implemented in various software packages [including *DASH* (David *et al.*, 2006); *EAGER* (Habershon *et al.*, 2003); *Endeavour* (Putz *et al.*, 1999); *ESPOIR* (Le Bail, 2001); *FOX* (Favre-Nicolin & Černý, 2002); *PowderSolve* (Engel *et al.*, 1999); *PSSP* (Stephens & Huq, 2002; Pagola *et al.*, 2017) and *TOPAS* (Coelho, 2000); for an extensive listing see for example Černý & Favre-Nicolin (2007)]. Indeed, armed with high-quality powder diffraction data (with good spatial and angular resolution) and an accurate description of the chemical composition of the sample (the molecular structure of all components and stoichiometry), global-optimization methods can routinely solve structures with significant structural complexity without recourse to additional constraints or restraints that encode other information sources. For example, the monoclinic $Z' = 2$ structure of chlorothiazide *N*,*N*-dimethyl formamide 2:1 solvate with six independent fragments equating to 36 external degrees of freedom was solved using simulated annealing against laboratory powder diffraction data (Fernandes *et al.*, 2007). However, structures containing 13 internal degrees of freedom have also been shown to present a considerable challenge to the global-optimization approach (Florence *et al.*, 2005*b*). Thus, in the context of solving complex structures *via* SDPD approaches, it is of particular interest to explore strategies that utilise additional information sources to supplement the available diffraction data and maximize the chances of success.

This chapter aims to highlight practical strategies where supplementary information can usefully contribute to maximizing the chances of successful structure determination across the workflow shown in Fig. 4.4.1. Whilst SDPD has been successfully applied to the study of a wide range of novel materials in recent years including inorganic (Deem & Newsam, 1989; Reinaudi *et al.*, 2000; Edgar *et al.*, 2002) and organometallic systems (Dinnebier *et al.*, 2000*b*; Ivashevskaja *et al.*, 2002; Mínguez Espallargas *et al.*, 2007) the focus here, driven by the author's experience, is on organic molecular structures containing large numbers of degrees of freedom and light, weakly scattering atoms. It is also worth considering how to confirm the accuracy of the global-optimization minimum and confirm that structures not only return a good graphical or statistical fit to the diffraction data but also are consistent with chemical knowledge (*i.e.* are chemically sensible). The aim is to obtain the best possible solution for input into a subsequent Rietveld refinement (Rietveld, 1969). Applications of potential-energy calculations will also be introduced. The use of high-quality X-ray diffraction data (either synchrotron or monochromatic laboratory capillary transmission data) is a prerequisite throughout a successful SDPD trial.

4.4.2. Molecular models

4.4.2.1. *Molecular volume*

An accurate estimate of the molecular volume of all fragments to be included in a search is of value in SDPD. For indexing, a reliable estimate of the volume occupied by each molecule within the lattice provides an indication of the expected cell volume, informing the indexing process. This information also provides reassurance that the chemical composition and stoichiometry is consistent with a proposed unit cell and symmetry prior to carrying out global-optimization trials, or it can help to identify any discrepancies and avoid wasted effort. Approximate values are typically sufficiently reliable for this purpose, although with many different methods available for calculating molecular volume this can result in quite broad variation in numerical values (Bondi, 1964; Gavezzotti, 1983; Connolly, 1985; Rowland & Taylor, 1996; Preiss *et al.*, 2009; Glasser, 2011). Crystal-structure information for related structures such as polymorphs can be useful, and local crystal-structure databases or systems such as the Cambridge Structural Database (CSD; Groom *et al.*, 2016) are excellent resources in this regard. For additional sources applicable also to inorganic systems see also Kaduk (2007) and references therein.

By way of example, Table 4.4.1 highlights the molecular volumes for two molecular structures obtained using four straightforward techniques. The three estimates are based on: a simple summation of atomic volumes using approximate volumes for similarly sized C, N and O atoms of 18 Å^3 (Kempster & Lipson, 1972) and 2 Å^3 for H atoms; summation of average atomic volumes derived for each element from the CSD (Hofmann, 2002); a volume calculated using the semi-empirical package *MOPAC2012*; and lastly the volume per molecule extracted from the CSD entries for each structure. The estimates for the aliphatic diol tetradecane-1,14-diol are in relatively close agreement (±20 Å^3) with the experimental value. In contrast, the simple atom-volume summation significantly overestimates the volume for the fused-ring structure of carbamazepine by 57 Å^3. The Hofmann method is as simple to apply, but gives more reliable estimates than the previous method in both cases. The semi-empirical optimization-derived values, calculated in under 20 s from an optimization on a standard desktop PC, are also in good agreement with experiment for both molecules. It is also worth highlighting the need to use the information as an approximate guide rather than as a strict selection criterion. For carbamazepine, for example, the experimental value in Table 4.4.1 is from the monoclinic form-III polymorph, whereas the trigonal form-II (CSD refcode: CBMZPN03; Lowes *et al.*, 1987) structure returns a molecular volume of 318 Å^3 as a result of the presence of solvent-accessible voids within the structure (Cruz Cabeza *et al.*, 2007; Fabbiani *et al.*, 2007).

4.4.2.2. *Fragment model selection: bond length and angles*

Prior chemical information is routinely exploited in global-optimization approaches by directly introducing the atomic connectivity of molecular fragments, typically using an internal-coordinate description. This allows covalent bond lengths, bond angles and torsion angles to be defined and parameters for optimization to be flagged (Shankland & David, 2002). This usefully reduces the number of degrees of freedom required to describe the position of *n* independent atoms in an asymmetric unit to a single set of fractional coordinates and three Euler angles. It is of course essential to use accurate geometric parameters in the internal-coordinate description to avoid introducing errors at this stage – errors that will prevent the global optimization locating a model that accurately describes the observed diffraction data. Standard bond lengths and angles for many chemical groups are widely available from carefully measured experimental values from related crystal structures [see the tabulated values in Allen (2002) and Chapter 9.5 of Volume C (Allen *et al.*, 2006)] and from computational methods (see for example Fogarasi *et al.*, 1992; Stephenson & Liang, 2006; Stewart, 2013). Existing crystal structures of related structural fragments are therefore a convenient and commonly used source of information for directly generating a *Z*-matrix internal-coordinate description. Computational methods have also been used to generate the input molecular geometry. Form-I β-resorcylic acid was solved by simulated annealing using an

HF/6-31G(d,p) gas-phase global conformational minimum in which O—H and C—H distances were normalized to 0.9 and 0.95 Å, respectively, for the optimization against the X-ray diffraction data (Braun *et al.*, 2011). As bond lengths and angles are largely unaffected by crystal-packing forces, they are fixed at their known values during the search. Care should be exercised when building models based on crystal structures of related structural fragments that have significant differences in ionization or in the size of substituents because of the potential impact on covalent bond lengths and angles, respectively.

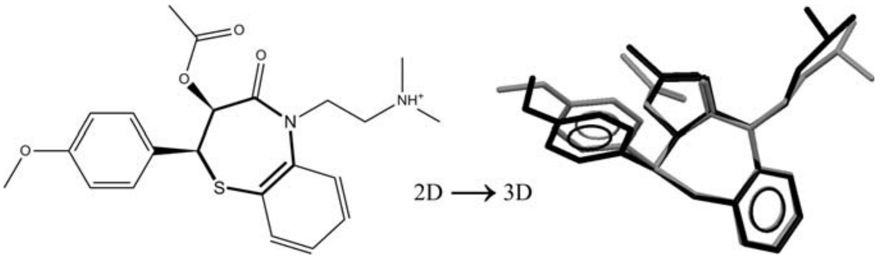

Figure 4.4.2
Automatic generation of reliable flexible-ring conformations in *Corina*. Left: 2D sketch of the diltiazem cation highlighting the 7-membered flexible ring. Right: overlay of the low-energy ring conformation produced from the sketch by *Corina* (grey) with the published single-crystal structure (black) (Kojić-Prodić *et al.*, 1984).

A number of software tools are also available that will automatically generate reliable three-dimensional (3D) coordinates from 2D sketches (see for example Sadowski *et al.*, 1994; Ebejer *et al.*, 2012). *Mercury* (Macrae *et al.*, 2008) also provides a set of convenient tools for editing molecular models, including editing groups or adding missing H atoms, to provide a reliable representation of the fragment. Regardless of the source of structural information used to build the molecular fragment model, it is important to check the accuracy of all input models to ensure that they are chemically sensible. In this regard, the *Mogul* (Bruno *et al.*, 2004) package contains a knowledge base of CSD-derived molecular geometries and provides a convenient and fast means of automatically checking the geometry of input molecular fragments.

4.4.2.3. *Flexible ring conformations*

Many small organic molecules contain flexible ring systems that have the potential to adopt alternative ring conformations, with the number of possible conformers increasing with the size of the ring (Cremer & Pople, 1975; Allen *et al.*, 1991, 1993; Brameld *et al.*, 2008). Closed rings are typically held fixed during the global-optimization search at a commonly observed (low-energy) conformation whilst the torsion-angle values in extended chains are allowed to vary. It is therefore useful to understand the conformational space that a given ring system can adopt during the assessment of the fragment geometry. This can be used to decide whether alternative conformers need to be considered in the global-optimization strategy.

Whilst the most commonly observed (or lowest-energy) conformer from database searches or conformational analysis will often be the correct conformation for a particular structure, flexible ring systems may of course also adopt higher-energy or less frequently observed conformations. For example, the tetrahydropyran ring in the crystal structure of 2,6-anhydro-*N*-methyl-D-glycero-D-ido-heptonamide (CSD refcode: LAFFAZ) adopts a twist-boat conformation in only this structure out of 21 related fragments in the CSD (Cottrell *et al.*, 2012). In this case, the initial selection of the most commonly observed or lowest-energy ring conformation would not result in a successful search. However, with access to suitable alternative models, such occurrences should not limit the ability to solve the structure. Also, high-speed parallelization of global-optimization methods allows different models to be tested with great efficiency (Griffin *et al.*, 2009).

In addition to using experimental data, there is a wide range of software packages that can be used to quickly assess ring conformations. *Corina* (Sadowski & Gasteiger, 1993; Sadowski *et al.*, 1994), for example, uses a set of structural rules and data tables with a simplified pseudo-force field to automatically generate multiple chemically reasonable low-energy ring conformations. Molecular structures can be drawn directly and converted from a 2D sketch *via* a graphical interface or entered *via* a standard 3D structure file format, including MOLFILE and PDB files. Conformations of the *S*,*S* diastereoisomer of diltazem were produced in *Corina* and compared with the conformation of the flexible 7-membered ring in the published crystal structure of diltiazem hydrochloride (CSD refcode: CEYHUJ01). Using a 10 kJ mol^{-1} cut-off value, two ring conformations were returned with the lowest-energy structure yielding an excellent match to the single-crystal structure with an r.m.s. deviation between all ring atoms of 0.055 Å (Fig. 4.4.2).

A different approach to individually testing distinct ring conformations is to search the conformational space of the flexible ring during the global optimization. This could be achieved by using slack constraints on ring bond lengths, enabling the search to access alternative arrangements (Černý & Favre-Nicolin, 2007). Also, for example, by removing the connecting bond altogether between the atoms C10 and C11 and opening the 7-membered dibenzazepine ring in carbamazepine, the two adjacent benzene substituents were allowed to rotate freely during the search (Fig. 4.4.3). Whilst this introduced two additional degrees of freedom, a completely unconstrained search of the ring's conformation space is performed. The final position and conformation of the ring is determined by fitting to the diffraction data. The trigonal $Z' = 1$ structure of carbamazepine

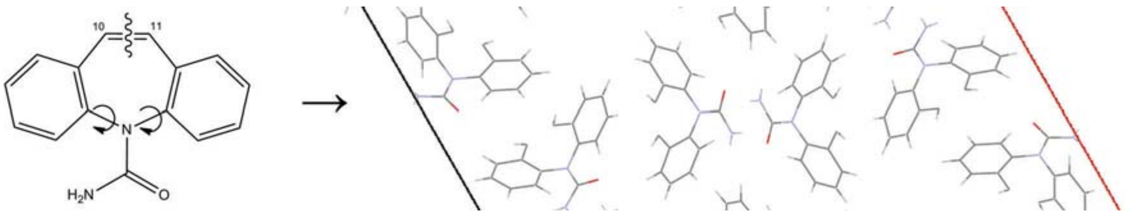

Figure 4.4.3
Determining ring conformation during global optimization using ring opening. The connectivity between C10 and C11 (highlighted) in the carbamazepine fragment model was removed and two additional torsion-angle variables around the N—C bonds were introduced (circular arrows).

form II can be solved in this way from laboratory powder diffraction data using simulated annealing. The structure was described using 9 degrees of freedom (3 position, 3 orientation and 3 torsion-angle parameters) and 100% of 50 simulated-annealing runs reached the target with 1×10^6 moves per run. The best solution returned an excellent final $\chi^2_{\rm profile}/\chi^2_{\rm Pawley}$ value of 2.1 (Florence *et al.*, 2005*b*) and the SDPD structure returned an r.m.s. deviation for all non-H atoms of 0.1 Å compared with the single-crystal structure.

4.4.2.4. *Torsion-angle constraints*

SDPD using global optimization has been shown to be highly effective in solving the crystal structures of highly flexible molecular systems with several variable torsion angles [*e.g.* atomoxetine hydrochloride: 6 torsions (Stephenson & Liang, 2006); telmistartan: 7 torsions (Dinnebier *et al.*, 2000*a*); famotidine: 9 torsions (Shankland & David, 2002); capsaicin: 11 torsions (David *et al.*, 1998); heptamethylene-1,7-bis(diphenylphosphane oxide): 12 torsions (Kariuki *et al.*, 1999); verapamil hydrochloride: 13 torsions (Florence *et al.*, 2005*b*)]. In the following sections, various strategies for increasing the probability of successfully solving crystal structures for flexible molecules are presented, focusing on the supplementary information on torsional flexibility and conformation that may be utilized when standard global-optimization approaches struggle.

4.4.2.4.1. *Crystal-structure-derived information*

For complex, flexible molecular structures the incorporation of prior chemical information in the form of torsion-angle constraints can be of considerable value. Their inclusion in the form of constraints does not reduce the number of degrees of freedom, but does reduce the extent of the search space that needs to be explored, focusing the search where the correct value is most likely to be found (Shankland *et al.*, 1998*a*). Ideally, methods for deriving and implementing torsional constraints should be straightforward, in order to facilitate their routine application in SDPD. Fortunately, this is readily tractable with the use of crystal-structure databases. In its simplest implementation, a torsion angle may be fixed at its most common value, *e.g.* fixing an H—N—C═O amide torsion to 180° based on an evaluation of amide groups in the CSD.

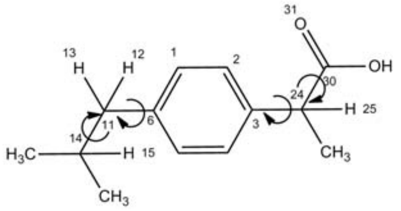

Figure 4.4.4
The structure of ibuprofen with flexible torsions highlighted (arrows).

For other groups it will be necessary to define a specific angular range for each flexible torsion angle based on conformational analysis of related crystal structures (Allen, 2002). A conformational analysis using semi-empirical energy calculations and CSD-based analysis of molecular conformations was used to obtain individual angular ranges for the four torsion angles in ibuprofen identified in Fig. 4.4.4 (Shankland *et al.*, 1998*b*). Four single-range torsion constraints (12—11—6—1 = 0–60°; 15—14—11—13 = 40–200°; 25—24—3—2 = −170–100°; 31—30—24—25 = 120–160°) were applied to the internal-coordinate description during a genetic algorithm search, increasing the frequency with which the global minimum was located in the structure solution of racemic ibuprofen using laboratory powder diffraction data (Shankland *et al.*, 1998*b*).

A simpler approach is to automatically extract modal torsion-angle constraints from the CSD using *Mogul* (Bruno *et al.*, 2004). Modal torsion constraints, in which multiple discrete ranges are defined for each torsion angle, offer a selective means of constraining a complex optimization problem. Individual torsion-angle values within crystal structures tend to form uni-, bi- or trimodal distributions and the conformation search space is restricted to one, two or three specific ranges. The common aliphatic fragment C—C—C—C returns a trimodal torsion-angle distribution with three distinct ranges separated by 120° (Fig. 4.4.5). Armed with such data for an unknown crystal structure, it is reasonable to assume that this torsion angle will adopt a value from within these ranges and constrain the search to sample only from within the trimodal distribution. An important caveat on the use of the CSD or other structural databases is the possibility

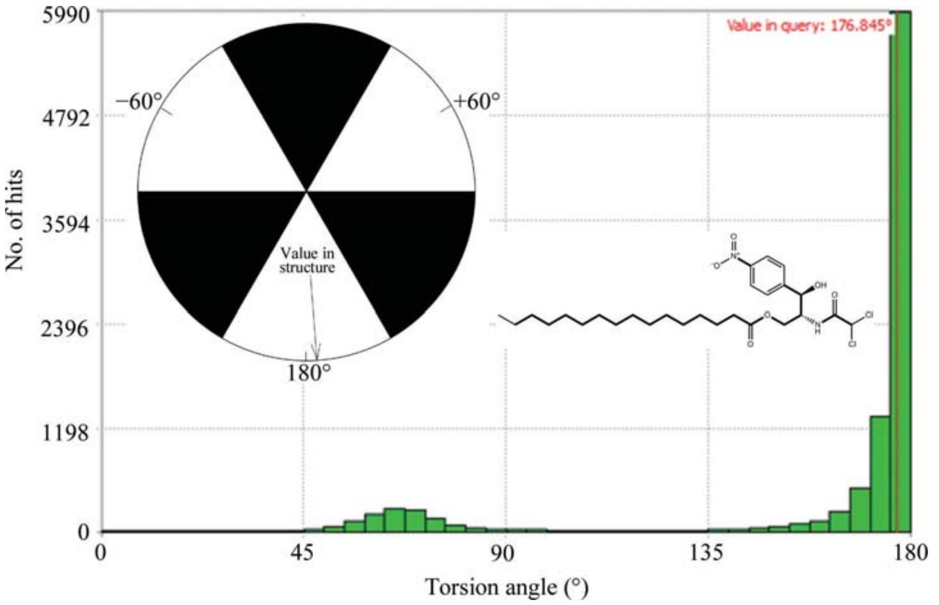

Figure 4.4.5
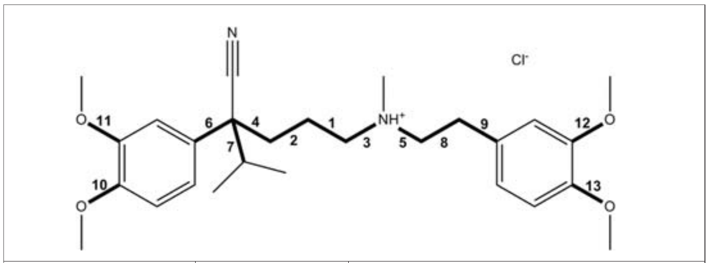
A trimodal torsion-angle distribution obtained from the CSD using *Mogul* for the C—C—C—C torsion in the query fragment (shown). All torsion values are mapped onto 0–180° (*x* axis) with the value in the query fragment being 176.8°. Inset: the associated trimodal search space in which the torsion-angle ranges shown in black are excluded from the search.

Table 4.4.2
Allowed ranges for the flexible torsion angles (τ1–13) identified in the verapamil cation using *Mogul* (from Florence *et al.*, 2009)



τ	Modal distribution type	Allowed torsion-angle search space (°)		
1, 2, 3, 4, 5, 7, 8	Trimodal	30–90	150–210	270–330
9	Bimodal	45–135	225–315	
6	Unimodal	0–360		
10, 11, 12, 13	Unimodal	−45–45		

that the actual value of any specific molecular torsion angle in the crystal structure being investigated may not lie within the ranges observed from other known structures. It is worth noting that where a simplex refinement is invoked at the end of each global-optimization run, angles outside this range may still be accessed (Florence *et al.*, 2009).

As the accessible conformational space around specific rotatable bonds in a flexible molecule may be influenced by steric effects from local functional groups, distributions based on a search of related molecular fragments will be most beneficial. An analysis of torsion-angle ranges in the compound verapamil hydrochloride (triclinic, $Z' = 1$, CSD refcode: CURHOM; Carpy *et al.*, 1985) highlights specific modal distributions for each of the torsions in the molecule (Table 4.4.2). This is a reasonably complex SDPD problem requiring 22 degrees of freedom (cation: 13 torsions plus 3 position plus 3 orientation; anion: 3 position), although with the availability of good-quality laboratory powder diffraction data (Florence *et al.*, 2005*b*) it is a useful test system for different SDPD approaches. The application of modal torsion-angle constraints to the effectiveness of an SDPD attempt reaching the target $\chi^2_{\rm profile}/\chi^2_{\rm Pawley}$ value (*i.e.* the global minimum) for verapamil hydrochloride was assessed using a simulated-annealing search algorithm (*DASH*: 800 runs, 2×10^7 moves, 0.01 cooling rate) against laboratory powder diffraction data in the range 3–42° 2θ (Florence *et al.*, 2009). Three separate trials were carried out: one in which the torsion values were fixed at the single-crystal conformation, a second in which all torsions were allowed to vary from 0 to 360° without restriction, and a third in which the torsions were restricted to the modal distributions shown in Table 4.4.2. As might be expected, owing to the simplification in the search by reducing the total number of degrees of freedom from 22 to 9, all of the fixed conformer runs reached the global minimum. The unrestricted and modal-constrained optimizations both had a lower success rate overall, consistent with the more complex search hypersurface being explored; however, they were essentially equally effective in reaching the target $\chi^2_{\rm profile}/\chi^2_{\rm Pawley}$ value, with 27 and 29 out of 800 runs respectively. The overall success rate is consistent with a previous SDPD study of verapamil hydrochloride (Florence *et al.*, 2005*b*). Notably when this approach was applied to a second complex SDPD problem (CSD refcode: XELBEV, $Z' = 2$, 30 degrees of freedom comprising 18 torsion, 6 position and 6 orientation; Florence *et al.*, 2009) the global minimum was only located from the runs including the modal torsion constraints (579/800 runs solved for the fixed single-crystal conformation; 0/800 solved for the unconstrained runs and 3/800 successfully solved for the modal torsion-angle constrained runs).

The implementation of the modal torsion distribution information in global-optimization searches has recently been further developed to include a modal distribution bias methodology (*DASH-v3.3*; CCDC Software Ltd/STFC, 2008). The modal distributions provide a statistical weighting for the selection of values included in the stochastic search. This method biases the selection of values used in the search towards highly populated regions of the torsion distribution but does not exclude any torsion angles. The application of the modal distribution bias in a SDPD study of verapamil hydrochloride [simulated-annealing search, laboratory powder data and fit range as per Florence *et al.* (2009)] showed a significant increase in the number of runs that reached the global minimum (24 out of 50; CCDC, 2015). This is an order-of-magnitude increase in the success rate of individual search runs compared with previous SDPD studies of this crystal structure and bodes well for tackling highly flexible molecules. Structure determination of this system was also assessed in the direct-space SDPD program *TALP* (Vallcorba *et al.*, 2012) and obtained the correct solution in 13 out of 100 runs, although it was noted that successful solution was dependent on the specific molecular model used and the search condition controls that were applied.

4.4.2.4.2. *Solid-state-NMR-derived information*

Solid-state NMR (SS-NMR) offers a powerful probe of structure and dynamics in molecular solids with numerous applications in materials and structural science (Brown & Spiess, 2001; Harris, 2004). SS-NMR can provide a wealth of crystallographically relevant information including determination of asymmetric unit, molecular symmetry and space group as well as information on disorder, molecular conformation and hydrogen bonding, and has been widely applied in studies of molecular crystals. In particular, SS-NMR techniques have been applied to conformational analysis of a range of flexible molecular molecules, revealing similarities and differences in the overall molecular conformations adopted in different polymorphic phases (Zell *et al.*, 2000; Hughes *et al.*, 2005). ^{13}C cross-polarization magic-angle-spinning (CPMAS) NMR was used to investigate the conformational differences between cimetidine in polycrystalline samples of three polymorphs and a monohydrate by measuring through-space interactions between atoms (Middleton

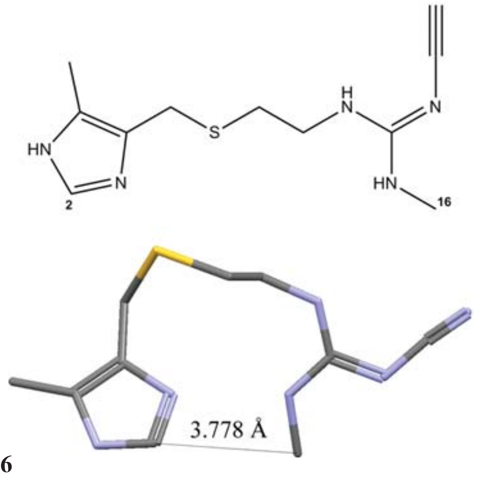


Figure 4.4.6
Top: structure of cimetidine molecule ^{13}C enriched at C2 and C16. Bottom: molecular conformation in the single-crystal structure of form-A cimetidine showing the equivalent C···C distance.

et al., 2000). By ^{13}C enrichment of the cimetidine at two sites (C2 and C16; Fig. 4.4.6) C···C separation distances were obtained describing the molecular conformations in each sample. The CPMAS NMR derived C2···C16 distance was 3.8 Å for form A compared with 3.778 Å in the published crystal structure (monoclinic, $P2_1/c$, CSD refcode: CIMETD).

The direct application of SS-NMR-derived torsion-angle information as constraints in SDPD has been demonstrated to excellent effect in a study of cimetidine form A using synchrotron diffraction data (Middleton *et al.*, 2002). The conformation of an ^{15}N labelled sample of cimetidine was determined in the form of four separate C···^{15}N through-space distances derived from rotational-echo double resonance (REDOR) NMR (Gullion & Schaefer, 1989; Gullion & Pennington, 1998). With SS-NMR-derived torsion-angle restraints applied, the performance of the search in locating the global minimum was significantly enhanced in terms of speed and reliability compared with a search with no torsional restraints. In effect, the application of the SS-NMR-derived torsion-angle information in this example simplified the global optimization to a more effective rigid-body search.

SS-NMR spectra simulated using the gauge including projector augmented wave (GIPAW) approach in combination with experimental SS-NMR data detailing two-dimensional correlations of ^{1}H and ^{13}C chemical shifts have been used to verify the accuracy of the structure of a 1:1 co-crystal of indomethacin and nicotinamide solved from powder diffraction data (Dudenko *et al.*, 2013). Hence, whilst in this case the SS-NMR-derived structural information was not utilized to direct the final refined crystal structure, such details can be helpful in providing independent confirmation that the structural model obtained is accurate.

4.4.2.5. *Intermolecular distance constraints*

The SDPD search space may also be reduced by introducing information describing intermolecular interactions between fragments in the structure. This can be done in the form of distance and/or angle restraints defining the contact between two fragments. For example, a CSD-derived distance restraint was applied to the $\mathrm{Cl^-}\cdots\mathrm{NH^+}$ separation (3 ± 0.3 Å) in SDPD attempts of verapamil hydrochloride. Although in this case it was not a prerequisite for successful structure solution given the quality of diffraction data available, the approach provides a useful tool in dealing with complex multicomponent crystal structures (CCDC, 2015). SS-NMR was used to identify hydrogen-bonding interactions between acetate and specific groups of the cortisone fragments in cortisone acetate polymorphs and was applied as a distance restraint in SDPD of form II (Harris, 2004). Another approach that has been applied in SDPD is to use energy penalties during the search to penalize nonsensical trial structures that have overlapping atoms (Stephenson & Liang, 2006). Whilst this can be effective in SDPD, such calculations are reliant on the accuracy of the energy calculation and also introduce a computational overhead on the overall SDPD process. A simple or 'anti-bump' cost function that uses minimum distance criteria only to avoid unlikely configurations has also been shown to be effective (Favre-Nicolin & Černý, 2002).

4.4.2.6. *H-atom location in structures solved from X-ray powder data*

As H atoms scatter X-rays very weakly, they often cannot be located independently in a structure determined from X-ray powder diffraction data. It is common practice therefore to fix H atoms in standard positions in the initial fragment model and retain these throughout the SDPD process (Fig. 4.4.1). With the application of appropriate Rietveld refinement strategies, reliable H-atom locations (*e.g.* for C—H bonds) can be achieved in the final structure. However, in many structures the orientation of N—H and O—H groups depends on intermolecular hydrogen-bonding interactions in the lattice. It is desirable therefore to ensure that a reliable, chemically sensible description of their locations is introduced into the final refinement. Following assessment of the crystal packing, this can be done manually by rotating the group defining the proton direction in order to satisfy the most probable hydrogen-bonding configuration.

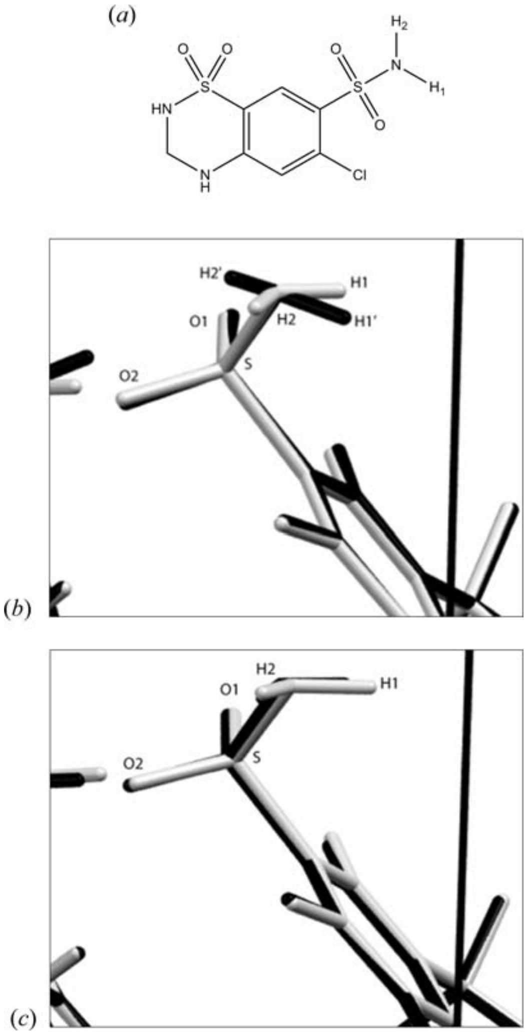

Figure 4.4.7
(*a*) Structure of hydrochlorothiazide (HCT) with H1 and H2 labelled; (*b*) overlay of HCT form-II SDPD (black) and single-crystal (grey) structures showing the discrepancy in N—H orientation around the N—S bond; (*c*) *CASTEP*-optimized SDPD (grey) and single-crystal (black) structures. From Florence *et al.* (2009).

Complementary experimental data can also contribute here. For example, ^{13}C tensor and ^{1}H/^{13}C correlation data were used to define the orientation of the five separate —OH groups in the SDPD structure determination of (+)-catechin 4.5-hydrate (Harper *et al.*, 2010). In an SDPD study of nimustine hydrochloride, the location of the protonation site on the pyrimidine ring was also successfully confirmed using SS-NMR (Beko *et al.*, 2012). This study also applied an energy minimization to all H-atom positions using the DREIDING/X6 force field prior to the final Rietveld refinement.

Once a global-minimum structure has been obtained, geometry-optimization calculations can be recommended where there is a particular interest in the reliable location of H atoms. The application of plane-wave density-functional theory (DFT) as a quantum-chemical aide in the accurate location of H atoms in organic crystals has been shown to be highly reliable in many cases and guidance on the practical application of these methods in this context is available (Deringer *et al.*, 2012). The thiazide diuretic hydrochlorothiazide has two hydrogen-bonded H atoms on a sulphonamide side chain and in the reported SDPD structure these had been positioned by manual rotation of the N—S bond to maximize contacts with surrounding H-atom acceptors (Fig. 4.4.7; Florence *et al.*, 2005*a*). First-principles DFT calculations in *CASTEP* (Clark *et al.*, 2005) significantly improved the accuracy of the orientation of the NH_2 group, showing excellent agreement with the locations identified from single-crystal diffraction (Florence *et al.*, 2009).

In a comprehensive analysis of 241 published crystal structures, dispersion-corrected DFT methods have been shown to reproduce experimental structures very accurately (van de Streek & Neumann, 2010). An energy-minimized r.m.s. Cartesian displacement (excluding H atoms) was used as an indicator of structural correctness: a correct structure obtained as the global minimum from a global-optimization search will correspond with an energy minimum to within less than 0.25 Å. In addition to assisting in the accurate location of H atoms, energy minimizations also have a useful application in the final assessment or validation of crystal structures and are a useful adjunct as part of an SDPD study.

4.4.2.7. *Crystal-structure prediction and crystal-structure solution*

Where it proves impossible to index a powder pattern, an SDPD attempt is halted and cannot progress to subsequent space-group assignment, intensity extraction or global optimization. Typically the researcher will seek to obtain better data, perhaps by recrystallization to remove any potential impurities or sharpen the diffraction peaks, or aim to recollect the data at a synchrotron. Given the advances made in the capability to predict crystal structures of molecular crystals *ab initio* (Day *et al.*, 2005, 2009), it is worth highlighting that crystal-structure prediction (CSP) can provide thermodynamically feasible model crystal structures. The crystal structure of form-I chlorothalonil was obtained by Rietveld refinement of the global-minimum lattice-energy structure from a CSP study against the experimental powder diffraction data (Tremayne *et al.*, 2004). In this case, the computational methods provided the structure in full, with the final refinement against the data confirming the veracity of the prediction. Hence, although crystal-structure prediction is not yet able to tackle large, flexible, multi-component pharmaceutical compounds as a matter of routine, just as advances in SS-NMR have extended the range of practical application in SDPD, computational methodologies for crystal-structure prediction and analysis show potential to become an increasingly powerful source of structural information.

4.4.3. Concluding remarks

Structure determination from powder diffraction data has progressed significantly over the last 15 years to the point where it can be viewed as a routine method for crystal-structure determination. Many structural problems can be tackled routinely where good-quality diffraction data and accurate molecular models are available. However, as the complexity of the structures investigated by SDPD increases, so the contribution of additional information becomes more valuable. With combined access to prior chemical knowledge, complementary analytical techniques and computational modelling techniques, the probability of success can be enhanced in increasingly challenging cases. The most appropriate approach to assist in a particular structural problem will often be case-specific and depend on several factors including available diffraction data quality, access to relevant chemical information, ability to utilize the information effectively within the search and the nature of the structure being investigated. However, with careful attention at each step of the SDPD process and with consideration for when supplementary information may be beneficial, the power of SDPD to solve complex, flexible, multi-component crystals with a high-degree of accuracy from the limited information content of a powder-diffraction pattern will continue to grow.

4.4.3.1. *Test data for SDPD*

As final remark, laboratory powder diffraction data for 35 compounds (Florence *et al.*, 2005*b*) are available for download from http://www.powderdata.net to allow interested readers to explore, test and compare different approaches to successful SDPD.

4.5. Solving and refining inorganic structures

R. Černý and V. Favre-Nicolin

4.5.1. The molecular/non-molecular and the organic/inorganic boundaries

An inorganic compound may be defined as a compound that does not correspond to the definition of organic compounds according to IUPAC (Rigaudy & Klesney, 1979). The separation of compounds by the inorganic/organic boundary is of minor importance for structure determination by diffraction methods. Even if the presence of only light elements in organic compounds decreases the diffraction contrast between atoms compared to the inorganic world, more important for diffraction is how the atoms build up larger building units and the crystal structure itself. Inorganic compounds usually do not contain isolated molecules. A molecular/non-molecular boundary is therefore relevant for the choice of a structure-determination method. Non-molecular compounds – also called extended solids – are constructed by bonds that extend ‘infinitely’ in three dimensions through a crystal. These non-molecular crystals usually crystallize with high symmetries and atoms often occupy special Wyckoff positions.

4.5.2. Modelling of non-molecular compounds

4.5.2.1. *Principles*

The modelling of non-molecular compounds is by nature complex; this is because they are extended solids, and therefore no obvious group of atoms (such as a molecule) can be isolated and used as a *building unit* (BU) for the entire structure (Fig. 4.5.1). This does not create a particular difficulty for *ab initio* structure-solution methods working entirely in reciprocal space (reciprocal-space methods, which we will abbreviate as RSMs). However, it becomes a problem for methods working entirely in direct space (direct-space methods or DSMs) and the use of *a priori* chemical knowledge about the compound. Any structure-solution algorithm working in direct space has to know how to define basic structural blocks of the crystal, BUs, which are then manipulated (optimized) by the algorithm. Moreover, the presence of high-order symmetries leads to a fragmentation of these BUs, as any group of atoms (*e.g.* an octahedron) can be located on a symmetry element, so that only a part of the atoms of a symmetry-constrained BU is truly crystallographically independent. Finally, the actual arrangement in space between BUs relative to the symmetry elements of the unit cell is *a priori* unknown.

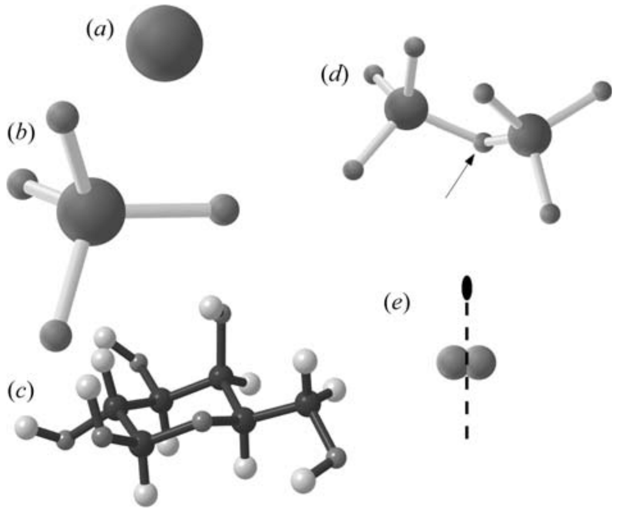

Figure 4.5.1
A non-molecular crystal can be described by primary building units (PBUs), which can be (*a*) isolated atoms, (*b*) coordination polyhedra, (*c*) molecules, or a more complex and flexible arrangement of secondary building units (SBUs). The choice of BUs is essential both to solving the structure and to ensuring that it is chemically and crystallographically sensible. One particular difficulty is identifying without *a priori* knowledge atoms (*d*) shared by several BUs or (*e*) a BU on a special position.

The basic principles to be followed when choosing the BU are the following:

(i) the model must describe the structure with as few parameters (degrees of freedom or DoF) as possible, so that the parameter space to explore is as small as possible;
(ii) the basic building units must allow the exploitation of any *a priori* chemical knowledge about the material, to provide an chemically unambiguous solution; and
(iii) all BUs must be constructed so that they can easily be linked to other BUs, in order to form an extended solid. This includes bonding with themselves in the presence of a symmetry element.

4.5.2.2. *Building units*

The choice of a BU is easy when isolated molecules or polyatomic ions are present in the crystal, such as in organic or coordination compounds where the molecules and ions are easily described by a finite number of internal coordinates (bonding distances, angles and torsion angles). A molecule or polyatomic ion is naturally a well defined BU that can be moved in the unit cell, and its conformation altered by modifying torsion angles. No sharing of atoms between the molecules or ions occurs.

The situation can become rather unclear when one tries to model the crystal structure of a non-molecular compound. The definition of a BU for a crystal such as Fe or NaCl is not unambiguous: should it be one atom, the first coordination sphere of each atom, a structural sheet of finite thickness, or the asymmetric unit? Pauling (1929) created the concept of BU when he defined coordination polyhedra for the description of structures, and stated Pauling’s rules. Coordination polyhedra, typically the first coordination spheres of selected atoms which will generate the whole inorganic crystal structure, can always be identified. These polyhedra will share corners, edges or faces in close-packed crystal structures and frameworks, but can also be chosen as isolated entities as in ionic crystals containing polyatomic ions. A wide range of polyhedra can be defined, and these are naturally described using bond distances, angles and torsion angles. The type of atomic coordination in non-molecular crystals can very often be predicted from their chemical formula, cationic valence state, the known structures of similar compounds and spectroscopic methods which are locally sensitive *e.g.* NMR, EXAFS, Mössbauer spectroscopy *etc*. The definition of BUs is easy for

Copyright © 2019 International Union of Crystallography

tetrahedral frameworks like zeolites, where the concept of primary building units (PBUs) and secondary building units (SBUs) is used (Meier & Olson, 1987). In the case of zeolites a PBU is a TO_4 tetrahedron (T being a tetrahedral atom), and SBUs are various fragments of the zeolite framework built from PBUs with the aim of using as few SBUs as possible (ideally just one) to build up the whole framework.

The concept of PBUs and SBUs may also be used for modelling an extended solid for structure-solution purposes using DSMs. In DSMs the PBUs are carefully selected from knowledge of the crystal chemistry of the compound under question, and are used as rigid or semi-rigid blocks which are then localized by a global-optimization algorithm within the crystal structure (unit cell) of the compound. The SBU may be used in the same way, *i.e.* as blocks constructed from a PBU or as additional information (restraints) in the global-optimization algorithm. Various SBUs are possible such as isolated polyhedral clusters, infinite polyhedral chains, sheets or frameworks.

A correct choice of PBU is important for the correct description of an *a priori* unknown structure, and may become decisive for the convergence of the global-optimization algorithm. We can distinguish three types of inorganic compounds from the point of view of PBU choice for structure determination:

Polyhedral compounds are mostly iono–covalent compounds (Pauling, 1929). The selection of a PBU is naturally a cation (but may also be an anion; see Krivovichev *et al.*, 2013) first coordination sphere. Examples are: salts, oxides, chalcogenides, halides, pnictides, silicates, complex and ionic hydrides, and also inorganic monomeric crystals like $Hf(BH_4)_4$ (Broach *et al.*, 1983) with isolated polyhedral PBUs.

Hybrid compounds are coordination polymers such as metal–organic frameworks (MOFs) (Tranchemontagne *et al.*, 2009) containing metal cations or their coordination polyhedra linked by molecular linkers as PBUs or SBUs, and also covalent organic frameworks (COFs) where the PBUs are simple molecular fragments like benzene rings connected by other molecular fragments of similar complexity (Côté *et al.*, 2005).

Close-packed compounds where the definition of the first coordination sphere polyhedron as a PBU is less evident. Examples are alloys and intermetallic compounds. The first coordination sphere polyhedra usually have a high number of vertices, such as in Frank–Kasper phases containing Kasper polyhedra (Frank & Kasper, 1958). In the case of quasicrystals the polyhedral clusters are themselves PBUs. In some cases the whole crystal is a PBU (nanoparticles). Modelling from free atoms seems to be more efficient in this case.

4.5.2.3. *Special positions and the sharing of atoms between building units*

When building a non-molecular crystal from the BUs, sharing of atoms between the BUs must be taken into account. Except in simple cases with small unit cells, the connectivity is *a priori* unknown. This is not a problem for RSMs, but in DSMs the global-optimization algorithm must be able to determine when BUs share corners, edges or faces, while also allowing BUs to move away from positions where they share atoms. A similar difficulty presents itself when an atom falls onto a special position and overlaps with its symmetry equivalents.

To cope with this, Deem & Newsam (1989) used a merging term in the cost function, which then evolved into a general and simple algorithm called the dynamical occupancy correction (DOC) by Favre-Nicolin & Černý (2002). For each proposed model, all atom positions in and near the asymmetric unit are generated, then for all unique atoms a neighbour table with all atoms closer than d_{min} (with d_{min} = 0.1 nm) is generated. The occupancy is then corrected as follows (Fig. 4.5.2):

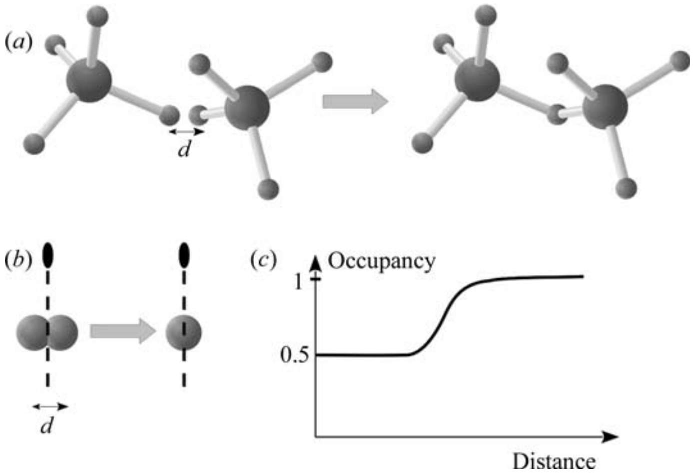

Figure 4.5.2
Ab initio structure-solution algorithms working in direct space must be able to automatically handle (*a*) atoms that are shared between individual building units and (*b*) atoms that are on special positions. In both cases, the algorithm can transform two overlapping atoms into a single one by (*c*) reducing the occupancy of the atoms when their distance apart falls below a threshold value. This 'dynamical occupancy correction' has the advantage of working without any *a priori* information, and is reversible.

$$\text{Occupancy}^{-1} = 1 + \sum_{\text{neighbours}} |d_{\min} - d_i|/d_{\min}. \qquad (4.5.1)$$

The sum is over all neighbours of the same atomic type. From this formula it is straightforward to see that if n atoms overlap ($d_i < d_{\min}$), the dynamical occupancy correction converges to $1/n$. After this correction has been applied, there will be n atoms with occupancy equal to or converging to $1/n$. Thus the algorithm for computing structure factors will use the correct electronic (or nuclear) density.

There are several advantages to this approach. It can handle any type of overlap (due to different BUs or symmetry-related) and allows a smooth transition (a progressive change of the occupancy) as the overlapping atoms get closer. Moreover, the atoms are not merged, so a direct-space algorithm can go back and forth between overlapping and non-overlapping atoms to search for the best solution.

The drawback of this approach is that it requires the calculation of a distance table between elements, which can take longer than the actual structure-factor calculation. Moreover, the ability to merge atoms also comes with a less obvious price: whenever it is used, there are too many atoms used to describe the unit-cell contents. Take, for example, a structure built from vertex-sharing octahedra: in this case the vertex atoms are shared between two octahedra, so that a description using only octahedra as a BU would use twice as many vertex atoms as necessary. This effectively increases the number of atoms, and thus both the number of parameters as well as the computing time for each trial structure. Even more important, looking at the three-dimensional model of the structure becomes challenging because of the high density of atoms in the unit cell (as long as the final solution has not been found, and the atoms are not perfectly overlapping). The recommendation is to switch off the DOC whenever possible, *i.e.* in the case of space groups having only general Wyckoff positions (fixed-point-free space groups): $P1$, $P2_1$, Pc,

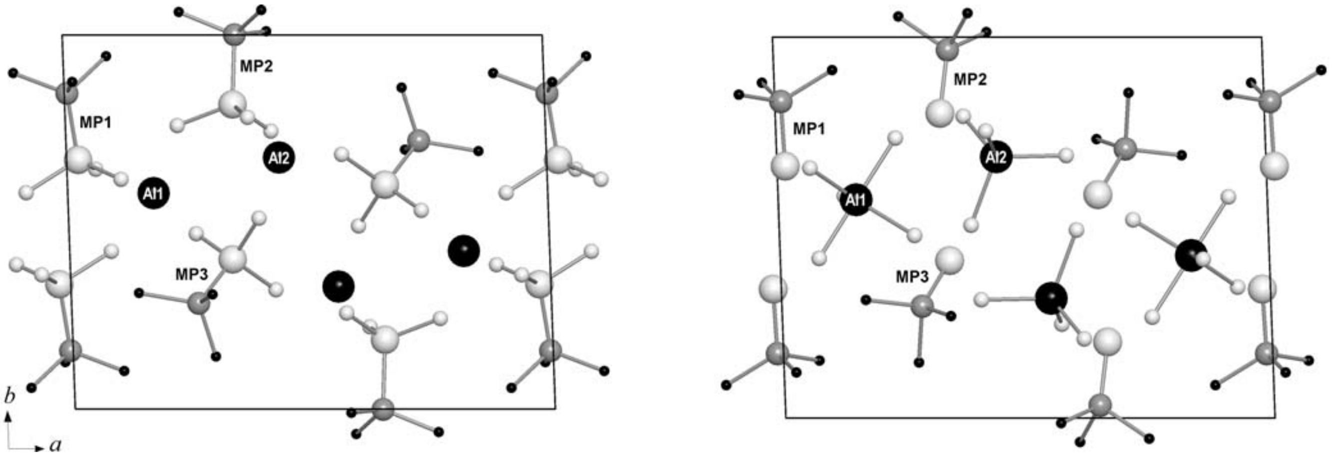

Figure 4.5.3
Modelling of the aluminium methylphosphonate structure using: (left) three H_3C-PO_3 blocks MP1–MP3 and two Al atoms, and (right) one AlO_5 trigonal bipyramid for Al1, one AlO_4 tetrahedron for Al2 and three H_3C-P groups MP1–MP3.

Cc, $P2_12_12_1$, $Pca2_1$, $Pna2_1$, $P4_1$, $P4_3$, $P3_1$, $P3_2$, $P6_1$, $P6_5$, and if no partly occupied sites are expected (see Section 4.5.2.4).

4.5.2.4. *Is there a need for precise unit-cell contents?*

The DOC can be an ideal tool to treat the uncertainty in unit-cell content and site occupancies. A good example is the hydrogen in interstitial hydrides like $NdNi_4MgH_{3.6}$ (Guénée *et al.*, 2003). When hydrogen is dissolved in the crystal lattice of an intermetallic compound, usually a great number of interstitial sites are partially occupied by H atoms, leading to an uncertainty in the total number of Wyckoff sites occupied by hydrogen. The DOC can easily treat this problem. The starting model for DSMs can contain more H atoms than needed for the correct structure. The excess H atoms are simply merged by the DOC. This means that when optimizing the structural model one does not need to specify at the beginning which Wyckoff sites (special or general) will be occupied by individual atoms, the connectivity between the BUs (such as sharing vertices between polyhedra) or even the exact chemical composition of the crystal. The only condition is that the starting model contains at least the correct number (or more) of independent BUs. Not only can excess atoms be merged by the DOC, but even whole BUs such as excess polyhedra!

This does not mean that the *a priori* knowledge of correct chemical composition may be underestimated when solving a crystal structure by DSMs. Direct-space modelling of relatively complex non-molecular structures can yield a relatively good fit for a wrong structure with the wrong chemical composition [see for example the case of $AZn_2(BH_4)_5$ (A = Li, Na) (Ravnsbaek *et al.*, 2009; Černý *et al.*, 2010)]. Such a structural model may have balanced interatomic forces as shown by density-functional theory (DFT) optimization, but it does not correspond to a stable polymorph under the given thermodynamic conditions. RSMs depend less on the correct knowledge of the chemical content of the unit cell, as they use it only for normalization of the structure-factor amplitudes and for interpretation of electron-density maps.

4.5.2.5. *Building units and the convergence of the DSM algorithm*

The choice of BUs often has an effect on the convergence of the global-optimization algorithm. A good example is the structure solution of aluminium methylphosphonate (Edgar *et al.*, 2002). For this material, individual PBUs were identified using ^{27}Al, ^{13}C and ^{31}P NMR spectra, which revealed the presence of three crystallographically inequivalent C-PO_3 units as well as two aluminium atoms in tetrahedrally and fivefold coordinated sites, respectively. From this *a priori* knowledge, two models were used to solve the structure (Fig. 4.5.3):

(i) using three H_3C-PO_3 blocks and two Al atoms (24 DoF, not counting the positions of H atoms);

(ii) one AlO_5 trigonal bipyramid, one AlO_4 tetrahedron and three H_3C-P groups (27 DoF, counting only five DoF for the H_3C-P groups since the H-atom positions cannot be found reliably).

In both cases the same structure was obtained. The inclusion of the H atoms and the use of an anti-bump cost function was very important in these optimizations, since it helped to differentiate C and O atoms, as well as (indirectly) P and Al, and therefore reduced the depth of local minima. Using the first model the solution required on average 0.7 million trials. The second model was much less successful during repeated runs (the distribution of the number of required trials to find the solution was wide, ranging from 0.3 to 16 million), even though it better exploited the NMR information on the aluminium coordination. This was because of the difficulty in finding the correct positions of the AlO_4 and AlO_5 groups, which are very similar from an electron-density viewpoint and almost isotropic so that their actual orientation is hard for the algorithm to pinpoint. In contrast, for the first model, two simple groups of identical building blocks (2 × Al and 3 × H_3C-PO_3) are used, where the Al and H_3C-PO_3 groups are easily distinguishable, anisotropic, and the invariance by permutation significantly reduces the parameter space to be explored. The role of the DoF (27 *versus* 24) is here less important than the nature of the PBUs.

4.5.2.6. *Random versus non-random DSM algorithms*

Once the BUs have been defined, several types of algorithms can be used to actually solve the structure:

(i) *Random, ergodic algorithms* such as the reverse Monte Carlo (RMC) or genetic algorithms (GAs) (see Chapter 4.3). These generate a very large number of trial structures by varying all the degrees of freedom and thus exploring the entire parameter space. This type of algorithm is thorough, but requires long computer running times. Additional chemical information applied in the choice of BUs and in the use of various cost functions based on coordination knowledge (anti-bump distances, crystal energy, bond-valence sums) is highly valuable in increasing the success rate of these algorithms.

(ii) *Topology-guided algorithms* (framework building). Where the type of crystal structure is known *a priori* (not just for the PBU, but also for the SBU) this kind of algorithm can be used. This approach is primarily used for framework compounds such as zeolites (Grosse-Kunstleve *et al.*, 1997) and MOFs (O'Keeffe & Yaghi, 2012; Tranchemontagne *et al.*, 2009) and in general for organometallic species (Masciocchi & Sironi, 2005) and the prediction of inorganic structures (Mellot Draznieks *et al.*, 2000).

(iii) *Crystal-chemistry guided algorithms*. These are based on quantum-chemistry calculations (Mercier *et al.*, 2006, 2007) or symmetry analysis (Evans *et al.*, 2003), and are useful for a very precise family of compounds where the structure is parameterized by a limited number of parameters. A good example is α-$Bi_2Sn_2O_7$, a 176-atom compound based on the pyrochlore structure (Evans *et al.*, 2003), which was solved from powder diffraction data by the symmetry analysis of superstructures based on a well described average structure. This approach can be particularly efficient for layered compounds, or when different polytypes are possible. An example of symmetry-guided refinement is parametric Rietveld refinement (Stinton & Evans, 2007) applied to the analysis of structural phase transitions (Müller *et al.*, 2010).

Crystal-chemistry knowledge can be used to accelerate the convergence of random algorithms by eliminating regions in the parameter space where the correct structure cannot exist. For example, the knowledge of the chemical composition and contents of the unit cell together with the space-group symmetry exclude some combinations of Wyckoff positions which cannot be occupied by a given atom type. This analysis is done *a priori* and is actively used in the random algorithm (Deng & Dong, 2011; Meredig & Wolverton, 2013) of DSMs, and can also be used in structure prediction with (Meredig & Wolverton, 2013) and without (Reinaudi *et al.*, 1998) the active use of diffraction data.

4.5.2.7. *The choice of the cost function in DSM algorithms*

A cost function based on additional chemical information in addition to the diffraction data should help the global-optimization algorithm in DSMs to find the global minimum of the diffraction-only cost function (see Chapter 4.3). In the case of non-molecular compounds, a simple anti-bump cost function penalizing the improbable atomic configurations provides the best results (Favre-Nicolin & Černý, 2002). Similarly, with DOCs the anti-bump cost function requires a time-consuming interatomic distances calculation, but the gain in the convergence of the optimization algorithm is more important than the time costs in most cases.

A cost function based on the crystal potential energy (for different types of the potential energy see Chapter 4.9) is a rigorous approach introducing additional exact information on the crystal structure besides the diffraction pattern. However, the calculations are highly time consuming unless simple potentials (mostly for ionic compounds) are selected. The improvement of the algorithm convergence is then comparable with a simple anti-bump cost function.

A cost function based on the calculation of bond-valence sums (BVSs) (Pannetier *et al.*, 1990) in iono–covalent crystals has a very narrow global minimum and a relatively flat hypersurface in parameter space. Because of this it is more useful for structure validation than for active use in global optimization.

Multiple cost functions may be used independently (Brodski *et al.*, 2005) or combined in one global cost function. The combination of different cost functions in one global optimization, known as Pareto optimization (Steuer, 1986), is yet to be evaluated in structure determination from powder diffraction. The weighting between individual cost functions depends on the complexity of the crystal structure, the quality of the powder diffraction data and crystallographers' experience.

4.5.3. Solving, refining and completing inorganic structures

4.5.3.1. *A general problem: poor quality powder data*

The *ab initio* structure determination of inorganic compounds often suffers from the low quality of powder data. Two common problems are line broadening and texture, which are typical problems for *in situ* studies. When it is isotropic, the line broadening just decreases the resolution of the powder pattern, and prevents the use of RSMs for structure solution. DSMs are then the only choice. Anisotropic line broadening due to the anisotropic crystallite size is a result of crystal growth (anisotropic growth conditions, anisotropic bonding in the crystal producing layered or columnar structures) or mechanical treatment of the sample (an extreme example is graphene production). A typical example of anisotropic line broadening due to anisotropic strain in the crystal is dislocation-induced line broadening. Anisotropic line broadening not only prevents the use of RSMs, but also complicates the profile modelling for DSMs. Texture is induced in inorganic samples either by sample preparation or by crystal-growth conditions as for *in situ* studies. The presence of texture in a standard powder diffraction experiment depends mostly on the shape anisotropy of grains in the sample, and it can be minimized by using Debye–Scherrer geometry in combination with an area detector (Ravnsbaek, Filinchuk, Černý & Jensen, 2010).

When working with DSMs, texture can be optimized jointly with the structural model. The first example of a successful structure solution on a strongly textured sample was for the high pressure phase of $NaBH_4$ ($BaSO_4$-type structure, $Pnma$, a = 7.2970 (11), b = 4.1166 (5), c = 5.5692 (7) Å at 11.2 GPa) (Filinchuk *et al.*, 2007). The preferentially oriented plane (h00) was identified and the magnitude of the texture optimized jointly with the positions of one Na atom and one BH_4 group.

4.5.3.2. *Indexing of multiphase samples*

The bottleneck of *ab initio* structural studies of new inorganic compounds is indexing the powder patterns, which is extremely challenging for multiphase samples. Solid-state-route synthesis produces samples which contain more than one phase; unreacted starting components can be present too. Modern methods of powder-pattern decomposition and indexing are needed and high-resolution powder diffraction data with high counting statistics are necessary in such cases. The correct indexing of the powder pattern of a new unknown compound is only possible after successful qualitative phase analysis of the sample. A successful indexing strategy for multiphase samples is 'decomposition-aided indexing', which utilizes *in situ* diffraction as a function of temperature (which is typically linearly dependent on time; this mode is known as 'T ramping') up to the decomposition/melting temperature of different phases (Černý & Filinchuk, 2011). This procedure allows the separation of diffraction peaks of individual phases (Fig. 4.5.4).

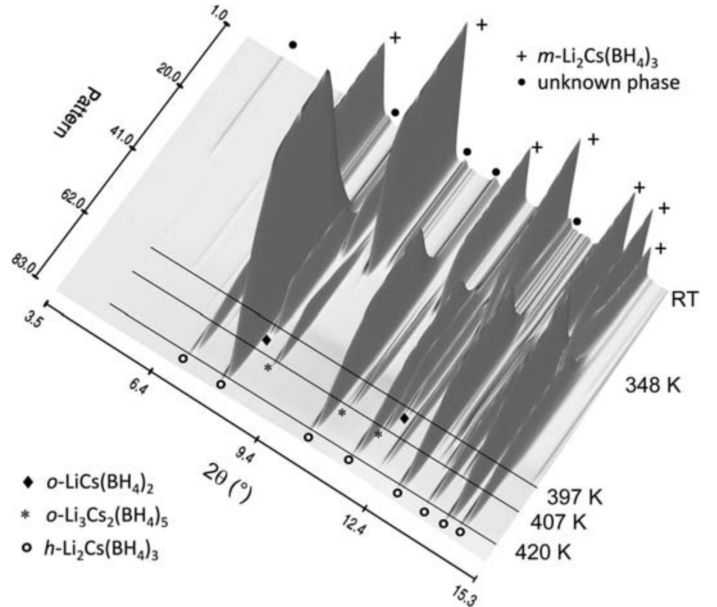

Figure 4.5.4
In situ synchrotron-radiation X-ray powder diffraction data as a function of temperature for a ball-milled sample of $LiBH_4$:$CsBH_4$ (2:1) (room temperature to 428 K, λ = 0.8210 Å). T ramping had to be used to attribute the observed peaks to individual phases and led to a successful indexing of the powder patterns. The letter in the name of each phase represents the crystal system: m for monoclinic, o for orthorhombic and h for hexagonal (Schouwink *et al.*, 2014).

4.5.3.3. *X-rays versus neutrons*

The choice of radiation used for powder diffraction experiments depends on many factors. The accessibility and price of the experiment (costs and time) are often the most important, in which case X-rays become the first choice. In the case of low-Z atomic structures, X-ray powder diffraction (XPD) may very well localize H atoms as hydrogen becomes a non-negligible X-ray scatterer, such as in $LiBH_4$ (Soulié *et al.*, 2002). The contribution of hydrogen to the X-ray intensity scattered by $LiBH_4$ is 26% while the contribution of deuterium to the neutron scattering by $LiBD_4$ is 52% (Filinchuk *et al.*, 2008). The precisions of the metal–hydrogen bond lengths obtained from XPD data are lower than those usually attained by neutron powder diffraction (NPD). Moreover, the positions of H atoms determined from X-ray diffraction data are displaced from the B atom along the B—H bond by ~0.08 Å because of displacement of the electron cloud, and by ~0.034–0.10 Å because of the libration motion of BH_4 groups, which is both temperature- and structure-dependent (Filinchuk *et al.*, 2008). Even charge densities in $LiBD_4$ have been reliably extracted from the synchrotron powder diffraction data using high counting statistics and maximum-entropy methods (Buchter *et al.*, 2011).

The arrangement of atoms in an inorganic compound may also show a small deviation from an arrangement with higher symmetry or shorter periodicity. Typical examples are metal hydrides. The deviation of metal-atom positions in a metal hydride from higher-symmetry positions is created by positioning H atoms in the matrix of metal atoms (it does not necessarily exist without hydrogen), which then becomes only slightly deformed. Because of the small deformation of the metal matrix and the low scattering power of hydrogen for X-rays, the splitting of peaks caused by lowering the symmetry is not very strong and the superstructure peaks are very weak in X-ray diffraction patterns; both are clearly visible only in neutron patterns. X-ray patterns with low background and high counting statistics are needed to detect the weak superstructure peaks. High angular resolution is necessary in both X-ray and neutron patterns to separate overlapping peaks and to detect the correct symmetry of the structure. The true symmetry can generally be revealed with confidence after successful indexing of the neutron powder diffraction pattern.

The high-temperature phase of $Y(BH_4)_3$ was determined from X-ray data as cubic [$Pm\bar{3}m$, a = 5.4547 (8) Å] and containing BH_4 tetrahedra rotationally disordered over two positions (Ravnsbaek, Filinchuk, Černý, Ley *et al.*, 2010). Only when NPD data were measured was the true cubic superstructure ($Fm\bar{3}c$, $2a$) with fully ordered BH_4 tetrahedra discovered (Fig. 4.5.5; Frommen *et al.*, 2010).

Interestingly, the only superstructure reflection (531) accessible within a typical XPD pattern (down to d = 1.4 $Å^{-1}$) has practically zero intensity, while it becomes the strongest reflection in the NPD pattern (Fig. 4.5.6).

Another example of a weak hydride superstructure is that of $Mg_6Co_2H_{11}$ (Černý *et al.*, 1992). An example of a strong pseudosymmetry of the metal lattice of a hydride is $LaMg_2NiH_7$ (Renaudin *et al.*, 2003).

4.5.3.4. *Chemical and positional disorder*

Chemical disorder is often observed in metal alloys where metal sites may have mixed occupancies. When the occupation of individual sites by different metals is not statistically random, it can be analysed provided that the scattering contrast between the

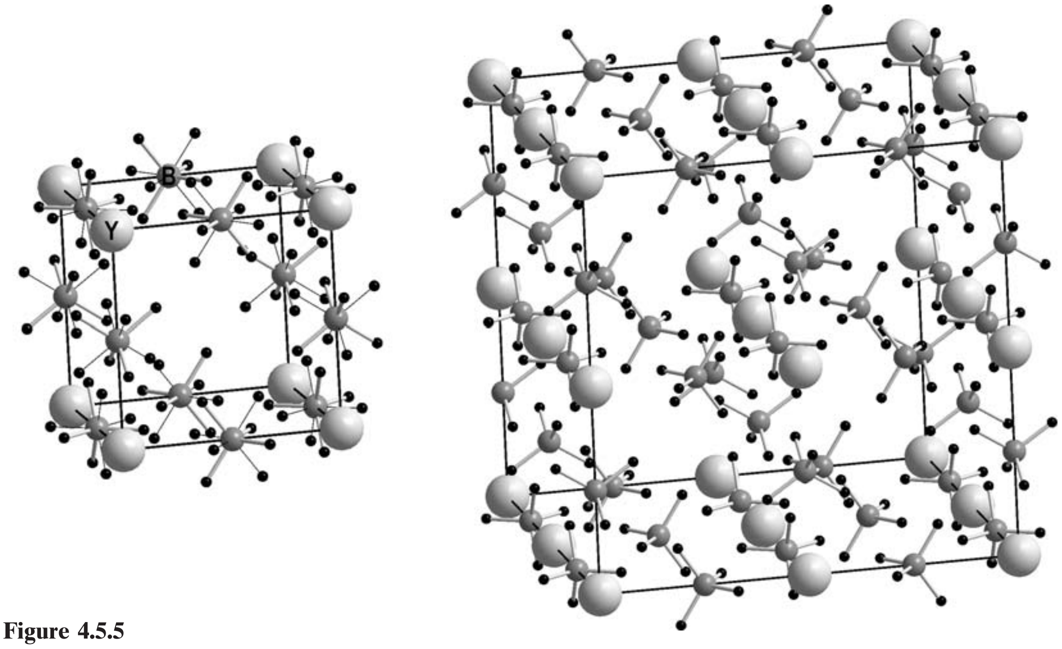

Figure 4.5.5
Yttrium borohydride appears to show positional disorder on the BH_4 groups when only XPD data are used (left: Ravnsbaek, Filinchuk, Černý, Ley *et al.*, 2010), but appears fully ordered when NPD data are also used (right: Frommen *et al.*, 2010). Reprinted from Frommen *et al.* (2010) with permission from Elsevier.

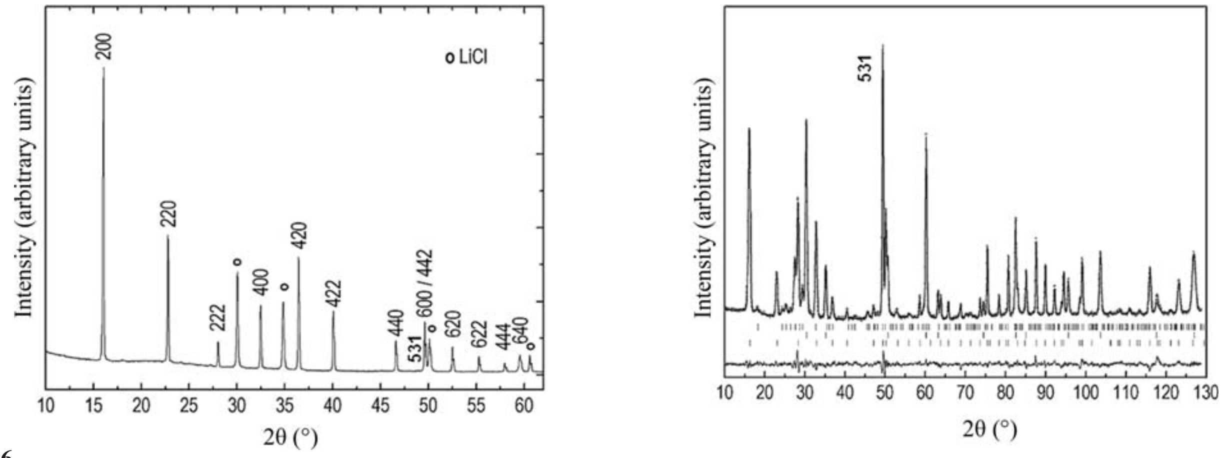

Figure 4.5.6
XPD (Cu $K\alpha_1$, left) and NPD (λ = 1.5558 Å, right) patterns for the high-temperature modification of yttrium borohydride. The peaks from LiCl are highlighted by open circles in the XPD pattern and the peak positions for the different refined phases are marked by tick marks in the NPD pattern: $Y(^{11}BD_4)_3$ (bottom), LiCl (middle) and $Li^{11}BD_4$ (top). The only superstructure reflection (531) which would allow the correct cubic lattice parameter to be detected has practically zero intensity in the XPD pattern, while it becomes the strongest reflection in the NPD pattern. Reprinted from Frommen *et al.* (2010) with permission from Elsevier.

metals is strong enough. Occupation can be quantified by either using the XPD and NPD data jointly or by resonant X-ray scattering. Note that for the case of n atomic species (including vacancies) on one Wyckoff site, one needs $n - 1$ diffraction patterns with different contrast between the scatterers in question.

Positional atomic disorder may show a local order (short-range order) which can be studied from the diffuse intensity of the scattered radiation. The diffuse scattering from polycrystalline samples may be studied by using the pair distribution function and Debye function (see Chapters 5.6 and 5.7) in direct space or RMC modelling in reciprocal space.

4.5.3.5. *Structure validation – theoretical issues*

Crystal structures solved from powder diffraction data must be validated. The first step is carried out in reciprocal space *via* the evaluation of how well the structural model explains the observed powder diffraction data. This is a necessary but not sufficient condition, as we see in Chapter 4.9; see also Section 4.5.2.4. There are a number of measures that can be used to evaluate this agreement, the most commonly used being the χ^2 and $R_{\rm wp}$ (Toby, 2006) values. However, these must be used with care. A good $R_{\rm wp}$ value will depend a lot on the quality and type of powder pattern recorded: 12% may be very good for a synchrotron powder pattern with very low noise, but would be very bad for neutron or laboratory data with a high background. It is also possible to compare the finally obtained $R_{\rm wp}$ to the value obtained using profile fitting (David, 2004). In practice, the best tool for evaluating the quality of the fit is still the eye of an experienced crystallographer (McCusker *et al.*, 1999).

The second step in the validation is the analysis of the crystal structure itself in direct space:

– Are there atoms ‘colliding with’ each other? If DSMs repeatedly find a global solution with atoms overlapping, an anti-bump penalty (see, for example, Favre-Nicolin & Černý, 2002) can be used to avoid this solution. Note that this should only happen if the quality of the powder pattern is low, and therefore includes insufficient information to ‘lock’ the DSM algorithm into the correct solution.

– Do the atomic environments make sense? A penalty based on bond-valence sum calculations (Pannetier *et al.*, 1990) can

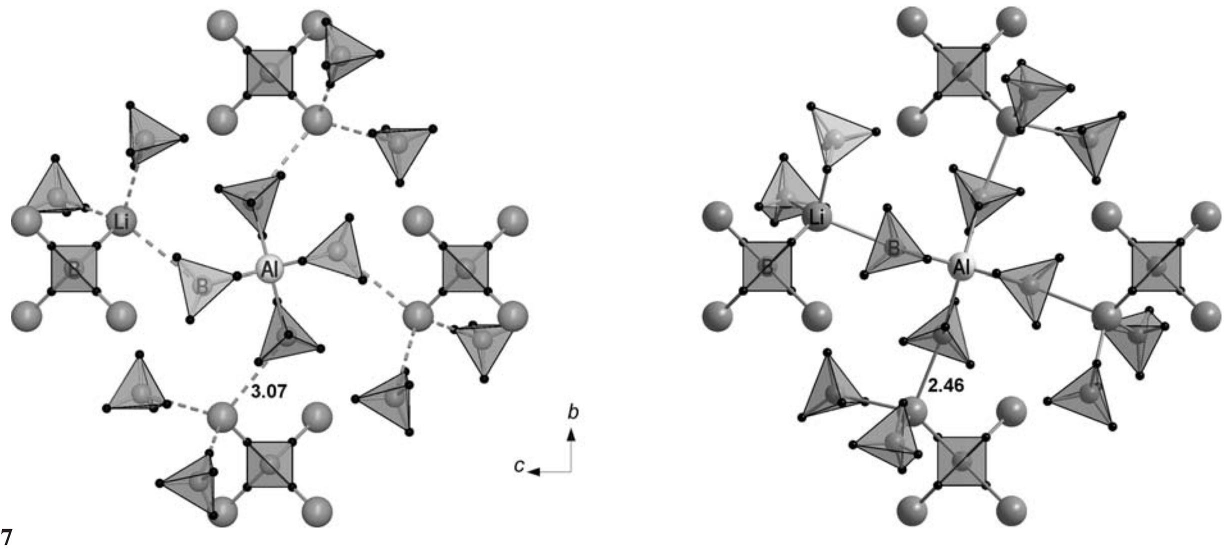

Figure 4.5.7
Structural model of $Li_4Al_3(BH_4)_{13}$ as solved from synchrotron XPD (left) and as corrected by DFT optimization (right). The Li–BH_4 contact changing the structure interpretation from ionic packing to a framework structure is 3.07 Å in the XPD structure (dashed) and 2.46 Å in the DFT structure (solid).

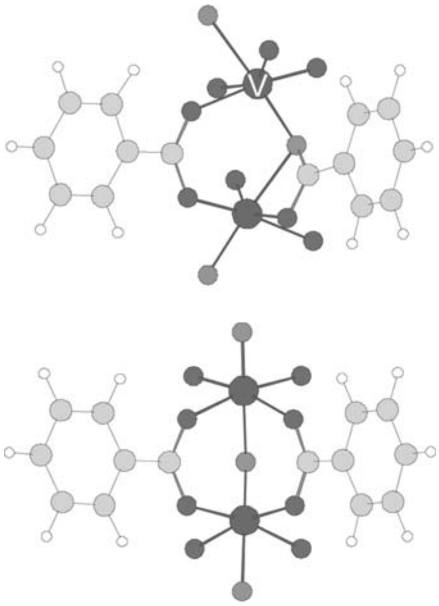

Figure 4.5.8
Structural fragment of a nanocrystalline inorganic–organic hybrid compound $VO(C_6H_5COO)_2$ (Djerdj *et al.*, 2009). The connectivity of VO_6 octahedra as proposed by DSM using synchrotron XPD (top) was corrected by DFT optimization (bottom).

pinpoint unlikely configurations. Again, if the valences are known *a priori*, they can be used as a criterion for the DSM optimization of the structure.

The third step should be a post-experiment optimization of the structure based on crystal energy minimization such as using DFT. This helps to validate new structures, locate light atoms (hydrogen) (especially when using high-pressure diffraction data) and even correct the symmetry and some structural details as shown by the following examples.

In the case of $Li_4Al_3(BH_4)_{13}$ (space group $P\bar{4}3n$) the DFT optimization (Lindemann *et al.*, 2010) of the experimental structure corrected the orientation of the complex anion $[Al(BH_4)_4]^-$ and so modified the bonding scheme in the structure from isolated complex ions $[(BH_4)Li_4]^{3+}$ and $[Al(BH_4)_4]^-$ to a three-dimensional framework structure. The corrected model was confirmed by the Rietveld refinement (Fig. 4.5.7).

A similar situation occurred for a nanocrystalline inorganic–organic hybrid compound $VO(C_6H_5COO)_2$ (Djerdj *et al.*, 2009), where the correct connectivity of VO_6 octahedron was revealed by DFT optimization of a structural model proposed by DSMs using synchrotron XPD (see Fig. 4.5.8).

The post-experimental DFT optimization of inorganic crystal structures allows the global minimum in Rietveld refinement to be reached, which is not easily done using only the diffraction data, and can be thus highly recommended. It is, however, important to keep in mind that *ab initio* calculations go beyond the validation of powder diffraction results. The DFT calculations may be a substitute for Rietveld refinement, and provide more accurate atomic positions. A variety of computer programs for theoretical calculations in the solid state are available, and most of them can be easily run on a PC. More details of the choices of computer programs can be found in a review from an Erice School in 2011 (Smrčok, 2011).

4.5.4. Examples

4.5.4.1. *Polyhedral compounds*

Metal oxides and salts are the most typical polyhedral compounds. Pauling's crystal-chemical rules are usually valid and allow for easy definition of PBUs. Typically, symmetry-guided algorithms are applied to this type of compound (Evans *et al.*, 2003). Although the use of DSMs is very beneficial for polyhedral compounds, one of the most complex polyhedral structures was solved *ab initio* from powder diffraction data using reciprocal-space techniques. This was a non-perovskite, $LaTi_2Al_9O_{19}$, which was originally solved with 60 atoms (Morris *et al.*, 1994) but was later shown to contain 31 atoms in the asymmetric unit (Kasunič *et al.*, 2011). Integrated intensities were extracted by Le Bail fit from a synchrotron powder pattern, and the structural model obtained by direct methods (*MULTAN84*; Main *et al.*, 1984) was then refined by Rietveld refinement (using *GSAS*). The structure was then revised based on BVS calculations and Rietveld refinement using the structural model from compounds with the same chemical composition.

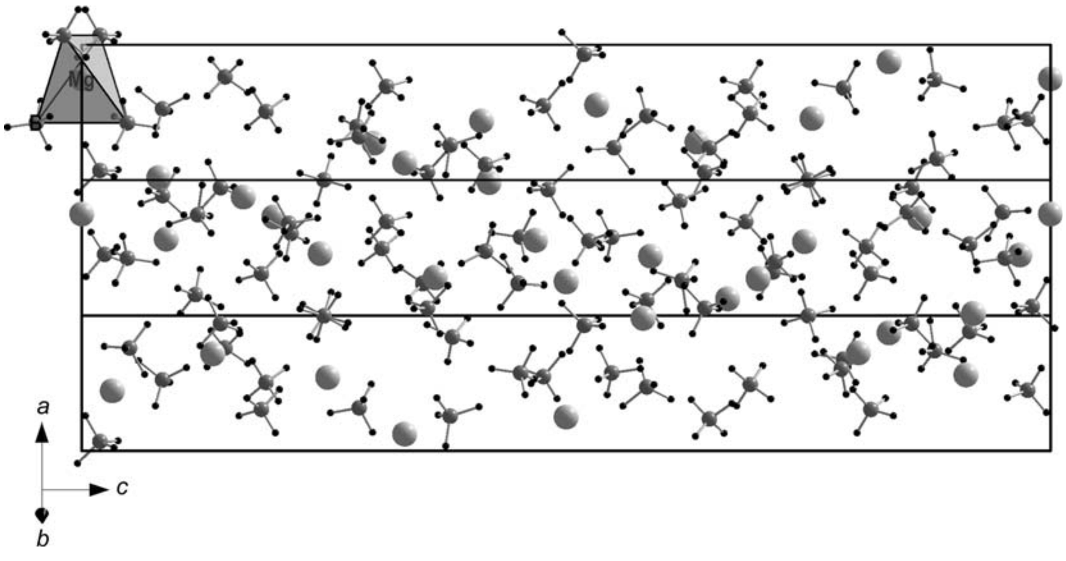

Figure 4.5.9
Structural model of $Mg(BH_4)_2$ as solved from XPD using a DSM (Černý *et al.*, 2007) and corrected by DFT optimization (Dai *et al.*, 2008) by incorporating the previously overlooked twofold axes of the space group $P6_122$, and finally refined against single-crystal data (Filinchuk *et al.*, 2009). The structure was modelled using five free Mg atoms and ten rigid tetrahedral BH_4 groups. Modelling using a super-tetrahedron $Mg(BH_4)_4$ (in grey) as an SBU did not improve the convergence of the DSM.

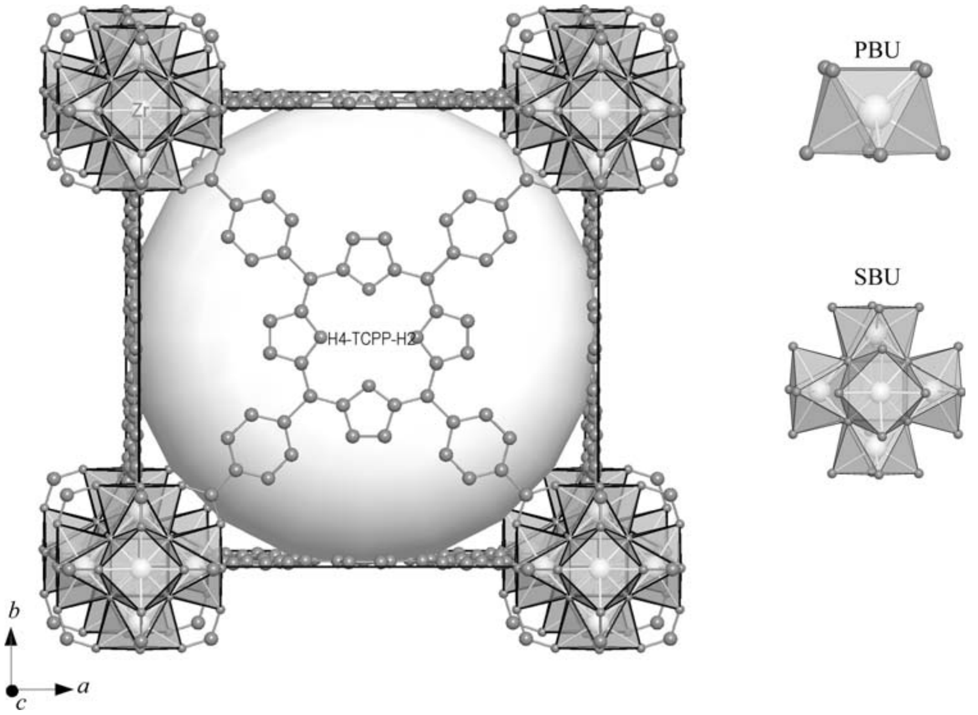

Figure 4.5.10
The crystal structure of MOF-525 (Morris *et al.*, 2012) built from the cuboctahedral SBU $Zr_6O_4(OH)_4$ connected by tetracarboxyphenylporphyrin (H_4-TCPP-H_2) linkers. H atoms are omitted for clarity. The SBU is built from six square-antiprismatic ZrO_8 PBUs. The resulting three-dimensional framework contains pores with a diameter of 20 Å, shown as a large sphere.

Zeolite structures are built from TO_4 tetrahedra as framework structures, and topology-guided algorithms for framework building are the most efficient for solving the structures of these compounds (see Chapter 4.6).

Magnesium borohydride $Mg(BH_4)_2$ (Černý *et al.*, 2007; Her *et al.*, 2007) can be also described as a polyhedral compound. Magnesium is tetrahedrally coordinated to four species which are, however, not single atoms but complex anions: $[BH_4]^-$ tetrahedra (Fig. 4.5.9). Starting from this complexity of anion, the advantage of modelling the structure from PBUs (magnesium coordination polyhedra) is lost, and better results are obtained from magnesium free atoms and the tetrahedral complex anion $[BH_4]^-$. Information on the cation coordination, which is *a priori* unknown but accessible from Raman and IR spectroscopies, may be used as an SBU in an antibump cost function.

This study is an excellent example of the power of both DSMs and RSMs in solving complex structures when well crystallized samples provide high-resolution powder diffraction data. With 55 atoms in the asymmetric unit, this compound represents one of the most complex structures ever solved from powder diffraction data. The correct structure was found independently by a DSM using the reverse Monte Carlo algorithm (Černý *et al.*, 2007) and by an RSM (Her *et al.*, 2007). In both cases high-resolution synchrotron data were required for indexing. In the DSM approach, the structure was modelled by five free Mg atoms and ten rigid tetrahedral BH_4 groups, and optimized jointly with synchrotron and neutron data. In the RSM approach, the structure was solved using only synchrotron data. The positions of Mg and B atoms were recognized in electron-density maps. In both cases the structure was refined by Rietveld refinement keeping the borohydride groups rigid. The difficulty in finding the correct orientation of BH_4 tetrahedra led to the overlooking of twofold axes in the $Mg(BH_4)_2$ space-group symmetry, which was originally identified as $P6_1$. The DFT optimization of the structural model (Dai *et al.*, 2008) suggested that the true symmetry was $P6_122$, which was then unambiguously confirmed by single-crystal X-ray diffraction (Filinchuk *et al.*, 2009). The fact that the structure solution was found independently by a DSM and an RSM in the lower Laue symmetry $6/m$ of the space group $P6_1$ rather than in the true Laue symmetry $6/mmm$ of the true space group $P6_122$ can also be understood by the presence of more degrees of freedom (*hkl* and *khl* are independent in $P6_1$) in $6/m$, which allowed for correction of systematic errors in the powder diffraction data (arising from grain statistics) of symmetry $6/mmm$.

A structure of similar complexity to $Mg(BH_4)_2$ can be solved even from low-resolution powder data provided that there is low noise in the data. This was the case for $Mn(BH_4)_2$ (Černý *et al.*, 2009) using an area detector and Debye–Scherrer geometry. The advantages of this setup, which allows *in situ* studies, are the simple sample environment and fast data collection, high data-collection rates, excellent time resolution, highly accurate measurements of diffracted intensities (good powder average) and a lower sensitivity to preferred-orientation effects. A combination of high counting rates with excellent reciprocal-space resolution provided by curved solid-state detectors (Mozzanica *et al.*, 2009) allows even more complex structures to be studied *in situ*. The use of a DSM was the only choice in the case of $Mn(BH_4)_2$, as the low-resolution powder pattern did not allow the extraction of reliable integrated intensities of overlapping reflections.

4.5.4.2. *Hybrid compounds*

Hybrid compounds are solved by various methods, but topology-guided algorithms are most specific to these types of compounds. Large MOF structures such as chromium terephthalate, MIL-101, having a cell volume of 702 000 $Å^3$, can be solved by topology-guided algorithms (Férey *et al.*, 2005). Zirconium MOF-525 is a good example of a successful application of such an algorithm to a hybrid compound (Morris *et al.*, 2012). The crystal is built from a zirconium(IV) cuboctahedral SBU, $Zr_6O_4(OH)_4$. This 12-connected SBU is then linked with 4-connected tetracarboxyphenylporphyrin (H_4-TCPP-H_2) linkers to make a three-dimensional MOF. On the basis of the connectivity of the BUs, initial structure matches were generated using nets that appear in the reticular chemistry structural resource (RCSR) (Ockwig *et al.*, 2005), a procedure that is frequently used to resolve COF structures (Côté *et al.*, 2007). Only three topologies in the RCSR combine 12,4-connected components. One was excluded because it incorporates tetrahedra, a geometry that is not accessible with the porphyrin BU. Another topology was excluded because the geometry of the 12-coordinate BU is not cuboctahedral. This allowed the identification of the only topology compatible with the local coordination in the BUs, which was then confirmed by Rietveld refinement, giving a cubic

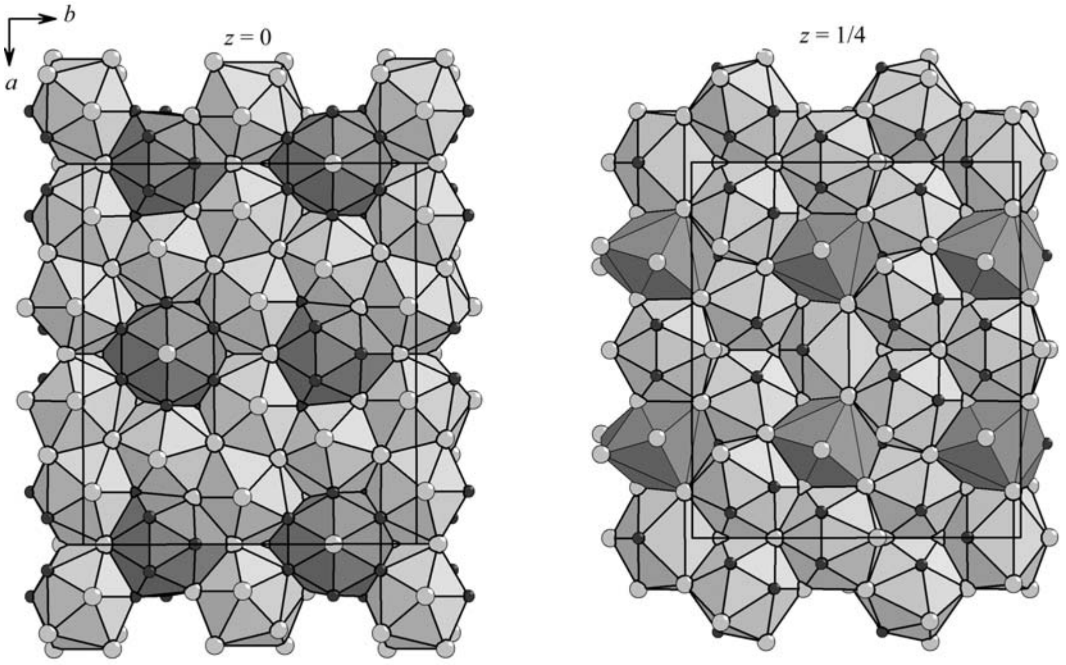

Figure 4.5.11
The crystal structure of the close-packed intermetallic phase MgIr (Černý *et al.*, 2004). The structure can be built from two layers perpendicular to the *c* axis situated at $z = 0$ and 1/4. The PBUs are then Ir-centred icosahedra (light grey) and Mg-centred Frank–Kasper polyhedra at $z = 0$ or Ir-centred polyhedra with a coordination number of 11 at $z = 1/4$ (dark grey). Owing to the difficulty in identifying the nature of the ligands in the polyhedra, modelling from isolated atoms was a better choice.

structure with cell volume of 7294 Å^3 containing pores 20 Å in diameter (Fig. 4.5.10).

4.5.4.3. *Close-packed compounds*

Topologically close-packed intermetallic phases are a difficult case for DSMs because of the complexity of BU choice. The compound MgIr contains 13 Ir and 12 Mg atoms in the asymmetric unit (Černý *et al.*, 2004). Its structure was originally solved from synchrotron XPD data using a DSM, and the structure was confirmed using single-crystal X-ray data. No additional information on the coordination of the Ir and Mg atoms was available, and the coordination number in close-packed phases can vary between 12 and 16. As a consequence, the structural model was built from isolated atoms (Fig. 4.5.11). The crystal structure was expected to be close packed, therefore the expected volume per atom was estimated to be 15–20 Å^3, giving between 250 and 330 atoms in the unit cell. In a final run (repeated many times) 13 Ir and 12 Mg free atoms were optimized simultaneously (75 DoF), and the same solution was always found in less than 5 min.

The final structure can be built from seven icosahedra centred on iridium with a different ratio between Mg and Ir atoms as ligands. Consequently, modelling with seven rigid icosahedra as PBUs was attempted, lowering the number of DoF to 42. Nevertheless, the convergence of this modelling was ~10 times slower, clearly owing to the fact that the icosahedra are not ideal (the central-atom-to-ligand distance varies between 2.45 and 3.52 Å) and owing to the problems with ligand identification. If the identification is carried out by the optimization algorithm using a random change ('swapping'), the DoF increases by 12 per icosahedron, and no associated increase in the optimization convergence was achieved.

4.6. Zeolites

L. B. McCusker and Ch. Baerlocher

4.6.1. Introduction

Zeolites are a class of microporous aluminosilicate framework materials with diverse industrial applications (Cejka *et al.*, 2007). Whether they are used as catalysts, desiccants, adsorbents, ion-exchangers or hosts for nanoparticles, the key to the suitability of a zeolite for a specific purpose lies in its structure. In general, a zeolite consists of a relatively rigid, anionic and microporous framework structure constructed from corner-sharing TO_4 (T = Si, Al, P or any other tetrahedrally coordinated cation) tetrahedra. The pores form channels and/or cavities of molecular dimensions. Within these voids there are cations (organic or inorganic) that compensate for the negative charge of the framework and water or solvent molecules that fill the rest of the space. The inorganic cations are generally labile and can be exchanged to some extent; organic cations can usually be burned off leaving just protons in the zeolite; and the water or solvent can be removed by simple heating without destroying the framework structure. For many applications, the calcined (heat-treated) form is used, because the pores are then accessible to other molecules.

The Structure Commission of the International Zeolite Association evaluates new 4-connected framework structures as they are reported, and if the framework connectivity is new and the structure analysis is considered to be reliable, a three-letter framework type code is assigned. The most recent printed information on these framework types is given in the *Atlas of Zeolite Framework Types* (Baerlocher, McCusker & Olson, 2007), but for up-to-date information the reader is referred to the *Database of Zeolite Structures,* which is freely available at http://www.iza-structure.org/databases. The latter is updated each time new codes are approved. In the rest of this chapter, relevant framework-type codes will be indicated in bold in parentheses.

Of the 231 zeolite framework types officially recognized by March 2016, only about half of them (107) were determined from single-crystal X-ray diffraction data. Seven more were solved from single-crystal electron-diffraction data. The remaining 117 were solved in one way or another from powder diffraction data (Fig. 4.6.1). Indeed, most newly synthesized silicate-based zeolites, which are of particular interest for industrial applications, are polycrystalline. As a result, a variety of methods for solving zeolite structures from powder diffraction data have been developed over the years (Fig. 4.6.2). Initially, the only option available was model building by hand (67 framework types). However, as the quality of powder diffraction data improved and computing power increased, other approaches became feasible. These included modifying classical direct methods to accommodate the limitations of powder diffraction data (19 framework types), automating some of the principles used in model building in the computer programs *Focus* (22 framework types) and *ZEFSA II* (3 framework types), and adapting the charge-flipping algorithm to deal with overlapping reflections (6 framework types). Each of these approaches to solving the initial phase problem will be described in Section 4.6.2.

However, there is more to a zeolite structure than the connectivity of its framework. For example, where are the non-framework cations and molecules and how are they bonded? What happens to the geometry of the framework and the positions of the non-framework species upon calcination and/or ion exchange? Where are the isomorphously substituted cations (*e.g.* Ge) in the framework? These questions are generally answered during the course of the structure refinement process, which is described in Section 4.6.3.

4.6.2. Framework structure determination

When a novel zeolitic material is found or produced, the first question is what its framework structure looks like. Is it new?

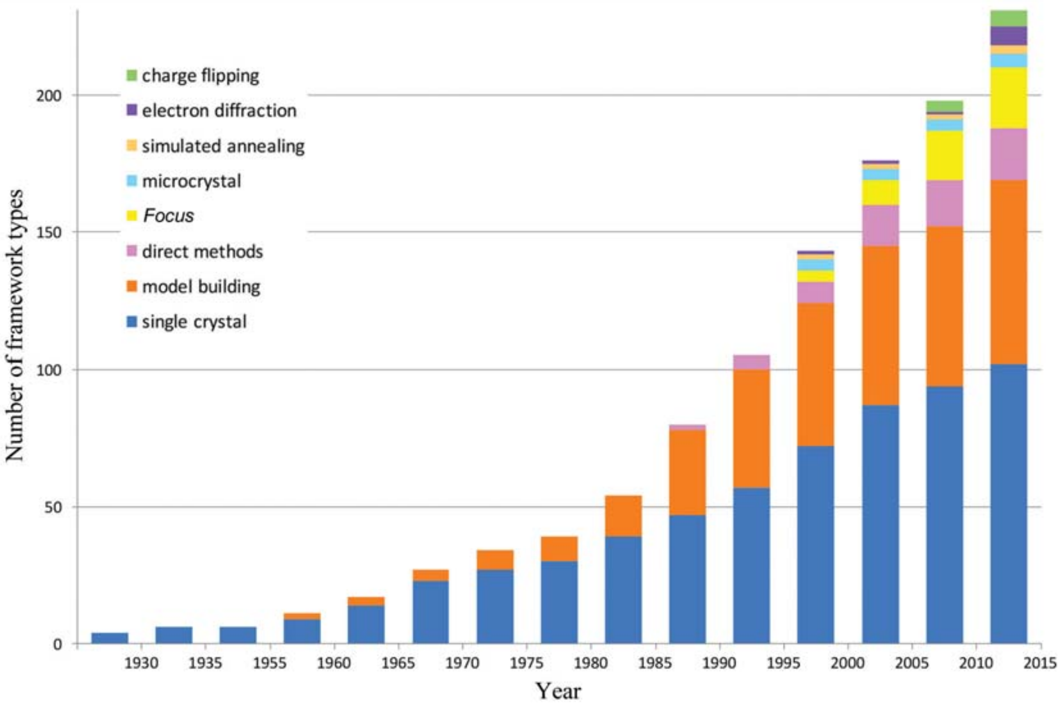

Figure 4.6.2
The evolution of methods used to solve zeolite framework structures.

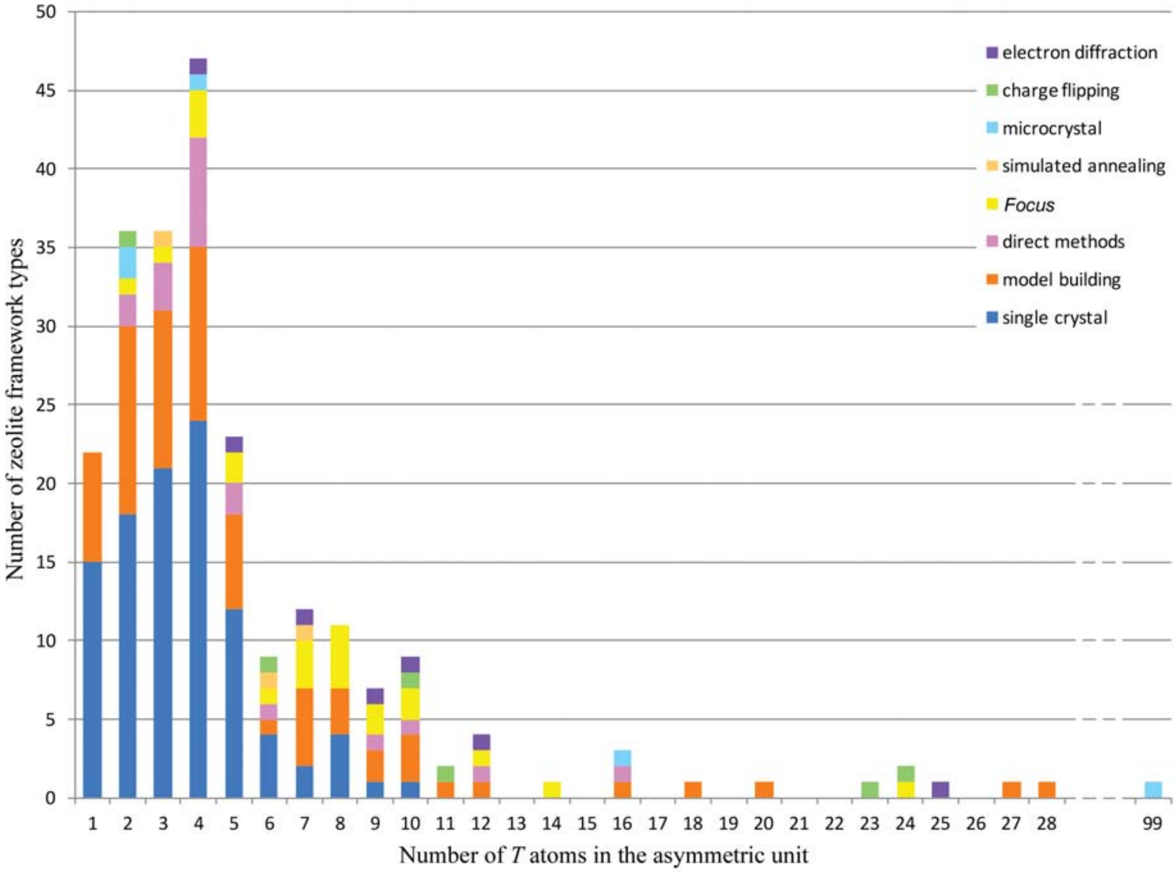

Figure 4.6.3
A histogram of the number of *T* atoms in the asymmetric unit for the 231 zeolite framework types, showing the methods used to solve their structures.

What kind of channel system does it have? If there are no single crystals available, X-ray powder diffraction techniques are usually applied to solve the initial phase problem and thereby establish the basic framework structure. There are different ways of viewing the complexity of a zeolite structure, but for the initial phasing process, the number of *T* atoms in the asymmetric unit is generally a good indicator, so these numbers are given along with the framework type code in the following sections. It is worth noting that 85% of the 231 framework types shown in Fig. 4.6.1 have 8 or fewer *T* atoms in the asymmetric unit (Fig. 4.6.3). These can generally be solved in a relatively straightforward manner. It is the last 15% that pose a challenge to powder diffraction techniques, and no single approach has emerged as being the best for these structures.

The normal approach for determining whether or not a new material has a known framework structure is to compare the measured powder diffraction pattern with those of all known zeolites. The simulated powder patterns for zeolites published by Treacy & Higgins (2007) or those available *via* the *Database of Zeolite Structures* can be used for this purpose. The latter have the advantage that they can be adjusted to reflect the peak shape and wavelength of the experimental pattern, but they must be generated and examined individually. The ICDD database of experimental powder diffraction patterns (http://icdd.com/products/), on the other hand, can be scanned automatically with a search/match routine, but the user must bear in mind that not all zeolites are present in this database, although efforts are underway to include them. This is why most synthesis laboratories have their own libraries, containing patterns taken from both experiments and the literature, for such searches. The low-angle reflections in a zeolite powder diffraction pattern are particularly sensitive to the extra-framework species in the pores (*e.g.* cations, water, organic structure-directing agent), so the initial comparison is best done in the mid- to high-angle region of the pattern. A new chemical composition may also alter the symmetry quite dramatically, and thereby obscure a structural relationship. In such cases, the identification of the unit-cell dimensions as discussed in the next section may help.

4.6.2.1. *Preliminary steps*

In order to progress to structure determination, the powder diffraction pattern must first be indexed, and this can be hindered by the presence of impurities. Because the synthesis conditions for zeolites only have to be changed very slightly in some cases to produce an entirely different zeolite, syntheses usually have to be optimized for a particular product. Even so, impurities cannot always be avoided. If the impurity can be identified, its diffraction pattern can be calculated and taken into account in the subsequent steps. However, if it is not identified, it is more difficult to judge which peaks belong to the phase of interest and which do not. The shapes of the peaks of the impurity phase are sometimes different enough from those of the majority phase to be distinguished (*e.g.* very sharp peaks from a salt or much broader peaks from a second zeolite phase that has crystallized under non-ideal conditions). If this is not the case and an impurity is suspected, the product from a second synthesis can be measured. It is unlikely that the amount of impurity will be identical in two independent syntheses, so the patterns can be compared to see if the relative intensities of a set of peaks differ in a consistent manner. Of course, scanning electron microscopy images can also be used to evaluate the purity of the material, and electron diffraction can also be used to facilitate indexing in difficult cases.

Once the unit cell has been established, the determination of the space group can be attempted. Systematic absences may be obscured by reflection overlap, so again electron diffraction may be useful to discriminate between the possible space groups. ^{29}Si magic angle spinning (MAS) NMR can also provide some useful information on the symmetry of pure SiO_2 materials, because there should be a signal for each crystallographically independent Si site with intensities corresponding to the multiplicities of the positions. Often several space groups have to be tried one at a time in the structure-determination procedure.

Once a unit cell and space group have been determined, the positions of the allowed reflections are known, and a profile fit, either LeBail (2005) or Pawley (1981), can be performed (see Chapter 3.5). Although it is generally relatively easy to define a peak-shape function that describes the profile of a single reflection in the pattern, it is not always easy to describe the whole pattern with this peak shape. The morphologies of zeolitic materials often exhibit extreme aspect ratios (*e.g.* long needles or thin platelets), and this leads to *hkl*-dependent (anisotropic) line broadening. In such cases, the *hkl* dependence (*e.g.* all 00*l* reflections are broader or sharper than the rest) must be determined and one or more anisotropic line-broadening parameters need to be refined.

The better the calculated diffraction pattern fits the experimental data, the more reliable the extracted reflection intensities. This is especially true for partially overlapping reflections, so for more complicated structures some extra effort at this stage can be worthwhile. Once a satisfactory profile fit has been achieved, structure solution can begin.

4.6.2.2. *Model building*

The classical approach to zeolite-framework structure determination is model building, and it is still used today in difficult cases where the more automated methods fail. The idea is to gather all the information known about the material from different characterization techniques (*e.g.* chemical analysis, thermogravimetric analysis, density determination, MAS NMR, IR spectroscopy, X-ray powder diffraction, electron microscopy) and to build a model that is consistent with all of these data. The powder diffraction pattern for this structural model is then calculated (using the peak-shape parameters determined in the previous step) and compared with the measured one. At this point it is the higher-angle data that are most important for the comparison, because the lower-angle (lower-resolution) data will be strongly affected by the presence of cations and molecules in the channels and cavities. If the fit looks promising, structure completion and refinement can be attempted (see Section 4.6.3). If it does not, the model needs to be modified and the procedure repeated.

One of the first zeolites to be synthesized in the laboratory was zeolite A (**LTA**, Breck *et al.*, 1956). The chemical composition was determined to be $NaAlSiO_4{\cdot}2.25H_2O$ and the density was 1.99 g cm^{-3}. Its powder diffraction pattern clearly indicated a cubic unit cell with $a \simeq 12.3$ Å and no systematic absences. By combining these pieces of information, the composition per unit cell could be estimated to be $|Na_{12}(H_2O)_{27}|[(Si,Al)_{24}O_{48}]$ [see McCusker *et al.* (2001) for a description of the |guest|[host] nomenclature recommended by IUPAC for microporous materials] with a total of 24 *T* atoms (12 Si and 12 Al) in a unit-cell volume of 1860 Å^3. Indeed, one of the characteristics of zeolite framework structures is that they normally have between 12 and 20 *T* atoms per 1000 Å^3. Adsorption experiments showed that only small molecules (with a kinetic diameter of less than 3.6 Å) could be adsorbed into the calcined material, and this indicated that the pore opening was probably an 8-ring (a ring formed by 8 corner-sharing TO_4 tetrahedra). This information alone was sufficient to deduce the framework structure, which has 8-rings arranged on the faces of a cube (Fig. 4.6.4). All 24 *T* atoms in the unit cell are related to one another by symmetry (*i.e.* it is a 1 *T* atom structure). If the strict alternation of the Si and Al atoms is also taken into account, the lattice parameter *a* must be doubled and the space group becomes $Fm\bar{3}c$.

A more recent and more complicated structure solved by model building is that of SSZ-59 (**SFN**, 8 *T* atoms, Burton *et al.*,

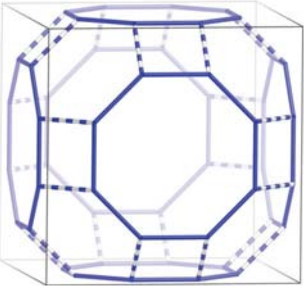

Figure 4.6.4
The framework structure of zeolite A (**LTA**) showing the 8-rings on the surfaces of the cubic unit cell and the linkages between them to form the *lta* cavity. Bridging O atoms have been omitted for clarity.

2003). In this case, it proved to be difficult to index the powder diffraction pattern satisfactorily. However, there was a strong reflection corresponding to a *d*-spacing of 2.51 Å, which was thought to be indicative of a 5 Å repeat distance. The adsorption capacity was very similar to that of UTD-1 (**DON**, 5 *T* atoms), which has one-dimensional 14-ring channels. Burton and co-workers therefore considered all framework structures with (1) 'butterfly units', which are typical of high-silica zeolites, (2) one-dimensional 10- or 12-ring channels and (3) 5 Å repeat distances along the channel.

This led to the frameworks **TON** (4 *T* atoms), **MTT** (7 *T* atoms) and **MTW** (7 *T* atoms). The concept of σ expansion (Barrer, 1978) between butterfly units to generate structures with 14-ring channels was then applied (Fig. 4.6.5). That is, the *T*–*T* linkage shared by neighbouring 'butterfly' units was replaced with a 4-ring. The idealized framework structures of the disordered zeolites ZSM-48 (***MRE**, 4 *T* atoms) and SSZ-31 (***STO**, 28 *T* atoms) are related to UTD-1 (**DON**) in a similar manner. Other variants of the expanded **MTW** framework in which layers were related by mirror planes rather than translation were also generated. The powder patterns calculated for these different models were quite distinct, and the measured pattern of SSZ-59 matched that of the expanded **MTW** framework very well. Subsequent Rietveld refinement (Rietveld, 1969) confirmed that this framework was the correct one.

It is obvious that model building is a time-consuming approach to structure solution that is strongly dependent upon the experience, ingenuity and patience of the model builder. Fortunately, alternatives have been developed over the last 20 years or so. These methods generally require computing power that was not available 30 years ago but is commonplace today. The high resolution of reflections in a powder diffraction pattern that can now be achieved at both laboratory and synchrotron sources has also contributed significantly to the development of several of these methods.

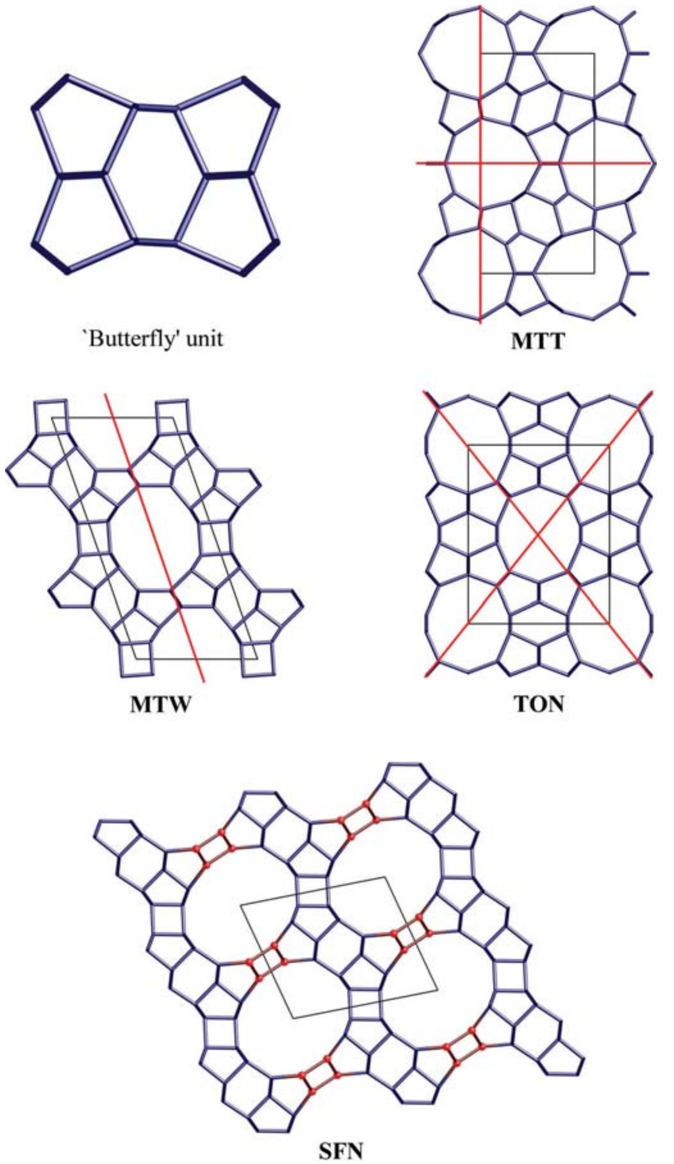

Figure 4.6.5
The 'butterfly' unit and projections of the three 10- and 12-ring framework types that have this unit, one-dimensional channels and a 5 Å repeat along the channel. The red lines indicate where a σ expansion could be applied between 'butterfly' units to create 14-rings. The *T*–*T* linkages along these lines would be expanded to 4-rings. The correct structure of SSZ-59 (**SFN**) is shown with the 4-rings resulting from the σ expansion of **MTW** highlighted.

Of course, an obvious way of advancing model-building technology is to use a computer algorithm to build the models and to test them against the measured data in an automatic manner. The first steps in this direction were taken by Deem & Newsam (1989). They used a simulated-annealing approach in which the cost function was based on pseudo-potentials for *T*–*T* distances, *T*–*T*–*T* angles and the number of *T*–*T* connections, which were derived from known zeolite structures. The unit cell, space group, the number of *T* atoms per unit cell and the number of unique *T* atoms were assumed to be known. This proof-of-principle study was developed further by Falcioni & Deem (1999) to include the powder diffraction pattern in the cost function, to introduce a biased Monte Carlo approach for the *T*-atom moves, and to incorporate parallel tempering into the annealing procedure. The latter allows the annealing scheme to be optimized by running several 'temperatures' in parallel and swapping between temperatures during the course of the simulated-annealing run. The program *ZEFSA II* was written by the same authors and can be downloaded without charge from http://www.mwdeem.rice.edu/zefsaII/. In addition to numerous known zeolites used by the authors to test the program, three novel structures, those of the aluminophosphate UiO-6 (**OSI**, 3 *T* atoms, Akporiaye *et al.*, 1996) the aluminosilicate ERS-7 (**ESV**, 6 *T* atoms, Campbell *et al.*, 1998) and the germanosilicate SSZ-77 (**SVV**, 7 *T* atoms, Earl *et al.*, 2008) were solved using this approach.

4.6.2.3. *Focus*

In model building, the powder diffraction pattern is used passively to check the resulting model. However, such data contain valuable structural information that might be harnessed to facilitate the model building. It was with this in mind that the program *Focus* (http://www.iza-structure.org/ under Other Links: Software) was devised (Grosse-Kunstleve *et al.*, 1997). It was reasoned that some of the ideas used in zeolite model building could be incorporated into a program to interpret electron-density maps generated using the diffraction data. A flowchart of the algorithm is shown in Fig. 4.6.6.

The structure-factor amplitudes extracted from the powder diffraction pattern are assigned random phases to generate an electron-density map. Because the phases are random, so is the map. Nonetheless, the program looks for a zeolite framework fragment in the peaks in the map, ignoring the heights of the peaks. It then takes the largest framework fragment it can find as a partial model and generates a new set of phases to combine with the measured amplitudes. This Fourier recycling procedure is then repeated until the phases converge or the maximum number of cycles is reached. It was found that alternating the largest framework fragment interpretation of the electron-density map with a more standard assignment of the heavier atoms to the larger peaks (but maintaining user-defined minimum distances between the different atom types) led to the fastest convergence, so that procedure is generally used. When the Fourier recycling procedure is finished, a new run is started with a new set of random phases.

Each time an electron-density map is produced, the program also searches for a complete 4-connected framework structure. If one is found it is classified and written to a file. The classification is based on coordination sequences (Brunner & Laves, 1971) rather than atomic coordinates, because the solutions may have different unit-cell origins. For each independent *T* atom in the framework, the number of next-nearest-neighbour *T* atoms (usually 4) is established. Then the number in the next shell of *T* atoms is counted (to a maximum of 12), and so on for ten shells. In most cases, these sets of coordination sequences are sufficient to distinguish one framework from another, but there are a few exceptions. Therefore, the vertex symbol (O'Keeffe & Hyde, 1997), which describes the smallest rings associated with the six tetrahedral angles of each *T* atom, is also used in the classification.

As the file of solutions grows, one usually dominates. It is found over and over again from different starting points. This is usually the correct framework structure and can be used as a starting point for structure completion and refinement (Section 4.6.3). As the number of independent *T* atoms in the framework increases, the number of possible solutions tends to decrease, so the histogram of the solutions for complex structures may consist of just a single result. Several examples of the application of the *Focus* method to structures of different complexities are described by Grosse-Kunstleve *et al.* (1999). One of the more recent applications was the solution of the structure of the borosilicate SSZ-56 (**SFS**, 14 *T* atoms) (Elomari *et al.*, 2009).

The *Focus* algorithm was recently adapted to work with electron-diffraction data. Tests showed that structure solution with such data, which may be incomplete or of poor quality, also benefits significantly from the additional chemical information (Smeets *et al.*, 2013).

4.6.2.4. *Direct methods*

Of course, the very powerful direct methods of structure solution developed originally for single-crystal data can also be applied to polycrystalline zeolites. However, it must be borne in mind that this approach relies heavily upon knowing which reflections are strong and which are weak, so the ambiguity arising from reflection overlap can have serious consequences. In simple cases, where reflection overlap is not too severe, a simple equipartitioning approach in the reflection-intensity extraction step can yield intensities of sufficient reliability to use single-crystal programs directly. This was done in the case of the high-silica zeolite Sigma-2 (**SGT**, 4 *T* atoms), for example (McCusker, 1988).

For more complex structures, where reflection overlap cannot be ignored, the computer programs *EXPO* (Altomare *et al.*, 2011) or *XLENS* (Rius & Frontera, 2007), which have been written specifically to work with powder diffraction data, are more likely to succeed. Examples include the structure of the germanosilicate IM-20 (**UWY**, 10 *T* atoms), which was solved using *EXPO* (Dodin *et al.*, 2010) and those of the germanosilicate ITQ-22 (**IWW**, 16 *T* atoms, Corma *et al.*, 2003) and the high-silica zeolite ITQ-32 (**IHW**, 9 *T* atoms, Cantin *et al.*, 2005), which were solved using *XLENS*.

4.6.2.5. *Charge flipping*

Model building is done in real space, whereas direct methods work with the diffraction data in reciprocal space. In the former, the diffraction pattern is used as a test of the correctness of the structure, while in the latter, chemical sense is used. In contrast, both diffraction data and chemical knowledge are used actively in the *Focus* algorithm. That is, it is a hybrid method working in both real and reciprocal spaces. Charge flipping, introduced for single-crystal data by Oszlányi & Sütő (2004, 2005) and adapted independently to powder diffraction data by Wu *et al.* (2006) and Baerlocher, McCusker & Palatinus (2007), is also a hybrid method. Its advantage over the *Focus* algorithm is that it is applicable to all types of materials, not just zeolites.

The algorithm is an elegantly simple one (Fig. 4.6.7). It begins in much the same way as *Focus*, by applying random phases to the extracted structure factors to generate a (random) electron-density map. Then instead of trying to interpret the map as

in *Focus*, the map itself is perturbed (in real space) by changing the sign of all densities below a user-defined threshold value (a small positive number). In essence, all negative electron densities, which are not physically meaningful, are made positive. A Fourier transform of this perturbed electron-density map yields a new set of structure-factor amplitudes and phases (reciprocal space). The new phases are assigned to the measured amplitudes and a new electron-density map is generated. In the single-crystal case, this procedure is repeated until the calculated amplitudes match the measured ones. For polycrystalline materials, however, some of the measured amplitudes are ambiguous, because of reflection overlap. The total intensity measured for each group of overlapping reflections (overlap group) is usually simply equipartitioned over the contributing reflections. In an attempt to improve this partitioning somewhat, an additional perturbation of the electron-density map based on histogram matching (Zhang & Main, 1990) was introduced into the powder charge-flipping algorithm in the program *Superflip* (Baerlocher, McCusker & Palatinus, 2007; Palatinus & Chapuis, 2007). The map is modified to match a histogram that reflects the chemical composition of the material (*i.e.* the number and height of the peaks in the map should correspond to the chemical formula), and the ratios of the structure-factor amplitudes obtained by Fourier transformation of this modified map are then used to repartition the measured intensity for each overlap group.

This approach is still quite new, but has already been used to solve six zeolite framework structures. A typical example is that of the aluminosilicate LZ-135 (**LTF**, 6 *T* atoms, McCusker *et al.*, 2009).

4.6.2.6. *Using additional information*

Even with all the methods described above at our disposal, some zeolite structures resist solution. In such cases, additional information is needed to supplement the powder diffraction pattern. Chemical knowledge is already used in *Focus* and *Superflip*, and in the more recent versions of *EXPO*, but there are also other possibilities.

In particular, partial phase information has proven to be a powerful enhancement. For example, the concept of a structure envelope (Brenner *et al.*, 1997), which is closely related to the molecular envelope used in protein crystallography, can be used to describe the pore system of a zeolite. Given the amplitudes and phases of just a few low-index reflections, such an envelope can be calculated. This periodic nodal surface (von Schnering & Nesper, 1991), which separates regions of high electron density from those of low electron density at a relatively low resolution, can be used to limit the parts of the unit cell in which the framework atoms are sought (Brenner *et al.*, 2002). Such an envelope can be enforced in both *Focus* and *Superflip*.

The phase information for the calculation of a structure envelope can sometimes be estimated from the powder diffraction data itself, but if a high-resolution transmission electron microscopy (HRTEM) image is available, the phases can be derived from the image (Hovmöller, 1992). This approach was used, for instance, in the solution of the very complex structure of the high-silica zeolite SSZ-74 (**-SVR**, 23 *T* atoms, Baerlocher *et al.*, 2008). In that case, the structure envelope was imposed in *Superflip* in real space (Fig. 4.6.8).

If the HRTEM images are of sufficiently high quality, more phase information can be extracted, and this can be included in the reciprocal-space part of any structure-solution algorithm. For TNU-9 (**TUN**, 24 *T* atoms), 258 phases were derived from three images, and only when these phases were included as starting phases in *Focus* could the structure be solved (Gramm *et al.*, 2006). In the case of IM-5 (**IMF**, 24 *T* atoms), starting phase sets were generated from an approximate model derived from HRTEM images. These phase sets (phases calculated from the model and then allowed to vary by a certain percentage in a random fashion) were then used as starting points for *Superflip* runs (Baerlocher, Gramm *et al.*, 2007).

Not only electron microscopy, but also electron-diffraction data can be used to supplement powder diffraction data. For example, in the case of the germanosilicate ITQ-37 (**-ITV**, 10 *T* atoms, Sun *et al.*, 2009), selected-area electron-diffraction patterns were used to pre-partition the overlapping reflections before the data were input to *Superflip*. It has also been shown that the phases obtained by applying two-dimensional (single-crystal) charge flipping to precession electron diffraction (PED) data are as reliable as those obtained from HRTEM images (Xie *et al.*, 2008). This means that the much simpler PED technique is a viable alternative to HRTEM for obtaining some starting phases to facilitate structure solution.

The fact that PED data can be used in this way led to a further development on the X-ray powder diffraction front. It was found that two-dimensional subsets of the reflection intensities extracted from a powder diffraction pattern could be used in much the same way (Xie, Baerlocher & McCusker, 2011). This 2D-XPD approach was tested on several very complex zeolite structures and then applied successfully to the novel

borosilicate SSZ-82 (**SEW**, 11 *T* atoms, Xie, McCusker & Baerlocher, 2011).

4.6.3. Structure refinement

Although the determination of a zeolite's basic framework structure is often difficult, it is only the beginning of the story. The non-framework species have to be located, and then the whole structure has to be refined using the Rietveld method (Rietveld, 1969; McCusker *et al.*, 1999) to yield a chemically sensible structure that reproduces the measured diffraction pattern satisfactorily. In the following sections, a few aspects of structure refinement that are particularly relevant to zeolitic materials are discussed.

4.6.3.1. *Space-group ambiguity*

Zeolite framework structures tend towards high symmetry, but sometimes details of the framework geometry or the influence of non-framework species require that the space-group symmetry be reduced. This can be something simple, like the elimination of a centre of symmetry that causes an Si—O—Si linkage to have an unreasonable 180° angle or the elimination of a mirror plane that is incompatible with an ordering of framework atoms (*e.g.* the alternation of Al and P in an aluminophosphate). But it can also be quite complicated. For example, an aluminophosphate with the simple cubic sodalite framework type (**SOD**, 1 *T* atom) was synthesized using dimethylformamide as both the structure-directing agent and the solvent. This produced a material with the unit cell tripled in one direction and a noncentrosymmetric space group (Paillaud *et al.*, 2005). Similarly, the ideal framework structure of UTD-1 (**DON**) has only 5 *T* atoms in the asymmetric unit (space group *Cmcm*), but in the refined structure (space group *Pc*) there are 32 independent Si atoms (Wessels *et al.*, 1999). Chemically unreasonable interatomic distances are often an indication that a reduction in symmetry should be considered.

4.6.3.2. *Geometric restraints*

Although zeolites tend to diffract out to high angles and to have relatively high symmetries, their structures are also quite complex. As a result, the ratio of observations to parameters is usually very low. Fortunately, zeolite frameworks are generally constructed from atoms with well defined bond distances and angles, and this information can be used to advantage in the refinement process. By including known interatomic distances (*e.g.* Si—O, O···O and Si···Si) as geometric restraints (Waser, 1963; Baerlocher, 1993), the observation-to-parameter ratio can be improved. Furthermore, the restraints keep the structural model chemically sensible when the atomic positions are refined. It should be emphasized that these geometric restraints are simply used as additional information. The final structural model must fit both the X-ray powder diffraction profile and the geometric restraints.

Experience has shown that starting with a high weight on the geometric 'observations' at the beginning of the refinement keeps the framework structure reasonable while missing atoms are located and the other parameters find their minima. The weight can then be reduced to allow the atoms more freedom. If an assumption about the geometry is incorrect, it will not be possible to obtain a good fit to both the profile and the geometric restraints. To find the source of the problem, the weight of the restraints can be reduced to see which restraints deviate furthest from the prescribed distances and then to consider possible alternatives.

In such a restrained refinement, the geometric 'observations' are treated as a second data set, and the quantity minimized in the refinement is then

$$S = S_y + c_w S_G,$$

where S_y is the weighted difference between the observed and calculated diffraction patterns, S_G is that between the prescribed and calculated geometric restraints, and c_w is the factor used to weight the two data sets with respect to one another. The geometric restraints can also be used without any diffraction data (*i.e.* $S_y = 0$ and $c_w = 1$) to optimize the geometry of a new framework model. This is a quick and easy way of checking whether or not a framework model is geometrically viable, as there are always more known interatomic distances in a zeolite framework structure than there are positional variables. The distance least-squares program *DLS-76* (Baerlocher *et al.*, 1976) was written for this purpose.

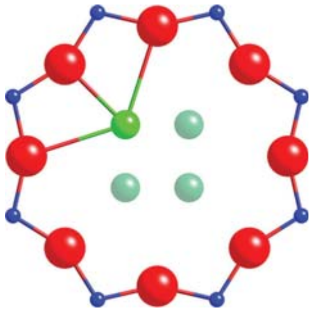

Figure 4.6.9
The disorder of the Na^+ ion (green) in the 8-ring of zeolite A (**LTA**). Only one of the four positions shown can be occupied at any one time.

4.6.3.3. *Disorder*

The cations and molecules in the pores of a zeolite framework structure rarely obey the high symmetry of the framework itself, and the result is that almost all zeolite structures are disordered in one way or another. For example, one of the Na^+ ion positions in zeolite A (**LTA**) lies off the centre of an 8-ring (Fig. 4.6.9) where it can coordinate to three O atoms of the framework. The symmetry of the framework would generate four equivalent positions in the 8-ring, but only one of these four can be occupied at any one time. In other words, these Na^+ ions are disordered with a maximum occupancy of 1/4. The disorder may be dynamic (*i.e.* the ion hops from one position to the next) or it may be static (*i.e.* the ions are arranged differently from unit cell to unit cell). The diffraction data cannot distinguish between these two possibilities.

The organic structure-directing agents (SDAs) used in many zeolite syntheses pose similar problems. A zigzag hydrocarbon chain of the SDA may lie across a mirror plane of the framework or a pentane ring may lie on a threefold axis, and this results in a cloud of electron density that is difficult to untangle into discrete atoms. However, if the geometry of the SDA is known, it may still be possible to interpret the electron-density cloud (see Section 4.6.3.4).

Another type of disorder can arise if an atom of the framework lies on a special position that forces the atom to adopt an unfavourable geometry. This is most often an O atom on a centre of symmetry. If this is the only ‘unhappy’ atom in the structural model, a reduction in the symmetry of the whole framework structure can be avoided by moving the atom off the special position to yield a more reasonable geometry and reducing its occupancy accordingly (*i.e.* adopting a disordered model).

4.6.3.4. *Locating non-framework species*

One of the key features of a zeolite structure is the location of the non-framework species in the pores. Although the framework structure itself defines the size, shape and dimensionality of the zeolite’s pore system, the cation positions are also important for catalytic, adsorption and ion-exchange applications. Furthermore, the location of the SDA is crucial to the understanding of the zeolite synthesis pathway. Fortunately, the phases calculated from the framework structure alone are usually sufficiently correct to generate interpretable difference electron-density maps, even from powder diffraction data. As in the single-crystal case, the difference map is biased towards the model because the phases from the model are assigned to the measured amplitudes that are used to calculate it. However, with powder diffraction data, a second bias is introduced because the amplitudes for overlapping reflections are also partitioned according to the model. This bias should always be borne in mind, but is not usually a problem.

With an approximately correct framework model, it is generally possible to get a good match to the measured powder diffraction pattern at high angles, but there will be large differences at low angles if the zeolite has not been calcined. That is, if there are species in the pores that have not yet been located, they will affect the low-angle (low-resolution) reflections most. Therefore, the measured and calculated patterns are best scaled to one another using only the high-angle ($d < 2.5$ Å) part of the pattern (Fig. 4.6.10). This will increase the discrepancy at low angle (and therefore the $R_{\rm wp}$ value), but these differences are real, so in fact cleaner maps are obtained (Fig. 4.6.11). If difference electron-density maps show significant peaks or holes at the positions of atoms already in the model, this is an indication that the scale factor and/or the background estimation need to be re-evaluated.

Interpretation of the peaks in the difference map is best done stepwise. The highest peaks with chemically sensible approaches to atoms already in the model are assigned first, and then another, improved difference map can be generated. This will generally allow cations and perhaps their immediate coordination spheres to be determined. As the peaks get weaker and more diffuse, however, the interpretation will become more difficult. At this point, information from other characterization techniques (in particular, chemical analysis, MAS NMR, thermogravimetric analysis, IR spectroscopy) and from related structures can be invaluable.

Locating a large organic SDA atom by atom can be very difficult, especially if there is disorder present. However, if the

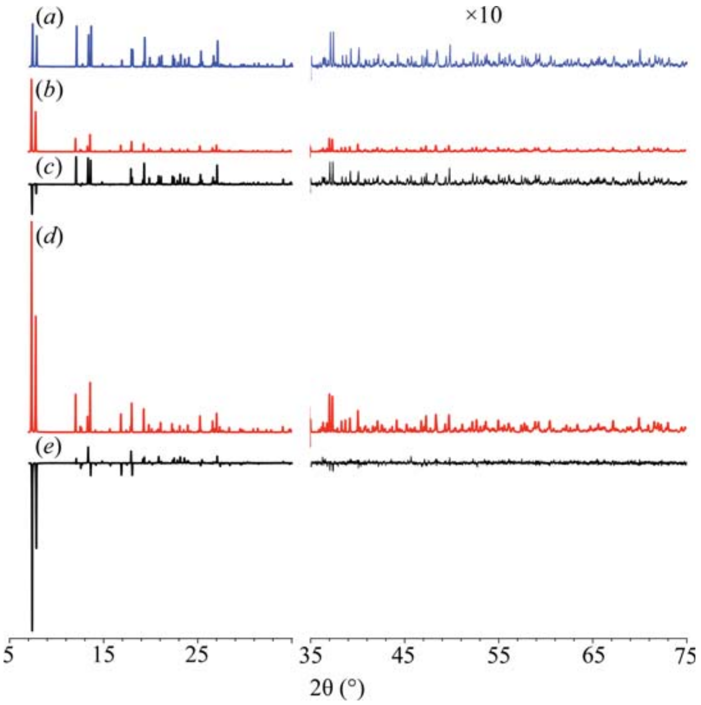

Figure 4.6.10

(*b*) The powder diffraction pattern calculated for the framework structure of SAPO-40 using the scale factor calculated for the whole pattern, and (*c*) the difference between (*a*) and (*b*). (*d*) The powder diffraction pattern calculated for the framework structure of SAPO-40 using the scale factor calculated for the high-angle data only, and (*e*) the difference between (*a*) and (*d*). Note the much smaller differences in the high-angle region in (*e*) compared with (*c*). The 35–75° 2θ section of all diffraction patterns has been scaled up by a factor of 10 to show more detail.

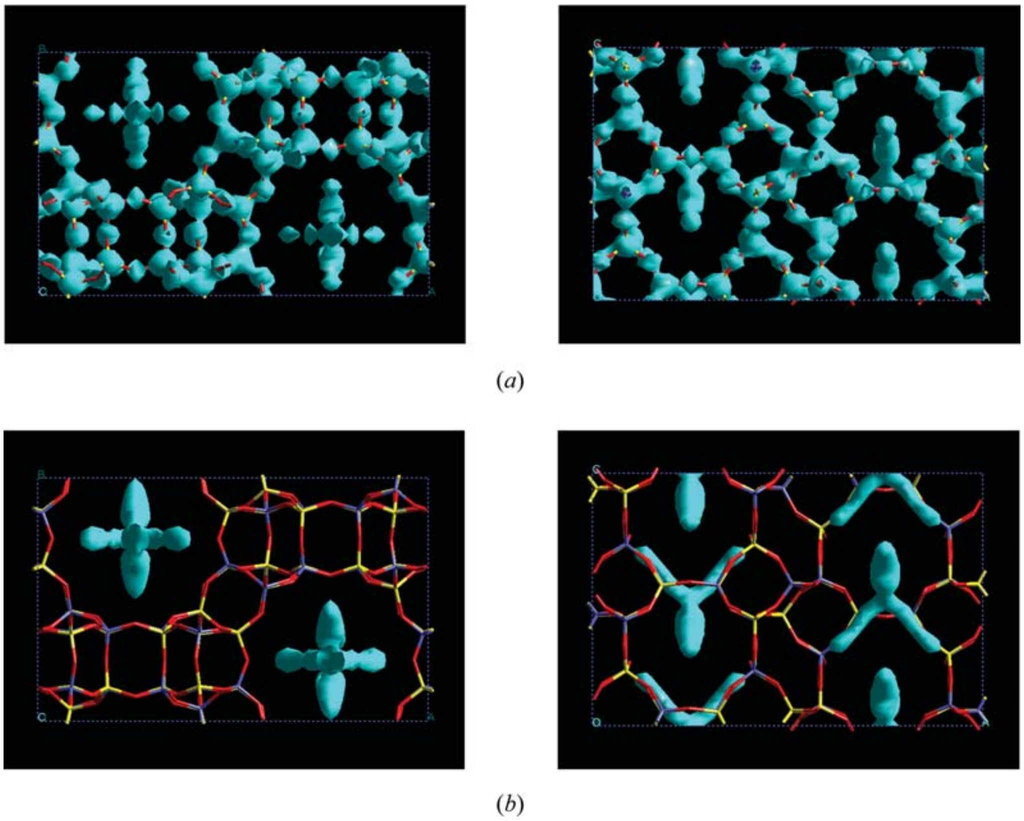

Figure 4.6.11
Difference electron-density maps (blue) calculated for SAPO-40 (**AFR**) along the [001] (left) and [010] (right) directions using (*a*) the scale factor calculated for the full diffraction pattern (Fig. 4.6.10*b*), and (*b*) the scale factor calculated for the high-angle data only (Fig. 4.6.10*d*). The framework structure has been overlaid to show the location of the pores. Note that in (*a*) there is more electron density on the framework atoms, which are already in the model, than in the pores, whereas only the electron density of the tetrapropylammonium ion in the pores is visible in (*b*).

geometry of the SDA is known and it is not too flexible, it can be added initially as a rigid body to get an approximate position and orientation, and then later refined using geometric restraints. The initial positioning of the SDA in the channels can be facilitated by applying a global-optimization algorithm like simulated annealing to test a large number of possibilities (Smeets *et al.*, 2016). Alternatively, computational chemistry can be used to estimate the best position of the SDA in the pores, and this can be used as a starting point for refinement. Geometric restraints should always be applied to keep the SDA bond distances and angles sensible. At least initially, ‘anti-bump’ restraints can be used to keep the atoms of the SDA a sensible distance away from those of the framework. It should be remembered that the SDA is an integral part of the synthesis process, and is unlikely to be randomly positioned in the structure. Although deciphering the atomic coordinates of an SDA may be a major undertaking, the effort can be rewarded with a unique insight into the synthesis process. Once all of the atoms have been included in the structural model, full Rietveld refinement with reduced weight on the geometric restraints can begin. It is at this point that details of the framework geometry become evident.

If the location of the SDA and/or solvent molecules proves to be too difficult, the material can often be calcined to remove these species, and then the empty framework structure can be refined. In our experience, the peaks in the diffraction pattern of the as-synthesized material are usually sharper, because the crystallites suffer somewhat during the removal of the non-framework species. However, the refinement of the framework structure alone may be easier. Of course, this means that the information about the role of the SDA in the synthesis process is lost.

4.6.3.5. *Rietveld refinement of SSZ-74*

The refinement of the structure of the zeolite SSZ-74 (**-SVR**, 23 *T* atoms, Baerlocher *et al.*, 2008) illustrates a number of the points made above. The structure was solved initially with *Superflip* using a structure envelope derived from an HRTEM image (see Section 4.6.2.6). The symmetry was ambiguous (*C*2/*c* or *Cc*), so *C*2/*c* was assumed to begin with. The initial model from *Superflip* had 11 Si atoms in the asymmetric unit forming an interrupted framework structure. However, there was a weak peak in the electron-density map that would complete a fully 4-connected net, so a twelfth Si atom was added at that position (Fig. 4.6.12*a*).

This structure yielded a good fit to the high-angle part of the diffraction pattern (R_F = 0.078, $R_{\rm wp}$ = 1.075, $R_{\rm exp}$ = 0.094, $R_{\rm res}$ = 0.018, where $R_{\rm res} = \{\sum_i w_i^2[d_i(\text{prescribed}) - d_i(\text{model})]^2/\sum_i w_i^2[d_i(\text{prescribed})]^2\}^{1/2}$, and a difference electron-density map was generated to locate the SDA [1,6-bis(*N*-methylpyrrolidinium)hexane] (Fig. 4.6.13). It was not clear how the SDA should be arranged in the electron-density cloud, so molecular modelling was used to get a starting model. This model (Fig. 4.6.12*b*) improved the fit to the diffraction pattern considerably (R_F = 0.065, $R_{\rm wp}$ = 0.189, $R_{\rm exp}$ = 0.094, $R_{\rm res}$ = 0.022). Then refinement of the framework geometry was started. However, the geometry of the twelfth atom was strained [Si(12)—O distances ranging from 1.62 to 1.67 Å, O—Si(12)—O angles ranging from 97.0 to 146.7°]. In an attempt to relieve this strain, the space group was reduced to *Cc* and the number of Si atoms increased to 24. Again the profile fit improved (Fig. 4.6.12*c*, R_F = 0.056, $R_{\rm wp}$ = 0.165, $R_{\rm exp}$ = 0.097, $R_{\rm res}$ = 0.014), but the distortion of the twelfth Si atom (now two Si positions) remained. In view of the fact that this Si position was not clear in the original solution from charge flipping, the

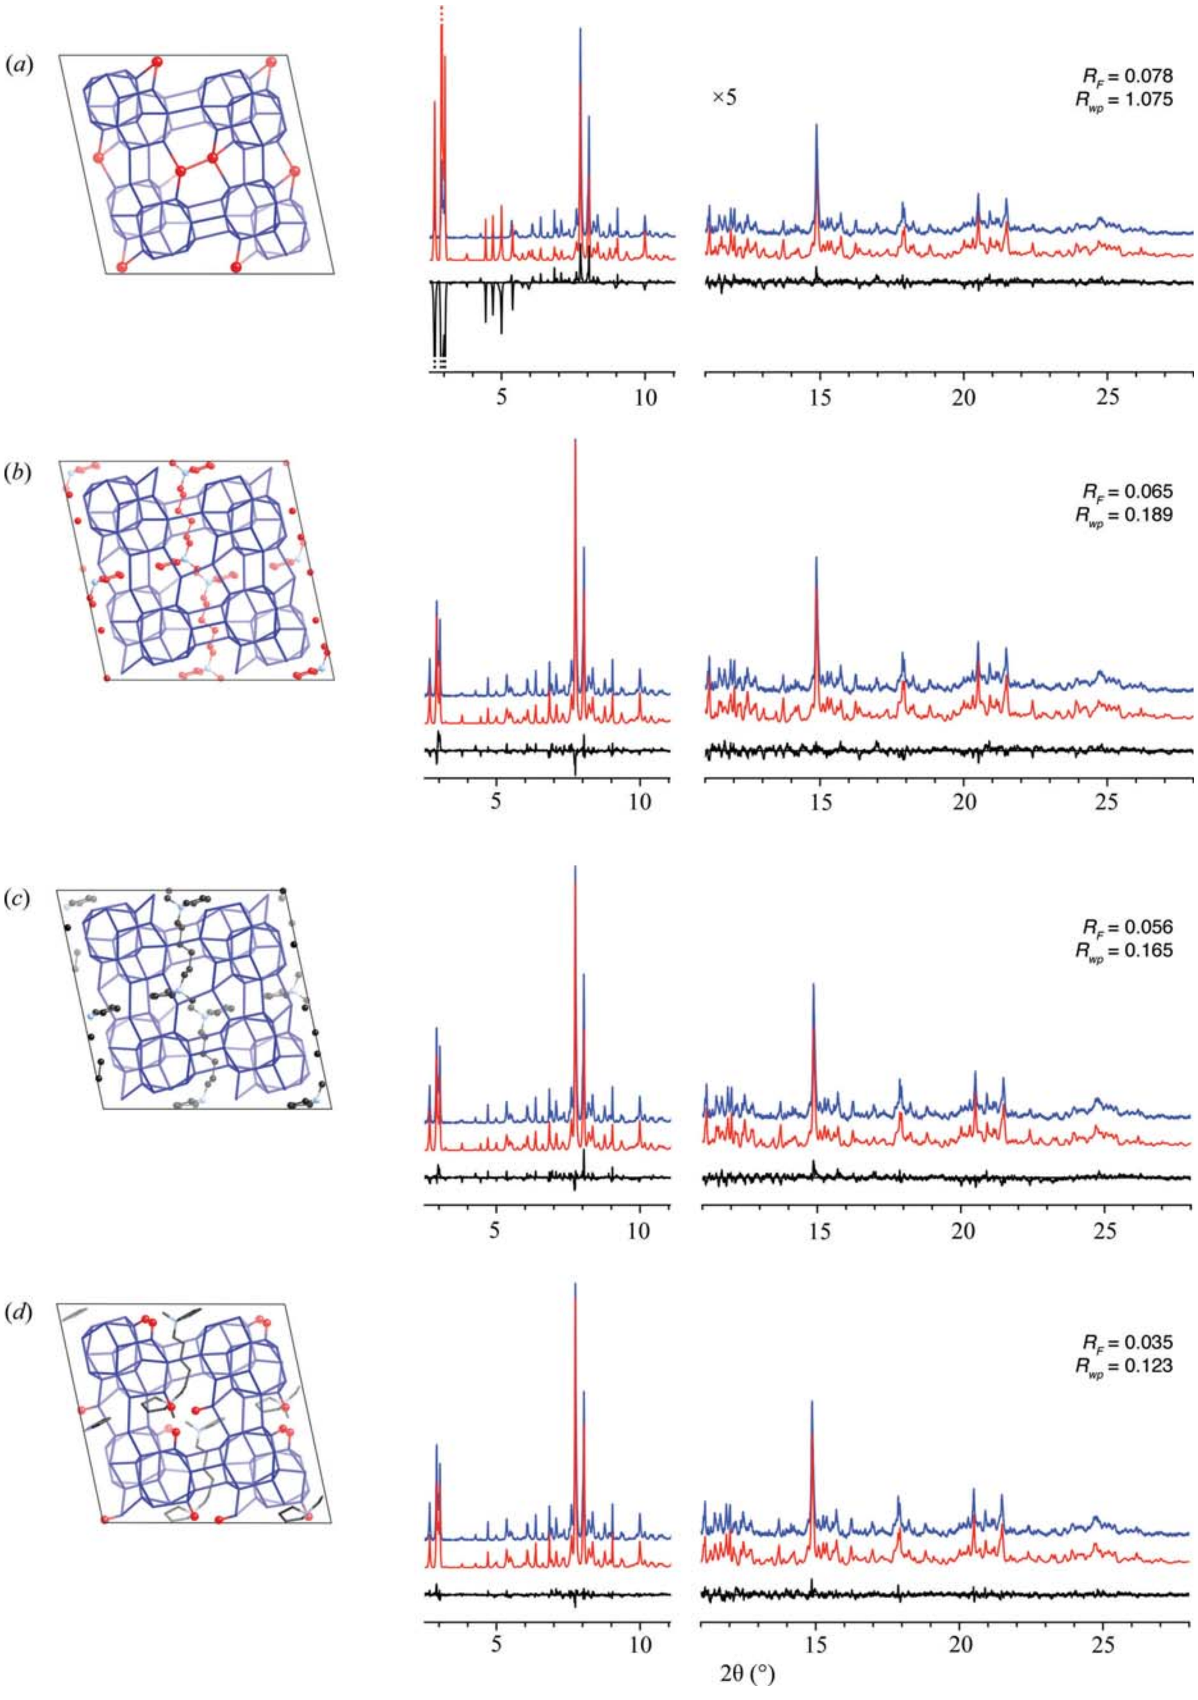

Figure 4.6.12
The structure completion and Rietveld refinement of SSZ-74 (**-SVR**). (*a*) The initial framework structure model in *C*2/*c* obtained from *Superflip* with a twelfth Si atom (highlighted in red) added to generate a fully connected net, and the corresponding profile fit. (*b*) The framework structure in *C*2/*c* with the SDA position and conformation obtained from molecular modelling. (*c*) The structure after reducing the symmetry to *Cc*. (*d*) The final structure with an ordered Si vacancy in the framework (terminal O atoms highlighted in red). Bridging framework O atoms have been omitted for clarity. The second part of each diffraction pattern has been scaled up by a factor of five to show more detail. The highest peak in (*a*) and the corresponding difference have been cut at 75% of the full height.

occupancy parameters of these two positions were refined. One of the two remained fully occupied, and the other disappeared. This resulted in an interrupted framework structure with 23 Si atoms in the asymmetric unit and an ordered Si vacancy, a distortion-free geometry, and an improved profile fit (Fig. 4.6.12*d*, $R_F = 0.035$, $R_{\rm wp} = 0.123$, $R_{\rm exp} = 0.097$, $R_{\rm res} = 0.009$). The ^{29}Si and ^{1}H MAS NMR spectra add further credence to this model. The former indicates the presence of an unusually high percentage of 3- rather than 4-connected Si atoms (Q^3 species) and the latter a strong signal that is consistent with a silanol/siloxy 'nest' (Koller *et al.*, 1995).

During the course of the refinement, the SDA molecule adjusted its position somewhat. This is not surprising, because the initial molecular modelling was performed with a fully connected framework structure, so the main SDA–framework interactions were steric in nature. However, with the Si vacancies, there are terminal O atoms that can be expected to interact more directly with the SDA, and indeed the N atoms of the two pyrrolidinium rings approach these terminal O atoms at hydrogen-bonding distances. That is, although the distances and angles of the SDA were restrained in the refinement, the molecule was able to adjust to a favourable conformation that makes chemical sense (Fig. 4.6.12*d*). No restraints on the SDA–framework distances were used. The final conformation was dictated by the diffraction data.

4.6.3.6. *Locating isomorphously substituted T atoms*

Perhaps one of the most challenging questions for a zeolite crystallographer is whether or not isomorphously replaced *T* atoms can be located. Even in a typical aluminosilicate, it is not always obvious where the Al atoms are. In only a few structures has a clear crystallographic ordering of these atoms been demonstrated (*e.g.* in zeolite A, the Al and Si alternate throughout the framework). In a more typical case, the Al will preferentially occupy certain positions, but the ordering is usually incomplete, and only the lengthening of the *T*—O distance [Si—O: 1.61 (1) Å; Al—O: 1.74 (1) Å] can be used to identify these sites and to estimate the Al content.

When the amount of the isomorphously substituted element falls below a certain level, its specific location in the framework structure usually remains a mystery. In some cases, however, a little insight can be gleaned. The most important factors that will determine whether or not a *T* atom site can be assigned to a particular element are (1) the amount of the substituted element in the framework, (2) the scattering power of the element with respect to that of the other *T* atoms (*i.e.* are they different enough?), (3) the ionic radius (*i.e.* can it be distinguished from other *T* atoms by bond distance?) and (4) the extent to which it is ordered. In some cases, anomalous dispersion can be used to advantage to enhance the contrast between an isomorphously substituted *T* atom and the others in the framework structure (Cox & Wilkinson, 1994).

Many attempts to locate Ti in titanosilicate **MFI**-type materials have been undertaken, for example, but no consensus has been found. The main problem in this case is that the amount of Ti is very low (Ti:Si *ca* 1:23) and it appears to be distributed over several of the 12 *T* sites. More success has been found in the realm of the germanosilicates ITQ-22 (**IWW**, 16 *T* atoms, Corma *et al.*, 2003) and SSZ-77 (14 *T* atoms, McCusker *et al.*, 2011), where the amount of Ge is significantly higher (Ge:Si *ca* 1:4.6 and 1:4.1, respectively) and Ge has a strong preference for double 4-rings in zeolite frameworks.

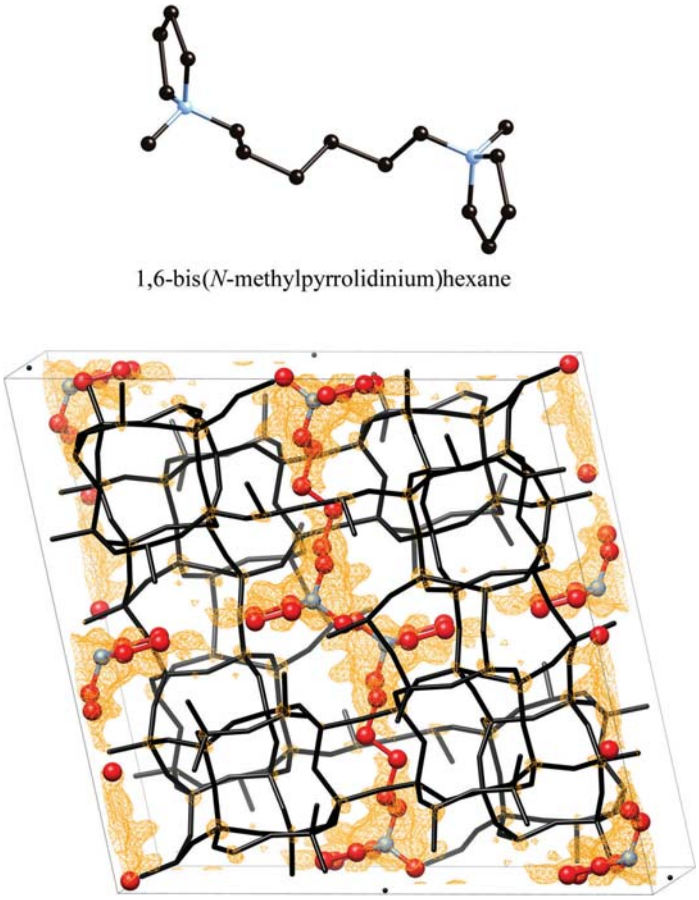

Figure 4.6.13
The structure-directing agent (SDA) used in the synthesis of SSZ-74 and the difference electron-density map (orange) generated from the pattern and model shown in Fig. 4.6.12(*a*). The framework structure (black) with the SDA position and conformation obtained from molecular modelling (N: blue, C: red) has been overlaid for comparison. Note that the SDA fits the electron-density cloud quite well.

A more indirect indication of where the Al is located in an aluminosilicate can be given by the positions of non-framework species (Pinar *et al.*, 2013). For example, metal cations can be exchanged for the protons in a calcined material, and they will be much easier to locate than the almost invisible H^+ ions. These cations can be expected to be associated with the framework O atoms that are bonded to the Al atoms. Similarly, a large molecule like pyridine can be adsorbed into a zeolite to probe where the protons (and thereby the Al) are located. These experiments can be expected to yield useful results as long as the Al is concentrated in specific positions and the associated O atoms are accessible to the cation or molecule used as a probe.

4.6.4. Conclusions

There are different levels of zeolite structure analysis that can be realized using powder diffraction data. In the simplest case, the positions of the reflections can be used to monitor unit-cell changes as a function of temperature, ion exchange or adsorption, or the peak widths to measure crystallite size. However, the structural information that lies in the intensities can also be deciphered by applying the methods outlined in this chapter. Whether the goal is to determine the framework structure of a new zeolitic material, to locate the non-framework species in the pores of a known framework structure, or to evaluate the most likely positions for isomorphously substituted framework cations, if the powder diffraction pattern contains the information, it can be extracted. The analysis of the structure of a polycrystalline zeolite is not necessarily easy or even straightforward, but it is possible, and the results are usually worth the effort.

4.7. Rietveld refinement

B. H. Toby

4.7.1. History

Powder diffraction was invented independently by Peter Debye & Paul Scherrer (1916) and Albert Hull (1917) for the purpose of descriptive crystal-structure determination, for materials where single-crystal specimens for materials were not available. Both groups and many others were successful in this work, but as the practice of single-crystal diffraction analysis improved, and structure refinement allowed quantitative structure determination to become routine, one of the key weaknesses of powder diffraction – the loss of information due to reflection overlap – became a major disadvantage. In the relatively few cases where structural refinement from powder diffraction was attempted, reflections that overlapped had to be discarded. Alternately, refinement software was created to treat the specific cases of groups of overlapped reflections for each structural study [for example, see Rietveld (1966)].

In the mid-1960s crystallographic analysis from powder diffraction was to see a major advance when the group of Bert Loopstra, Bob van Laar and later Hugo Rietveld at the Reactor Centre Netherlands in Petten considered the peak-overlap problem (van Laar & Schenk, 2018). Building on initial work in describing how peak widths changed for constant-wavelength (CW) neutron diffractometers (Cagliotti *et al.*, 1958) and 'profile decomposition' [using the nomenclature of Young (1993)] to determine intensities of overlapped reflections (van Laar, 1965), a method was developed for the fitting of crystallographic parameters, as well as experimental and sample parameters that dictate peak shapes (Rietveld, 1967). A computer program in ALGOL was later documented and distributed (Rietveld, 1969). The Petten group rapidly adopted this approach in their crystallographic work (Loopstra & Rietveld, 1969*a*,*b*). Rietveld would soon recast his code in the more widely used Fortran programming language and while that work was never reported in the literature, the code was widely distributed and used as the basis for the work of many others, for example the initial crystallographic fits to X-ray diffraction (Young *et al.*, 1977) and to pulsed-neutron diffraction data (Worlton *et al.*, 1976; Von Dreele *et al.*, 1982).

Several terms have been used to name this crystallographic method, such as 'profile refinement' and 'full-pattern fitting', but these unfortunately obscure the fact that the goal is crystallographic fitting rather than determination of peak shapes. In the words of Ray Young, an early adopter of this work, 'it was Rietveld who first worked out computer-based analytical procedures (quite sophisticated ones for the time, as it turned out) ... who put them in the public domain ... and who very importantly, freely and widely shared his computer program. It is for these reasons that the method is appropriately referred to now as 'the Rietveld method', or 'Rietveld refinement', or 'Rietveld analysis'.' (Young, 1993). Rietveld's method is general for all types of materials, could make use of intensities for even severely overlapped reflections as well as reflections with no intensity, and thereby made quantitative crystallographic analysis possible for materials that did not form single crystals, even when complex with low symmetry.

Rietveld implemented his analysis for only CW neutron diffraction, but did include treatment for magnetic scattering: the interaction between neutrons and unpaired electrons. His code also treated experimental complexities such as low-angle peak asymmetry (better described as axial divergence asymmetry), crystallite size broadening and preferred orientation. van Laar and others significantly improved the treatment of low-angle asymmetry some years later (van Laar & Yelon, 1984; Eddy *et al.*, 1986; Finger *et al.*, 1994). Initial use of CW neutrons simplified fitting, as these measurements usually offer very simple Gaussian peak shapes and also had the advantage that measurements are routinely made over a wide Q range ($Q = 2\pi/d = 4\pi\sin\theta/\lambda$). Subsequent work, fitting to X-ray diffraction data, required treatment of both Gaussian and Lorentzian broadening (Young *et al.*, 1977; Wiles & Young, 1981). Fitting to neutron time-of-flight (TOF) powder-diffraction data presented considerable technical challenges, since now one must correct for many wavelength-dependent effects, such as absorption and source flux (Worlton *et al.*, 1976; Von Dreele *et al.*, 1982; Albinati & Willis, 1982). Most significantly, TOF neutron diffraction peaks will have highly asymmetric shapes because of the rapid rise and slower bleed-off of neutrons leaving the spallation moderators. This peak shape changes considerably with wavelength, since the moderator 'shaping constant' changes with neutron energy (Jorgensen *et al.*, 1989), also see Chapter 3.3. While the equations and number of terms needed to describe TOF peak shapes are significantly more complex than those for CW X-rays and neutrons, recent work to decouple sample-dependent and instrument-dependent profile contributions greatly decreases the complexity of analysis of TOF data (Toby & Von Dreele, 2013, 2014). TOF data are often preferred as they can offer very high resolution coupled with great Q range.

When Rietveld analysis was initially applied, the method was questioned because the derived parameters, and in particular the standard uncertainties on these parameters, did not match results obtained from refinements using integrated intensities (Sakata & Cooper, 1979). The discrepancies between Rietveld results and those obtained from refinement based on intensities from peak integration were later explained as being due to the neglect of correlation information in the integrated peak approach (Prince, 1981). The same results are obtained with integrated intensities if the correlation information from the peak integration is carried forward into a second least-squares fit through use of a weight matrix, obtained from the covariance in the first fit. This adds considerable complexity to the process, since when independent observations are used in a fit, only the diagonal values in the weight matrix are non-zero; thus, the weights can be simplified as a list of values corresponding to each observation. Prince's masterful brief work continues to be relevant to those who argue over the proper way to fit a parametric equation to results from a series of crystallographic measurements, for example over a series of pressures or temperatures, since it shows the results are equivalent if performed with proper weighting.

The scope of materials studied with Rietveld analysis extends from the simplest chemical systems to phase analysis of very complex mixtures of Portland cement clinker (Morsli *et al.*, 2007).

Copyright © 2019 International Union of Crystallography

To the astonishment of many, Rietveld analysis can be applied to structural study of proteins (Von Dreele, 1999). Powder diffraction has even been used successfully to determine structures of proteins that were previously unknown (Von Dreele *et al.*, 2000; Margiolaki *et al.*, 2007).

Rietveld analysis requires too many computations to perform without computer software. A plethora of different computer codes for Rietveld analysis has been developed in the subsequent 40+ years (far too many to properly survey here), but some of the historically important codes are mentioned here. The original Fortran code from Rietveld served as the basis for many subsequent improvements and adaptations, but other programs are complete reimplementations and do not share any code from Rietveld. The adaptation of Rietveld's code by Hewat was widely distributed (Hewat, 1973). Likewise the *DBW* (later *DBWS*) code, which first implemented Rietveld analysis with laboratory X-ray data, was also widely used (Wiles & Young, 1981). The same is true for the *TOFLS* program, which first implemented Rietveld analysis for neutron TOF data (Von Dreele *et al.*, 1982).

At present, some of the most widely used packages for crystallographic analysis include: *Topas* (Coelho, 2007), *FullProf* (Rodríguez-Carvajal, 1993), *Jana* (Petricek *et al.*, 2006), and the *GSAS/EXPGUI* combination (Toby, 2001; Larson & Von Dreele, 2004). All functionality in *GSAS/EXPGUI* has been reimplemented in the new and more modern *GSAS-II* package, which also offers much greater functionality; citation of *GSAS-II* is growing exponentially (Toby & Von Dreele, 2013). In addition, there are also widely used programs devoted to a particular type of analysis or research community, for example the *MAUD* package is typically used for residual stress (better labelled as microstrain) or texture analysis (Lutterotti *et al.*, 1999) or the *RIETAN-FP* package, which implements maximum-entropy methods and includes documentation in Japanese (Izumi & Momma, 2007).

4.7.2. Rietveld *versus* single-crystal refinements

In contrast to a single-crystal refinement, where structural parameters are fitted to 'observed' structure factors, in a Rietveld fit one must describe all the items that affect the complete diffraction pattern. This requires that additional parameters must be added to the fitting model. These extra parameters predict the peak positions and describe the peak shapes, in addition to the structural parameters, which determine reflection intensities. The peak positions are directly determined by the lattice constants plus one or more correction terms, which vary with the type of instrument. Many factors influence the shapes of diffraction peaks: instrumental effects, crystallite size and residual strain broadening. In addition, Rietveld analysis must model both non-Bragg scattering effects, air scattering and other instrumental imperfections, as well as systematic corrections to the intensities and the background. This is in contrast to the single-crystal case, where these effects are removed as part of the data preprocessing.

Thus, the parameters needed in a Rietveld fit fall into four categories: (i) structural parameters, which include atom positions, occupancies and displacement parameters; (ii) lattice constants; (iii) instrumental parameters, which will differ for different types of measurements, but will usually be independent of the sample; and (iv) sample-dependent parameters that may depend on the specific specimen in use, because of treatment history and sample-preparation effects.

In contrast, a single-crystal refinement only fits the first set of parameters, the structural parameters. The other three categories of parameters add additional complexity to a Rietveld fit. Further, the structural information in a powder-diffraction data set is usually reduced relative to a single-crystal data set. One reason for this is the reflection overlap that occurs for powders but not single crystals. In addition, however, the total background scattering that is spread out over the full Ewald sphere in the single-crystal measurement becomes concentrated into a line in powder diffraction and thus becomes a larger and less separable contribution. Thus, with powders, intensity measurements are less accurate and it is usually harder to discern weak reflections. For this reason, where good-quality single crystals are available, structural studies using them are usually to be preferred.

Despite the advantages of single-crystal measurements, powder diffraction makes valuable contributions to structural science. This is because for many materials only polycrystalline samples can be produced; this is particularly true early in the materials discovery process. For other materials, the single crystals that are available may not be compositionally representative of the bulk phase or may be marred by effects such as twinning, which hinder accurate measurement of structure factors from single crystals. A powder-diffraction experiment is also often much simpler than a single-crystal one, particularly under extreme conditions. Finally, it should be noted that some of the additional parameters determined in a Rietveld fit are valuable for physical characterization of the specimen, and thus Rietveld fits are also commonly used for texture, microstrain and crystallite size measurements. Finally, powder diffraction usually provides much greater accuracy and precision for lattice-constant determination than does a routine single-crystal measurement. For all these reasons Rietveld analysis is a growing field.

4.7.3. Multiphase and multiple data set fitting

For early Rietveld fits, if a material contained a minor impurity phase, the regions of the powder pattern surrounding peaks from that impurity had to be excluded from the fit. However, this can only be done where an impurity has a very simple structure or is present at very small concentrations. A better practice is to include structural information for both phases in the model to obtain an optimal fit. This allows the relative abundance of each phase in the mixture to be quantified, since the scale factor for each phase is proportional to the number of unit cells of that phase in the specimen. This in turn allows the relative phase abundance to be stated in weight or mass units. Most modern Rietveld analysis codes allow multiple phases to be included in a fit. This is now used routinely for quantification of crystalline phases in a material, for example in cement clinker materials where more than ten component phases may be identified. Adding a known amount of a crystalline phase (as an internal standard) can be used to allow the Rietveld method to quantify amorphous content as well.

In order to take best advantage when multiple measurements are made on a single sample, the Rietveld method was adapted to fit a single model to multiple data sets. The most obvious use for this is to combine results from neutrons with those from X-rays. As an example, a particular synthetic jarosite contains both vanadium and hydrogen atoms; a combined X-ray single-crystal/neutron powder study provided accurate information about both atoms, despite the insensitivity of X-rays to the location of hydrogen atoms and the insensitivity of neutrons to the location of vanadium atoms (Grohol *et al.*, 2003). Neither data set alone was sufficient to fully elucidate the structure. It can also be advantageous to perform a combined refinement even where all data sets are collected with a single type of data. This is sometimes done where diffractometer settings will optimize resolution in different Q ranges or where temperature or preferred-orientation settings are used to separate overlapped reflections (Von Dreele *et al.*, 2000; Baerlocher *et al.*, 2004). Now that high-quality powder-diffraction patterns may be collected in fractions of a second, it becomes possible to use Rietveld analysis for parametric refinements to map out structural transitions, such as phase, lattice and order-parameter changes with temperature, chemical potential, time *etc*.

4.7.4. The mechanism of Rietveld fitting

The computations in a Rietveld fit require minimizing the weighted sum of the squares of differences between the observed powder-diffraction data points, $y_{\text{obs},i}$, at position Q_i and simulated measurements, $y_{\text{calc},i}$, computed from the combined structural, instrumental and experimental model. Thus the fitting function, S,

$$S = \sum_i w_i \left(y_{\text{obs},i} - y_{\text{calc},i}\right)^2,$$

is minimized, where w_i is the weight value for $y_{\text{obs},i}$, which is related to its standard uncertainty by $w_i = \sigma^{-2}(y_{\text{obs},i})$, where $\sigma(y)$ is the expected experimental uncertainty on observation y. The minimization has been done historically with Newton–Raphson least squares [see Chapter 8.1 in Volume C (Prince & Boggs, 2006)]. The Levenberg–Marquardt modification of the Newton–Raphson algorithm improves convergence when variables are highly correlated by emphasizing the diagonal terms in the Hessian matrix, which moves the minimization closer to a steepest-descent algorithm. The method of singular value decomposition can be used to re-parameterize refinements to utilize more a more orthogonal set of parameters, reducing correlation by removing underdetermined degrees of freedom (Mercier *et al.*, 2006). The more modern Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm has also been proven to work well, though it only approximates the Hessian. Note that the covariance matrix, which is the inverse of the Hessian, is used to determine uncertainties on fit parameters once convergence is reached (Prince, 2004).

The $y_{\text{obs},i}$ values above are the experimental measurements, while the calculated measurement values, $y_{\text{calc},i}$, are computed using a sum over reflections *hkl* near the current data point using the computed structure factors, F_{hkl}, and peak profile functions, $P(Q_{hkl} - Q_i)$, by

$$y_{\text{calc},i} = B_i + I(Q_i) \sum_{hkl} m_{hkl} F^2_{hkl} O_{hkl} P(Q_{hkl} - Q_i), \tag{4.7.1}$$

where B_i is the background at the point; $I(Q_i)$ represents the product of the intensity adjustment terms, which will include a scale factor and Lorentz–polarization corrections and may include wavelength- or angle-dependent correction terms, such as absorption corrections, spectral corrections *etc*. The m_{hkl} term is the multiplicity of reflection *hkl*; O_{hkl} is an optional intensity adjustment due to preferred orientation; and Q_{hkl} is the location of reflection *hkl*. The structure factors, F_{hkl}, are computed from Fourier transform of the scattering from the unit cell using the standard relationship. The units used for Q are usually the as-collected units, which may be an angle or time-of-flight, and thus Q_{hkl} will be computed using Bragg's law and the lattice constants, but corrections to adjust for deviations of the recorded position from the true Bragg value are needed. Typical corrections may be a scalar, to correct for a 2θ zero offset term, or a more complex function, to account for specimen displacement and transparency in a Bragg–Brentano diffractometer, may be employed (Chapter 3.1). In the case of TOF diffraction, calibration constants are used to convert the time of flight to absolute units and *vice versa*.

4.7.5. Types of profile functions

Three different computational approaches have been used for generation of the profile function, $P(Q_{hkl} - Q_i)$:

(1) Use empirical functions that reproduce the experimentally observed peak shapes, in some cases using *ad hoc* curves derived directly from the actual experimental data.

(2) Use physically based terms that are parameterized to model physical phenomena such as strain or crystallite broadening in generalized and approximate equations. This is the most commonly implemented approach.

(3) The fundamental-parameters method computes a peak-shape function through the convolution of every aberration arising from the diffraction instrument and from the sample, usually in terms of physically meaningful values, though often some *ad hoc* adjustments are also needed (Cheary & Coelho, 1992).

Each of the previous approaches has its adherents, although empirical peak-shape methods are likely to introduce small systematic errors in lattice constants, since they do not properly account for shifts in diffraction peaks due to low-angle asymmetric peak broadening (Finger *et al.*, 1994; van Laar & Yelon, 1984; Eddy *et al.*, 1986). The fitted values from an empirical peak shape have no physical meaning, but both physically based parameters and fundamental parameters will provide terms that further characterize a sample, for example with crystallite size or strain information. Of the two methods, application of fundamental parameters requires much closer attention to the details of the experimental geometry, but can add extra rigour to a result by demonstrating that the entire experiment is behaving in an understood and reproducible manner (NIST, 2010).

4.7.6. Observed structure-factor estimates

Rietveld also addressed a second difficult algorithmic problem in his 1969 work. This was to produce a simple and stable method for estimating the intensities for each reflection in the diffraction pattern. Deconvolution methods are slow and leave an insolvable ambiguity for the apportioning of intensities from reflections that have very close positions and thus are completely unresolved. The approach used by Rietveld notes that, for every computed point in the pattern, a proportion of the intensity from each reflection can be determined from equation (4.7.1), which can be rewritten as

$$(y_{\text{calc},i} - B_i)/I(Q_i) = \sum_{hkl} C_{hkl,i} F^2_{hkl},$$

where $C_{hkl,i}$ accounts for all the correction terms and peak proportion, which have been computed for the refinement. This equation can be inverted to relate the structure factor to a sum over i points in the diffraction pattern:

$$F^2_{hkl} = \sum_i (y_{\text{calc},i} - B_i)/\left[I(Q_i) C_{hkl,i}\right].$$

Note that, in practice, $C_{hkl,i}$ drops to negligible values for data points more than a few peak widths from the peak centre, so that only points near the reflection need to be considered in this sum. This relationship can then be used to apportion the observed intensity into an estimate of the observed structure factors $F_{\text{obs},hkl}$ by applying the same ratios of intensity values as are applied to each of the computed structure factors using

$$F^2_{\text{obs},hkl} = \sum_i (y_{\text{obs},i} - B_i)/\big[I(Q_i)C_{hkl,i}\big].$$

Since the $C_{hkl,i}$ values are determined using the crystal-structure model, the accuracy of the structure-factor estimates is only as good as the quality of that model, but this is often the best estimate that can be made.

These estimated structure factors, $F_{\text{obs},hkl}$, are commonly used in two ways. As will be discussed later, an R factor can be computed with them to compare the agreement between the $F_{\text{obs},hkl}$ and F_{hkl} values and they can be used for Fourier map computations. Note that, owing to the approximate nature of the structure-factor estimation, in practice only the strongest few peaks in a difference Fourier computed from $(F_{\text{obs},hkl} - F_{hkl})$ will indicate missing or extra scattering material from the structural model. Weaker peaks in Rietveld Fourier maps are more likely to be spurious than those from single-crystal diffraction where structure factors are determined directly.

4.7.7. Estimating observed structure factors without a structure

The Rietveld method has been applied to the problem of estimating reflection intensities when no structural information is known in two different ways. Pawley developed an algorithm similar to the Rietveld fit where reflection intensities are treated as refinable variables in place of refining structural parameters (Pawley, 1981; Chapter 3.5). To do this requires special treatment for exactly and very nearly overlapped reflections. The covariance matrix from a Pawley fit can be used to estimate the uncertainty in intensity apportionment for overlapped reflections, which can be applied to speed up computations for iterative *ab initio* structure solution algorithms (David *et al.*, 2006; Stephens & Huq, 2002; Pagola & Stephens, 2010).

The alternative to the Pawley technique, known as the Le Bail intensity extraction method, is a clever adaptation of the Rietveld intensity estimation algorithm (Chapter 3.5). This algorithm applies the Rietveld intensity estimation algorithm in an unconventional way. First, the simulated diffraction pattern is computed with all F_{hkl} values arbitrarily set to unity. This provides a set of $F_{hkl,I}$ values that are independent of any structural model. With these $F_{hkl,I}$ values the $F_{\text{obs},hkl}$ values are computed as before. The algorithm is iterated by replacing the previous F_{hkl} values with the just-determined $F_{\text{obs},hkl}$ values. Each time this replacement is done and the intensity extraction algorithm is repeated, the agreement between the observed and simulated pattern improves and within a few cycles the changes become insignificant. This method also treats reflection intensities as arbitrary values (somewhat similar to the Pawley approach) but a steepest-descent-type fit is used for the $F_{\text{obs},hkl}$ values. Where reflections are completely overlapped, the Le Bail method will apportion intensity to reflections according to their relative multiplicities. Von Dreele later modified the Le Bail approach to use a partial structural model to compute the initial F_{hkl} values rather than set them to unity (Larson & Von Dreele, 2004). This will often converge faster and provide a more accurate apportionment for overlapped intensities when the structural model is fairly complete.

Reflection intensities from the Pawley or Le Bail methods are useful for *ab initio* crystal structure solution by real-space or reciprocal-space approaches (see Chapters 4.2 and 4.3). These methods can also be useful to model a single impurity phase in a mixture, where that phase has a known unit cell but an unknown structure, or where the phase is highly textured or occurs as too few grains to provide representative intensities. Thus, the fit proceeds where the peaks arising from the impurity phase are treated as having arbitrary intensities and are subtracted as best as possible from the pattern.

The Pawley or Le Bail method is also valuable as a method for obtaining starting values for non-structural parameters in a crystallographic fit or occasionally for sample characterization, where perhaps only peak-broadening terms are desired. To do this, one must first optimize the reflection intensities and then introduce additional non-structural parameters into the fit. Pawley refinements tend to be more stable than Le Bail fits because of the decoupling of the steepest-descent fit of intensities and the least-squares fit of the other parameters, but with care both methods do work. Many Rietveld practitioners will use a Le Bail or Pawley refinement to establish initial estimates for lattice, peak-shape and background parameters before exploring the details of the crystal structure. During the initial structural refinements, the non-structural parameters are fixed at these initial estimates, which speeds and simplifies the structural fitting process. In the final stages of the refinement, these fixed parameters are again re-optimized along with the structural parameters.

4.7.8. Agreement factors

An important question in crystallography is how to quantify the quality of the fit between the model and the data. For this purpose, agreement factors, such as R factors, are commonly used. To determine the quality of a Rietveld fit, many different quantities have been proposed (Toby, 2006). The same problem faces all these agreement factors: a single value is being used to measure the quality of fitting to the peak shape, peak positions and background, as well as intensity mismatch errors, where the last quantity is most crucial for understanding the quality of the structural model. Attempts have been made to adjust these agreement factors to remove the background from consideration, but this cannot be done rigorously and no mechanism can separate the peak-shape and position errors from the intensity disagreements.

Another disadvantage of all powder-diffraction agreement factors is that they cannot be interpreted on an absolute scale to determine the quality of a fit. This is in contrast to single-crystal refinements, where quantities such as R_{wF} will have a relatively small range of values and are commonly, though perhaps overly, used as a judge of the quality of the experimental fit.

The most commonly used term for gauging the quality of a Rietveld fit is the weighted-profile R factor, R_{wp},

$$R_{\text{wp}} = \left[\sum_j w_j (y_{\text{obs},j} - y_{\text{calc},j})^2 / \sum_j w_j y^2_{\text{obs},j}\right]^{1/2}.$$

The R_{wp} term is sometimes compared to the statistically expected R factor, R_{exp},

$$R_{\text{exp}} = \left[(j - \nu)/\sum_j w_j (y_{\text{obs},j})^2\right]^{1/2},$$

but this comparison is built into a statistical quantity called the reduced χ^2 (chi-squared), which is defined as

$$\chi^2 = \frac{1}{j - v}\sum_j w_j (y_{\text{obs},j} - y_{\text{calc},j})^2 = \left(\frac{R_{\text{wp}}}{R_{\text{exp}}}\right)^2.$$

In the above the number of data points is j and the number of refined parameters is v. Closely related to the reduced chi-squared is the goodness of fit (GOF), where $\text{GOF}^2 = \chi^2$.

The R_{wp} value is a good metric to follow the progress of a refinement and can be used to compare how well different models match the same set of experimental data, but the values have no meaning on an absolute scale. This is made clear by a thought experiment in which the same pattern is measured twice, but for one measurement the background is artificially increased. If a refinement is performed on both sets of data, fits that are equivalent will be obtained (other than a difference in the background parameters). However, a much lower R_{wp} value will be seen for the data set with a higher background, simply because the $\sum_j w_j y^2_{\text{obs},j}$ term is larger because of the extra background intensity multiplied by the large number of points in the pattern. Even though there will be a large difference in the R_{wp} values, there will be no significant difference in the actual fit quality.

The reduced χ^2 does have a statistical expectation value of unity, but still cannot be used on an absolute scale as a judge of refinement quality. The expectation value can be understood by noting that when data are properly weighted, w_j is the square of the reciprocal of the standard uncertainty, or $w_i = 1/\sigma^2(y_{\text{obs},j})$. In a statistically ideal fit, where all differences between the observed and simulated measurements are due only to statistical fluctuations, the standard uncertainty, $\sigma(y_{\text{obs},i})$, is the expectation value for $[\langle(y_{\text{obs},j} - y_{\text{calc},j})^2\rangle]^{1/2}$. Thus, $\chi^2 = 1$ when no systematic errors are present and $\chi^2 > 1$ with an imperfect model (or stated equivalently, with systematic errors in the data), but if $\chi^2 < 1$ occurs, then at least some of the uncertainties must be overestimated. Thus, χ^2 provides information about how far the model is from an ideal fit, but only if the uncertainty estimates are accurate.

The reason why the reduced χ^2 should not be used as an absolute measurement of the quality of a structural fit is because, given a model with a certain imperfection, the poorer the quality of the data set, the closer the χ^2 value will be to unity. Note that, improving the data-set quality by counting longer to reduce the statistical uncertainty will decrease the average $\sigma(y_{\text{obs},j})$ values, resulting in an increase in χ^2. Improving the sensitivity of the data set to imperfections in the model, for example by improving resolution, or by measuring the pattern over a wider Q range, will increase the average values of $|y_{\text{obs},j} - y_{\text{calc},j}|$, likewise increasing χ^2.

Nonetheless, when χ^2 is significantly different from unity, the reason for this should be understood. Visual review of a graph showing the observed and computed patterns and their difference (or even better, with these results normalized by the weighting values) will show if there is a poor fit to the reflection intensities (implying an inaccurate structure), in comparison with problems in fitting the background, peak shape or peak positions, or even the presence of an unfitted minor impurity phase.

One other sometimes useful type of R factor is called the Bragg R factor. This is computed from the estimated reflection intensities in a manner similar to that carried out for single-crystal fits. There are several versions of this R factor, but the most commonly published one is R_F,

$$R_F = \sum_{hkl}\left|F_{\text{obs},hkl} - F_{\text{calc},hkl}\right| / \sum_{hkl}\left|F_{\text{obs},hkl}\right|.$$

Similarly, R_F^2 can be computed using F^2_{hkl} values or occasionally R_I is computed from reflection intensities, I_{hkl}. For this reason the terms R_{Bragg} or R_{B} are ambiguous in comparison with R_F and R_F^2. This agreement factor does try to appraise the differences between observed and computed values due to imperfections in the structural fit, but non-structural problems in the fit can interfere with the determination of the structure factors, raising the Bragg R factors. On the other hand, the intensity-partitioning model biases the R factor towards providing lower values. Nonetheless, it does provide some information about the quality of the crystallographic fit, but it should be kept in mind that this value has no statistical validity and will be overly sensitive to minor discrepancies in the most intense reflections since it is unweighted.

4.7.9. Restraints and constraints in Rietveld refinement

Since powder data usually provide considerably fewer independent observations of the material's structure than would a single-crystal experiment, it is often impossible to follow the crystallographers 'rule of thumb' to have ten independent structure-factor observations for each refined parameter. While every data point in a diffraction pattern is a statistically unique observation and appropriate for use in a statistical test (such as the Student T test), the number of observations providing information about the structure is much smaller (Altomare *et al.*, 1995; Sivia, 2000). This will be of the order of the number of discernible peaks in the pattern, counting locations where reflections are located even where no peak intensity is observed. When the number of observations is lower than desired for a model, it is often wise to reduce the degrees of freedom in the model, either by simplification or by introduction of penalty functions that prejudice the model towards results that have been well established (for example, common bond distances and angles). This is also common practice when large complex structures, such as proteins, are fitted using single-crystal data.

Models can be simplified by the introduction of constraints. Each constraint replaces two or more parameters with a single new parameter, resulting in a model with fewer degrees of freedom. Some crystallographic examples of this include replacing the six atoms comprising the C atoms in a phenyl ring with an idealized hexagonal arrangement of the six atoms. If this rigid body is allowed to move and rotate freely, there will now be at most only six positional parameters (three rotations and three translations) in place of the 18 positional parameters needed to describe six independent atoms. Another example of a constraint is where a choice is made that atoms of the same type and in similar bonding environments will have approximately the same isotropic displacement parameters by using one refinable parameter for the set in place of a parameter for each of the similar atoms. Constraints are implemented in different ways in modern Rietveld codes, but the ability to constrain multiple parameters into a single one was available even in Hugo Rietveld's original code.

The use of restraints (sometimes misleadingly called soft constraints) effectively adds new 'observations' to the data set used in fitting. These 'observations' are not directly measured for the sample, but may be found statistically for a wide range of materials or from other *a priori* knowledge. Restraints provide a target value for some value derived from the refined parameters, for example a bond distance or bond angle. The fitting function, F, is then expanded by an extra set of terms,

$$F = \sum_i w_i (y_{\text{obs},i} - y_{\text{calc},i})^2 + \sum_j w_j (r_{\text{in},j} - r_{\text{fit},j})^2$$

where $r_{\text{in},j}$ is the input value for the restraint and $r_{\text{fit},j}$ is the value derived from the model. The w_j term usually incorporates both an uncertainty in the $r_{\text{in},j}$ value and a weighting factor. It is common to make weights as large as or even larger than the number of data points in a refinement in the initial stages of a fit, so that the $r_{\text{fit},j}$ values are not allowed to diverge far from their restraints. Different Rietveld codes offer differing types of restraint functions.

Both restraints and constraints introduce the crystallographer's preconceptions about the model into the fit and thus can conceal an unexpected result (see Chapter 4.9). Thus, it is important to test that constraints and restraints are indeed appropriate. Note that when restraints and constraints are needed, it is because the number or accuracy of the observations is not sufficient to discern the correct model from others that introduce deviations that we expect to be implausible. However, we would not expect these implausible results to agree with the data much better than the 'correct' one does. Thus, when the restraints and constraints are removed or relaxed in the model, the fit quality should improve slightly (since there are now more degrees of freedom), but not very significantly. Should a much better fit be obtained without the constraints or restraints, this model should be examined carefully for evidence that inappropriate assumptions have been made. As an example, if all O atoms in a complex oxide are constrained to have the same U_{iso} value, then there may not be any direct evidence that one of the O-atom sites is only half occupied. Only when the constraint is removed will the U_{iso} value for the overfilled site rise significantly above that of the average, since twice as much scattering density has been placed in the model than is actually present. Refining or fixing the occupancy as half-filled for that site will lead to a much more accurate model, although the impact on the agreement factors may be small.

4.7.10. The order in which to introduce parameters in a fit

One challenge for crystallographers learning to use the Rietveld method is to understand in what sequence parameters should be varied when performing the fit. With a well behaved model, it should not matter in what order parameters are added to the model, but in practice this is only true when all of the starting parameter values are reasonably close to the optimal ones. When an attempt is made to fit too many parameters at once the refinement can diverge. A good example would be attempting to fit a pattern where the lattice constants and scale factor are both far from the correct values. If both sets of parameters are refined together, then the least-squares refinement can result in an improved fit by reducing the scale factor to a value close to zero, since most of the peak intensity is computed in areas where little is observed. Once the scale factor has been set to a very small value, the fit quality becomes highly insensitive to the values of the lattice parameters, since the computed pattern now contains only tiny peaks. At this point, the lattice constants are likely to refine to unreasonable values, since they have so little impact on the refinement. Once that happens, the refinement can be deemed as diverged – it is unlikely to find the global minimum for the refined parameters no matter how many cycles of fitting are tried. With some computer programs, parameters can refine to values that cause the program to crash, for example negative lattice constants. In such cases, manual intervention is needed to reset the model to a better starting point or to change the order in which parameters are introduced. As an example, if the previous refinement is started by fixing the scale factor manually to a reasonable value, to bring observed and calculated intensities on to the same scale, and there is some overlap between the observed and computed peaks, it is usually possible to refine the lattice parameters alone to reach a reasonable fit. Once that is done, the scale factor can be added to the fit. However, it is far better to start with accurate lattice parameters, in which case the scale factor and lattice parameters *can* be refined together initially. Often the easiest way to derive accurate lattice parameters is to index the pattern (see Chapter 3.4).

The rule of thumb for adding parameters to a refinement is this: one should successively add parameters to the fit in an order such that each new parameter or set of related parameters will result in the largest improvement of the fitting function. (This is a cumbersome way of saying 'deal with the biggest errors first'.) The experienced user of Rietveld refinements will have an intuitive feeling for this by graphically examining the differences between the observed and computed diffraction patterns. Note that it is rarely necessary to remove parameters from a fit once added, except when high levels of correlation occur. Instrumental parameters are best determined by fitting to data for standards or at least well characterized materials with the current instrumental settings before attempting an unknown. The process of fitting sample and structural parameters is much simpler without needing to establish good starting values for instrumental parameters as well.

While no recipe will fit all projects, a rough guide for the order in which to add parameters is to start by refining the scale factor and background, and then confirm that the lattice parameters are close to correct. If not, adding them as well may cause the refinement to fail, so one can try the approach described above or correct them manually and repeat the previous refinement. It is often useful to add a specimen-displacement parameter at this point when using Bragg–Brentano data, as displacement is often the largest source of systematic error in the peak positions. Once the scale, background and lattice parameters are fitted reasonably well, one must check that the computed peak profiles are a reasonable approximation to the experimental ones; if not, this will need to be addressed before going any further. If the structural parameters are quite far off, it may be difficult to improve the peak shapes by refining them. Best practice is to characterize the instrument response function for a diffractometer with a standard having minimal size and microstrain broadening prior to initiating Rietveld analysis on a sample, so that only profile contributions from sample size and microstrain need be considered. However, when this is not done, the compendium of profile coefficients from Kaduk & Reid (2011) may serve as useful refinement starting point. Alternately, a Le Bail or Pawley fit can be used to concentrate on fitting the profile terms.

If the computed pattern falls off much more quickly with increasing Q than the observed data, it usually indicates that the atomic displacement parameters are too high. Likewise, very low displacement parameters will cause the computed pattern to have a more gradual decrease in intensities. Surface roughness and beam spillover are often the cause of anomalously low displacement parameters, so these effects need to be understood and eliminated. If either is true at this stage in the refinement, it may be best to refine a single overall U_{iso} or B_{iso} value for all atoms. However, if it appears that the discrepancies between the observed and computed patterns are largely independent of Q, optimization of displacement parameters may be deferred until later.

Once one has obtained reasonable values for the non-structural parameters previously discussed and the atomic displacement parameters are of the right order of magnitude, one can include the refinement of atomic coordinates. Start by adding only the atoms that contribute most to the pattern – high-multiplicity and high-Z atoms (for X-rays) or high-scattering-length atoms for neutrons. Once this is done, the movements of atoms should be reviewed by keeping track of bond distances and angles. Should these values move outside of a reasonable range, the refinement may be diverging. This can be addressed through introduction of bond-distance constraints with a high weight, to keep the structure from drifting off to something implausible. Once all atomic positions, consistent with symmetry constraints, have been refined, one then usually adds isotropic atomic displacement parameters ($U_{\rm iso}$ values) for individual atoms to the refinement, starting with atoms that have the greatest scattering power. In more complex structures it may be necessary to assign a single $U_{\rm iso}$ value to a group of atoms with similar mass and coordination.

It is worthwhile performing a refinement where all the isotropic displacement parameters ($U_{\rm iso}$'s) are refined freely even where this model has too many parameters for the number of observations. The reason for this is to look for individual $U_{\rm iso}$ values that differ significantly ($\gg 3\sigma$) from what would be expected either for similar materials under similar conditions or for other atoms in the material. Values of $U_{\rm iso}$ that are very small or negative may indicate that the model is under-representing the scattering density on that site, perhaps because the wrong type of atom has been placed there or partial occupancy has been incorrectly assumed. Large values of $U_{\rm iso}$ are of greater concern. These can indicate that too much scattering density is present in the model, perhaps as a consequence of unmodelled vacancies or incorrect site assignments *etc*. Note that when data are collected over a narrow Q range (common with Cu $K\alpha$ data), displacement parameters are usually not well determined and it is difficult to learn much from the $U_{\rm iso}$ values. Unless data are collected over a very wide Q range, it is usually impossible to refine occupancy factors and displacement parameters for the same site.

If a good fit is not obtained at this point, one should review a difference Fourier map to look for atom sites that are missing from the model. Preferred orientation or anisotropic broadening will sometimes produce large deviations between observed and computed intensities and a good crystallographic fit may be impossible without including appropriate terms in the model.

Once the crystallographic model has been fitted well to the data, one should ensure that all appropriate non-structural parameters (for example, the peak-shape parameters) are added to the refinement, if not done previously; likewise, the correction terms for diffractometer positioning calibration, for example, 2θ zero point or sample displacement *etc.*, should be included.

To complete the refinement, it is worthwhile to consider whether preferred orientation or anisotropic broadening may be present at a subtler level. Adding the appropriate terms to the model and seeing if the agreement improves significantly is a way to test for this. If significant improvement in $R_{\rm wp}$ or χ^2 is not seen, reset the terms to remove the correction and remove the parameters from the fit. Also, at the end of the fitting process, it is good to see whether restraints can be removed from the model, or at least whether their weights can be reduced significantly. With data of exceptional quality, one may even try anisotropic refinement for atoms that dominate the scattering.

It is very important to review the final Rietveld fit graphically, to visually identify and understand the sources of discrepancies between the fit and the observed pattern. It is common to try out many different options for treating remaining discrepancies. It is equally important to review the model for chemical plausibility (Kaduk, 2007*a*,*b*; Chapter 4.9). Past members of the IUCr Commission on Powder Diffraction have published an excellent guide to the practice of conducting and reporting a Rietveld refinement (McCusker *et al.*, 1999).

4.7.11. Examples

Several detailed tutorials on Rietveld fitting are provided with the *GSAS-II* software system (Toby & Von Dreele, 2013) at https://subversion.xray.aps.anl.gov/pyGSAS/trunk/help/Tutorials.html and http://bit.ly/GSASIItutorials. They include:

$Y_3(Fe_{0.58}Al_{0.42})_2(Al_{0.70}Fe_{0.30})_3O_{12}$ – an yttrium iron aluminium garnet using constant-wavelength neutron data collected on the D1a powder diffractometer at ILL, using a wavelength of 1.909 Å.

$Ca_5F(PO_4)_3$ – fluoroapatite using constant-wavelength laboratory X-ray powder data.

$PbSO_4$ – lead sulfate using combined neutron (D1a at ILL, λ = 1.909 Å) and laboratory Bragg–Brentano (Cu $K\alpha$ radiation) powder data. The neutron pattern was collected at low temperature and the X-ray pattern was collected at ambient conditions, so the lattice parameters differ for the two data sets.

$Na_2Ca_3Al_2F_{14}$ (NAC) – sodium calcium aluminium fluoride using data collected at ambient conditions using both synchrotron (11-BM, Advanced Photon Source) and TOF neutron data (POWGEN, Spallation Neutron Source). The sample contains a CaF_2 (unreacted starting material) impurity.

$CuCr_2O_4$ – a sequential refinement using multiple data sets collected from 7 to 300 K.

4.7.12. Conclusions

Rietveld analysis is a complex process, since it must fit structural, sample and instrumental terms, but it can provide results that cannot be obtained in other ways or values at their ultimate precision. Structural determination from single-crystal diffraction is usually preferred where appropriate specimens are available, but for many materials or measurement conditions powder diffraction is preferred. For this reason, use of Rietveld analysis is growing.

My knowledge of this field and its history has benefited greatly from a large number of gracious mentors, who took the time to talk or correspond with me during my younger years. These individuals include Drs David Cox, Judith Stalick, Robert Von Dreele, Frank Rotella, Jim Jorgensen, Alan Hewat, Ted Prince, Tony Santoro, Ray Young and many others; I cannot thank them enough. I also thank Dr Diane P. Toby for her efforts to help me write this more clearly. This work would not have been completed without the US Department of Energy (DOE) support of the Advanced Photon Source, an Office of Science User Facility operated for the DOE Office of Science by Argonne National Laboratory, through DOE Contract No. DE-AC02-06CH11357.

4.8. Application of the maximum-entropy method to powder-diffraction data

O. V. Magdysyuk, S. van Smaalen and R. E. Dinnebier

4.8.1. Introduction

Applications of the maximum-entropy method (MEM) to X-ray powder-diffraction data include the determination of accurate charge-density and spin-density distributions, localization of the missing atoms in incomplete structure models, and analysis of the modulation functions for aperiodic structures. In all these applications the MEM must overcome the limitations imposed by the reduced information content of powder-diffraction data as compared with single-crystal diffraction data. At the same time, great care should be taken not to apply the MEM outside its range of validity. Results obtained by the MEM should be carefully checked.

The electron-density distribution is related to the structure factors in X-ray diffraction by a Fourier transformation. This relationship is used in many applications of the MEM, and the most accurate analyses are based on the availability of a complete set of structure factors up to a certain high resolution. Single-crystal X-ray diffraction experiments provide accurate values for the amplitudes of, in principle, all the structure factors. Phases of these structure factors may be obtained from a structural model or other sources. The information obtained by X-ray powder-diffraction experiments is even more limited than the missing phase information in single-crystal diffraction data, owing to the projection of three-dimensional reciprocal space onto the one-dimensional 2θ axis and the resulting intrinsic and accidental peak overlap (Fig. 4.8.1). The latter effect increases with increasing size of the unit cell. The intensities of individual reflections *hkl* can still be extracted from powder-diffraction data, but their accuracy depends on the degree of overlap of reflections and on the quality of the powder pattern. Thus, powder averaging of the diffraction data strongly reduces its information content. The typical resolution of powder-diffraction data of $[(\sin\theta)/\lambda]_{\max} \simeq 0.6\ \text{Å}^{-1}$ prevents the determination of accurate electron densities by means of multipole refinements or Fourier transformation.

In neutron and X-ray scattering, the problem of the complex Fourier inversion of a limited set of noisy data has to be solved to determine the corresponding real-space scattering density. The electron (nuclear) density $\rho(\mathbf{r})$ in the unit cell of an ideal crystal is the inverse Fourier transform of an infinite number of structure factors $F(\mathbf{H})$:

$$\rho(\mathbf{r}) = \frac{1}{V}\sum_{\mathbf{H}} F(\mathbf{H})\exp\left(-2\pi i\mathbf{H}^T\cdot\mathbf{r}\right), \qquad (4.8.1)$$

where $\mathbf{H} = hkl$ is a reciprocal-lattice vector, V is the volume of the (direct) unit cell and $\mathbf{r} = (x, y, z)$ is the position vector of a point in direct space. The summation in equation (4.8.1) extends over the entire reciprocal lattice.

Most experiments provide a limited number of observed structure factors $F_{\rm obs}(\mathbf{H})$. Thus the summation runs over a finite number of Fourier amplitudes, and the Fourier transform is affected by series-termination errors (*e.g.* spurious peaks with positive densities that do not correspond to atoms in the structure, or local minima of unphysical negative densities). It has been shown that a Fourier map free from series-termination effects can be obtained by Fourier inversion of a complete set of structure factors up to at least $\sin(\theta)/\lambda = 6\ \text{Å}^{-1}$ (de Vries *et al.*, 1996; Roversi *et al.*, 1998; Mondal *et al.*, 2012), a resolution far beyond any realistic experimental resolution. Another disadvantage of the Fourier synthesis for computing electron densities is its inability to incorporate additional information about the density map, such as enforcing strict positivity of this map.

The concept of the entropy of a map of strictly positive values goes back to Shannon (1948*a*,*b*). The term ‘informational entropy’ refers to the mathematical similarities between this concept and the thermodynamic entropy. Maximizing the entropy of a map has become a powerful tool for solving reconstruction problems suffering from incomplete and/or noisy information. This method forms the basis for statistical mechanics and it plays an important role in the analysis of experimental data in a wide range of fields, such as astronomy, medicine, economics and condensed-matter physics. Ideally, the MEM gives a distribution that is consistent with the given information, is least biased with respect to missing information and does not introduce correlations in the results beyond those that are required by the data (French, 1978; Shore & Johnson, 1980, 1983; Gull & Skilling, 1984; Navaza *et al.*, 1983; Navaza, 1985, 1986; Livesey & Skilling, 1985). From the maps that fit the data, the criterion of maximum entropy (MaxEnt) selects the map with the least input information, thus giving the most probable result.

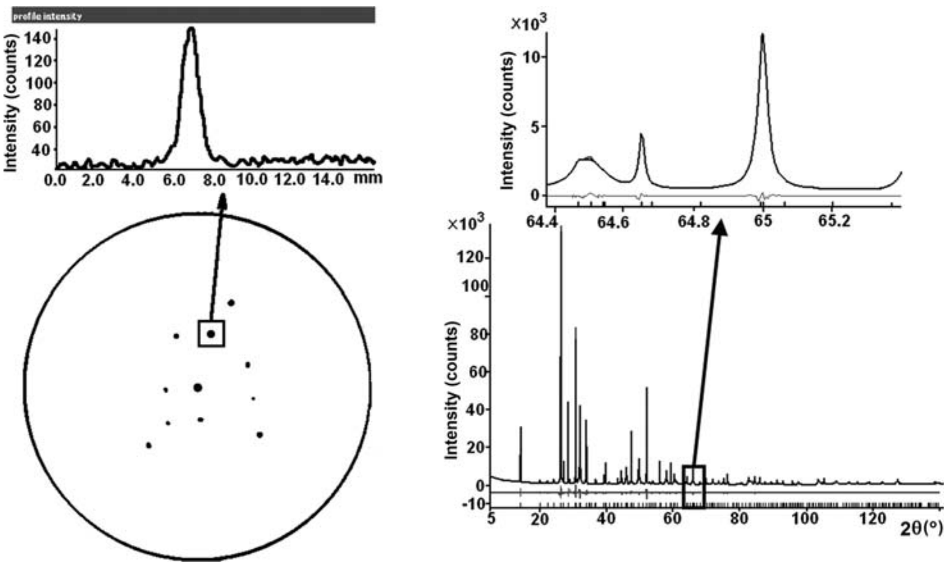

Figure 4.8.1

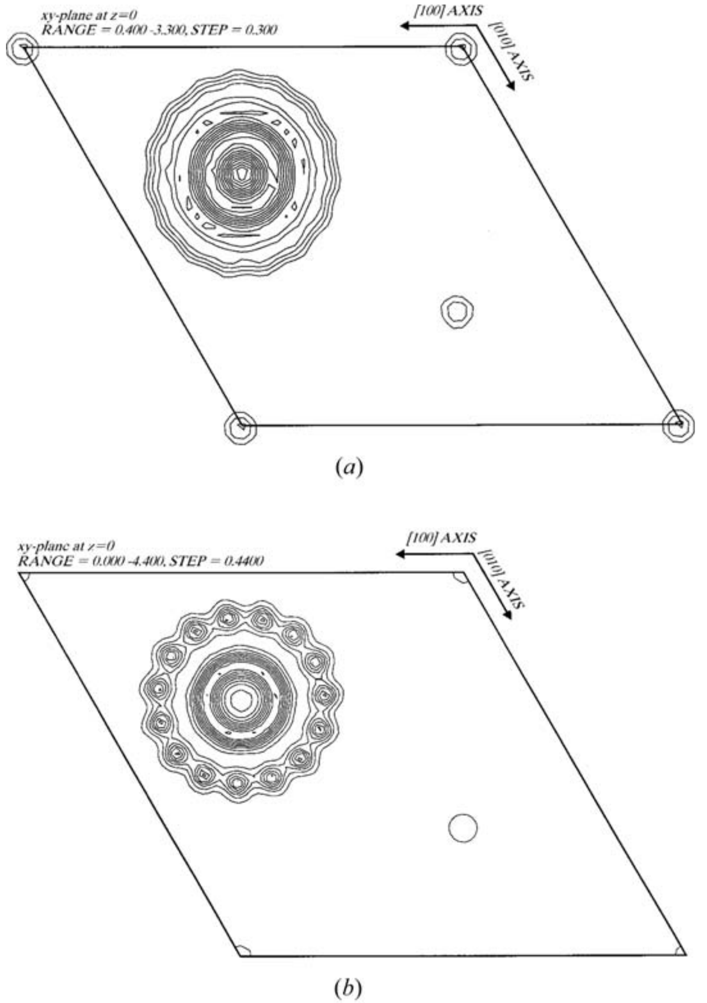

Figure 4.8.2
Electron-density distribution for threefold disordered pentamethylcyclopentadienyllithium (Li[$C_{10}H_{15}$], LiCp*). Shown are sections containing: (*a*) the planar fivefold ring in the Fourier map based on $F_{\rm obs}$, $\varphi^{\rm calc}$; (*b*) an MEM map based on $F_{\rm obs}$, $\varphi^{\rm calc}$ up to a resolution of $[\sin(\theta)/\lambda]_{\max} = 0.6$ Å^{-1} (from Dinnebier *et al.*, 1999).

The electron density in the unit cell is one type of map with strictly positive values, which thus has an entropy according to Shannon (1948*a*,*b*). The concept of entropy maximization was introduced into the field of crystallography to handle series-termination effects in Fourier maps. The MEM can successfully work with structure factors from powder diffraction for which $[\sin(\theta)/\lambda]_{\max} \geq 0.6$ Å^{-1}. Series-termination effects are much less prominent in MEM-optimized electron-density maps than in Fourier maps obtained with the same data. This is illustrated by application of both methods to the diffraction data of LiCp* (with structure-factor amplitudes $F_{\rm obs}$ and phases $\varphi^{\rm calc}$ calculated for a structure model with threefold disorder of the cyclopentadienyl ring; Dinnebier *et al.*, 1999). The electron density of the Fourier map exhibits almost cylindrical symmetry and individual atoms cannot be discerned (Fig. 4.8.2*a*), while the MEM electron density exhibits local maxima for each of the fifteen disordered positions of the methyl carbon atoms along the ring (Fig. 4.8.2*b*).

Another example is the electron-density distribution of Si (Fig. 4.8.3) calculated from powder X-ray diffraction data $F_{\rm obs}$ and phases $\varphi^{\rm calc}$ from a structure model (Sakata & Sato, 1990; de Vries *et al.*, 1996). The inverse Fourier transformation does show the atomic maxima, but it also contains severe series-termination effects within the regions of chemical bonds. On the other hand, the MEM applied to the same data but now using a procrystal electron density as prior or reference density clearly shows the electron density within the chemical bonds between the Si atoms. From Fig. 4.8.3, it follows that the Fourier map is not suitable for accurate charge-density analysis.

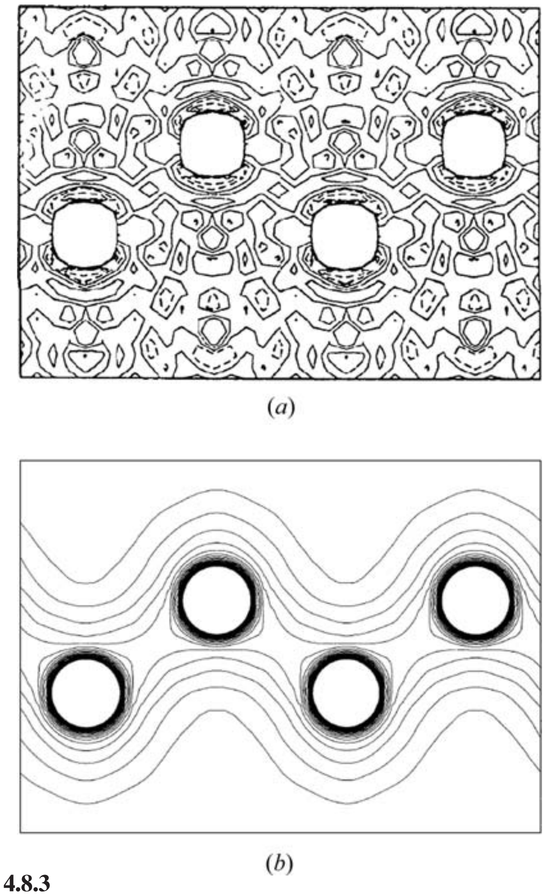

Figure 4.8.3
Electron-density distribution in the (110) plane of Si, calculated from powder X-ray diffraction data. (*a*) Inverse Fourier transform based on $F_{\rm obs}$, $\varphi^{\rm calc}$, contour level from −2.4 to 1.6 e Å^{-3} with step size 0.8 e Å^{-3} (from Sakata & Sato, 1990); (*b*) MEM electron density based on $F_{\rm obs}$, $\varphi^{\rm calc}$ (with procrystal prior); contour level from 0 to 2.5 e Å^{-3} with step size 0.1 e Å^{-3}. 4.8.2. The principle of maximum entropy

The success of the MEM for deriving accurate electron-density (or nuclear-density) distributions from powder-diffraction data relies on the fact that these density maps are strictly positive. The entropy S of a discrete electron density is defined as

$$S = -\sum_{i=1}^{N_{\rm pix}} \left[-\rho_i + \rho_i^{\rm prior} + \rho_i \ln\left(\frac{\rho_i}{\rho_i^{\rm prior}}\right)\right], \qquad (4.8.2)$$

where the electron density is represented by its values $\rho_i = \rho(\mathbf{r}_i)$ on a sufficiently fine grid of $N_1 \times N_2 \times N_3 = N_{\rm pix}$ pixels over the unit cell, $\mathbf{r}_i$ being the position of pixel i. The grid must obey the crystal symmetry: each grid point must be transformed onto itself or onto another grid point by all symmetry operators. The values of $\rho_i^{\rm prior}$ define the prior (or reference) electron density. The prior density can be a constant function, thus called a flat or uniform prior. Alternatively, it can represent any desirable distribution of the available electrons over the unit cell.

Analysis of the electron-density distribution in the unit cell requires the determination of the values ρ_i at every point i of the grid. Of all possible electron-density maps only some are consistent with the measured diffraction data. The basic principle of the MEM is that the optimal image is defined to be the image with the maximum value of the entropy functional S, while one or more constraints of the type $C_j = 0$ ($j = 1, \ldots, N_C$) are fulfilled. The constraints should include at least one constraint involving the observed data. The technique of maximizing the entropy favours smooth maps, since the unconstrained maximum of S [equation (4.8.2))] is given by the prior density: $\rho(\mathbf{r}_i) = \rho^{\text{prior}}(\mathbf{r}_i)$.

4.8.3. Prior densities in MEM calculations

As part of Bayesian statistics, the MEM includes the so-called prior electron density ('prior' in short), equation (4.8.2). The prior is an essential part of the MaxEnt formalism, especially for powder-diffraction data. Fine features of the electron density, like the atomic charges or the distribution of the electron density within chemical bonds, are only revealed by the MEM if a sufficiently informative prior is employed (Zheludev *et al.*, 1995; Schotte *et al.*, 1995; de Vries *et al.*, 1996; Roversi *et al.*, 1998; Papoular *et al.*, 2002; Palatinus & van Smaalen, 2002; van Smaalen *et al.*, 2003; Buchter *et al.*, 2011). The same condition holds for MaxEnt reconstruction of extended X-ray absorption fine structure (EXAFS) analysis (Gull & Skilling, 1984).

The prior electron density is chosen to reflect as much as possible our state of knowledge about the true electron density. The best prior that can be obtained from a standard Rietveld refinement of powder-diffraction data is the thermally smeared electron density of the independent-atom model (IAM). The IAM density is a superposition of the spherically symmetric electron densities of free atoms convoluted with their thermal motion and placed at the positions in the structure model (Palatinus, 2003). An electron density constructed in this way is called a procrystal electron density [$\rho^{\text{IAM}}(\mathbf{r})$]. The IAM describes the major part of the electron density, but it does not fully account for the effects of bonding on the electron density. The deformation of the electron density due to the bonding is determined by the difference $\rho^{\text{MEM}} - \rho^{\text{IAM}}$ (van Smaalen *et al.*, 2003; Palatinus, 2003).

Recently, procrystal electron densities free from series-termination effects have been created by inverse Fourier transform of the structure factors calculated for an IAM or a multipole model up to a resolution of $\sin(\theta)/\lambda > 6.0$ Å^{-1} (Mondal *et al.*, 2012). An alternative method (Papoular *et al.*, 2002) is based on the evaluation of the electron density by means of an analytical Fourier transform, using the analytical approximation of the atomic form factors:

$$f_a\left(\frac{\sin\theta}{\lambda}\right) = \sum_{i=1}^{n} a_i \exp\left(-b_i \frac{\sin^2\theta}{\lambda^2}\right), \tag{4.8.3}$$

where a_i and b_i have been determined by comparison with the atomic wave functions, with $n = 5$ in Waasmaier & Kirfel (1995), and with $n = 6$ in Su & Coppens (1997) and Macchi & Coppens (2001).

For MEM calculations the atomic form factor in equation (4.8.3) should be expressed as a function of the diffraction vector $\mathbf{H}$ in the reciprocal crystal coordinates (Papoular *et al.*, 2002; Palatinus, 2003):

$$f_a(\mathbf{H}) = \sum_{i=1}^{n} a_i \exp\left(-\frac{b_i}{4}|\mathbf{H}|^2\right) = \sum_{i=1}^{n} a_i \exp\left(-\frac{b_i}{4}\mathbf{H}^T \boldsymbol{G}^* \mathbf{H}\right), \tag{4.8.4}$$

where $\boldsymbol{G}^*$ is the reciprocal metric tensor

$$G^*_{ij} = \mathbf{a}^*_i \cdot \mathbf{a}^*_j. \tag{4.8.5}$$

The anisotropic dynamic atomic form factor is defined as a convolution of the static atomic electron density with the anisotropic harmonic thermal motion of the atom (Palatinus, 2003), and is expressed in reciprocal space by multiplying the atomic form factor by the corresponding Debye–Waller factor that involves the displacement tensor $\boldsymbol{U}$ [*International Tables for Crystallography*, Volume B (Shmueli, 1996)]. This gives the anisotropic dynamic atomic form factor d_a,

$$d_a(\mathbf{H}) = \sum_{i=1}^{n} a_i \exp\left(-\frac{b_i}{4}\mathbf{H}^T \boldsymbol{G}^* \mathbf{H}\right) \exp\left(-2\pi^2 \mathbf{H}^T \mathbf{A}^* \boldsymbol{U} \mathbf{A}^* \mathbf{H}\right). \tag{4.8.6}$$

The matrix $\mathbf{A}^*$ is a diagonal matrix containing the lengths of the reciprocal-space basis vectors $\mathbf{a}^*_i$:

$$A^*_{ii} = \left|\mathbf{a}^*_i\right|^2; \quad A^*_{ij} = 0 \text{ for } i \neq j, \tag{4.8.7}$$

$$\begin{aligned} d_a(\mathbf{H}) &= \sum_{i=1}^{n} a_i \exp\left[-\mathbf{H}^T\left(\frac{b_i}{4}\boldsymbol{G}^* + 2\pi^2 \mathbf{A}^* \boldsymbol{U} \mathbf{A}^*\right)\mathbf{H}\right] \\ &= \sum_{i=1}^{n} a_i \exp\left(-\mathbf{H}^T \boldsymbol{M}_i \mathbf{H}\right), \end{aligned} \tag{4.8.8}$$

where $\boldsymbol{M}_i = [(b_i/4)\boldsymbol{G}^* + 2\pi^2 \mathbf{A}^* \boldsymbol{U} \mathbf{A}^*]$. The dynamic electron density of an atom is given by the Fourier transform of d_a:

$$\rho_a(\mathbf{r}) = |\boldsymbol{G}^*|^{1/2} \sum_{i=1}^{n} a_i \frac{\left|\boldsymbol{M}_i^{-1}\right|}{(2\pi)^{3/2}} \exp\left(-\mathbf{r}^T M_i^{-1} \mathbf{r}\right). \tag{4.8.9}$$

Finally, the procrystal electron density is obtained as the sum of atomic electron densities.

The prior density can be a constant (flat prior) with a value equal to the average electron density in the unit cell. Experience has shown that in the case of a uniform (flat) prior, the MEM-reconstructed electron density contains artifacts of larger magnitudes than the electron densities in bonding regions. Such MEM densities are thus not suitable for the investigation of the fine features of the electron densities. Use of a procrystal prior electron density reduces the artifacts and the resulting MEM-reconstructed electron density contains information about the redistribution of the electron density due to bonding and gives more accurate atomic charges.

Ongoing debates about the need to use a prior density in MEM calculations and about the type of prior density arise from misunderstandings of the role of the prior density in the procedure for applying the MEM for the determination of accurate charge-density distributions, and of the possibilities and limitations of the method. The prior density provides the correct estimate of the initial values of the structure factors of missing reflections and decreases the dynamic range of MEM calculations, thus making the MEM calculations numerically more stable.

The MEM reconstructions of the electron density of simple structures of Si and Be were initially performed with flat priors and revealed non-nuclear maxima in the electron density between the Si—Si and Be—Be bonds (Sakata & Sato, 1990; Iversen *et al.*, 1995). These non-nuclear maxima are not artifacts intrinsic to the MEM, but they represent low-level noise due to the use of a flat prior and a data set of limited resolution. They are not present in MEM electron-density maps calculated with procrystal densities (de Vries *et al.*, 1996). The sets of structure factors that were not measured (usually high-angle reflections) are extrapolated by the MEM to obtain the solution with the maximum entropy. Incorrect estimation of the non-measured structure factors by the MEM leads to the errors in the reconstructed MEM density. The prior information in the form of a procrystal electron density is a good estimate for the non-measured structure factors (Palatinus, 2003).

4.8.4. Crystallographic MEM equations

The basic equations and algorithms for MEM were developed in the field of image reconstruction for radio astronomy and were then adapted to different crystallographic problems (French, 1978; Collins, 1982; Collins & Mahar, 1983; Wilkins, 1983; Wilkins *et al.*, 1983; Navaza *et al.*, 1983; Bricogne, 1984; Navaza, 1985, 1986). In crystallographic applications of the MEM, the 'image' is the electron-density map and the data are structure factors of Bragg reflections. Here they will be considered for the case of X-ray powder-diffraction experiments. Since all MEM algorithms work with a discrete electron density, all MEM equations will be derived for the grid case and we will not use the analytical formalism. Readers who are interested in the analytical formalism should see Bricogne (1984) and Gilmore (1996).

The maximum-entropy criterion selects the electron-density map of maximum entropy among the maps that fulfil the constraints (Gull & Skilling, 1984). The data are supposed to be noisy with a Gaussian distribution of their estimated standard uncertainties (s.u.'s). Therefore the most probable solution is not the map corresponding to an exact fit to each reflection, but the map that satisfies the condition for so-called F constraints:

$$C_F = -\chi^2_{\rm aim} + \frac{1}{N_F}\sum_{i=1}^{N_F} w_i \left(\frac{|F_{\rm obs}(\mathbf{H}_i) - F_{\rm MEM}(\mathbf{H}_i)|}{\sigma(\mathbf{H}_i)}\right)^2 = 0, \tag{4.8.10}$$

where N_F is the number of observed structure factors $F_{\rm obs}(\mathbf{H}_i)$ with standard uncertainties $\sigma(\mathbf{H}_i)$; $F_{\rm MEM}(\mathbf{H}_i)$ is obtained by discrete Fourier transform of the current estimate of the charge density $\{\rho_i\}$. The standard version of the MEM employs $w_i = 1$ and $\chi^2_{\rm aim} = 1$.

The second constraint that is usually used in crystallographic applications of the MEM is the normalization of $\{\rho_i\}$ to the expected number of electrons, $N_{\rm el}$, in the unit cell of volume $V_{\rm UC}$:

$$C_N = N_{\rm el} - \frac{V_{\rm UC}}{N_{\rm pix}}\sum_{i=1}^{N_{\rm pix}} \rho_i = 0. \tag{4.8.11}$$

These constraints are chosen in a way that requires them to become zero when the conditions they represent are fulfilled. The amplitudes of the structure factors $F_{\rm obs}(\mathbf{H}_i)$ are determined experimentally and therefore each trial $\{\rho_i\}$ can be rejected or accepted based on its agreement with the experimental data.

The *unconstrained* maximum of the entropy [equation (4.8.2)] is given by $\rho_i = \rho_i^{\rm prior}$ for all points i. This means that the MEM reproduces the prior, which is indeed the best estimate for the electron density if data are not available. In particular, if only the total number of electrons per unit cell is known, the best estimate is a flat electron-density distribution.

Having N_C constraints, we should perform the constrained maximization of the entropy with respect to the $N_{\rm pix}$ values $\{\rho_i\}$. This optimization problem is solved by the application of the method of undetermined Lagrange multipliers λ_j (Palatinus, 2003):

$$Q(\{\rho_i\}) = S(\{\rho_i\}) - \sum_{j=1}^{N_C} \lambda_j C_j(\{\rho_i\}). \tag{4.8.12}$$

Differentiating the above equation with respect to ρ_i gives the condition

$$\frac{\partial Q}{\partial \rho_i} = \frac{\partial S}{\partial \rho_i} - \sum_{j=1}^{N_C} \lambda_j \frac{\partial C_j}{\partial \rho_i}. \tag{4.8.13}$$

Written explicitly for the two constraints C_F and C_N [equations (4.8.10) and (4.8.11)] and using the definition of entropy [equation (4.8.2)] we obtain

$$\frac{\partial Q}{\partial \rho_i} = -\ln\left(\frac{\rho_i}{\rho_i^{\rm prior}}\right) - \lambda_F \frac{\partial C_F}{\partial \rho_i} - \frac{V_{\rm UC}}{N_{\rm pix}}\lambda_N. \tag{4.8.14}$$

The maximum of Q follows from $\partial Q/\partial \rho_i = 0$ for all ρ_i, resulting in the formal solution for ρ_i,

$$\rho_i = \rho_i^{\rm prior} \exp\left(-\frac{V_{\rm UC}}{N_{\rm pix}}\lambda_N\right) \exp\left(-\lambda_F \frac{\partial C_F}{\partial \rho_i}\right), \tag{4.8.15}$$

where $\partial C_F/\partial \rho_i$ depends on all $\{\rho_i\}$. Substitution into the normalization condition [equation (4.8.11)] yields

$$\sum_{i=1}^{N_{\rm pix}} \rho_i^{\rm prior} \exp\left(-\frac{V_{\rm UC}}{N_{\rm pix}}\lambda_N\right) \exp\left(-\lambda_F \frac{\partial C_F}{\partial \rho_i}\right) = \frac{N_{\rm el} N_{\rm pix}}{V_{\rm UC}}. \tag{4.8.16}$$

The combination of equations (4.8.15) and (4.8.16) allows the elimination of the Lagrange multiplier λ_N. The final result for the normalized electron density is

$$\rho_i = \frac{N_{\rm el} N_{\rm pix}}{V_{\rm UC}} \rho_i^{\rm prior} \exp\left(-\lambda_F \frac{\partial C_F}{\partial \rho_i}\right) \Big/ \left[\sum_{i=1}^{N_{\rm pix}} \rho_i^{\rm prior} \exp\left(-\lambda_F \frac{\partial C_F}{\partial \rho_i}\right)\right]. \tag{4.8.17}$$

Equation (4.8.17) together with equation (4.8.10) gives a set of $N_{\rm pix} + 1$ nonlinear equations in the $N_{\rm pix}$ parameters $\{\rho_i\}$ and the Langrange multiplier λ_F. They cannot be solved analytically, because $\{\rho_i\}$ is included on both sides of equation (4.8.17).

4.8.5. MEM algorithms

Several iterative algorithms have been developed for solving the MEM equations (4.8.10) and (4.8.17). All approaches start with the prior density as zeroth-order approximation to the electron density:

$$\rho_i^{(0)} = \rho_i^{\rm prior}. \tag{4.8.18}$$

4.8.5.1. *Exponential modelling algorithm (Gull & Daniell, 1978; Collins, 1982; Collins & Mahar, 1983)*

The simplest algorithm is the exponential modelling algorithm (Gull–Daniell algorithm). For a small value of λ_F and starting with $n = 0$, the approximate solution $\{\rho_i^{(n)}\}$ of iteration n is used to evaluate the right-hand side of equation (4.8.17), thus providing the next estimate, $\{\rho_i^{(n+1)}\}$, for the electron-density map. The iteration is continued until convergence, *i.e.* until $\rho_i^{(n+1)} = \rho_i^{(n)}$ for all i. Then the value of λ_F is increased by a small amount, and iterations are again continued until $\rho_i^{(n+1)} = \rho_i^{(n)}$. The whole procedure is considered to be converged once the constraint equation (4.8.10) is fulfilled.

The Gull–Daniell algorithm in its initial form is known to be unstable, and several extensions have been proposed (Wu, 1997).

Significant improvement of this algorithm was achieved for the *ab initio* phasing of structure factors from single-crystal and powder-diffraction data (Bricogne & Gilmore, 1990; Gilmore *et al.*, 1990, 1991, 1999; Bricogne, 1988, 1991, 1993; Gilmore & Nicholson, 1994).

4.8.5.2. *Sakata–Sato algorithm (Sakata & Sato, 1990; Sakata et al., 1990, 1992, 1993; Kumazawa et al., 1995)*

This approach is similar to the Gull–Daniell algorithm, except that at each iteration step n not only the right-hand side of equation (4.8.17) is evaluated by substitution of $\{\rho_i^{(n)}\}$ for $\{\rho_i\}$, but also the prior density is replaced by $\{\rho_i^{(n)}\}$. The iterations commence with a fixed, suitably chosen value of λ_F. The iterations are considered to be converged once the constraint equation (4.8.10) is satisfied, *i.e.* when C_F drops below zero.

The Sakata–Sato algorithm implies that the prior is updated in every cycle, a procedure which violates the statistical principles at the foundation of the MEM. However, the algorithm has been shown to perform well in many applications, and thus is justified by the results rather than by a firm theoretical foundation (van Smaalen *et al.*, 2003).

The value of λ_F has an intricate effect on the iterations. The procedure does not converge for too large values of λ_F. Experience has shown that reliable MEM-optimized electron densities are only obtained if the value of the constraint [equation (4.8.10)] decreases in each step of the iteration. This can be achieved for sufficiently small λ_F, and the MEM-optimized electron density does not depend on the value of λ_F (Sakata & Sato, 1990; Kumazawa *et al.*, 1995). However, too small values of λ_F lead to very slow convergence, such that true convergence might not be reached within finite time. It is thus necessary to increase the value of λ_F after several iterations, or to employ the criterion of decrease of the value of the constraint at every cycle for automatic determination of an optimal value of λ_F (van Smaalen *et al.*, 2003).

4.8.5.3. *Cambridge algorithm (Bryan & Skilling, 1980, 1986; Burch et al., 1983; Skilling & Bryan, 1984; Gull & Skilling, 1987, 1999)*

The Cambridge algorithm for finding the map with the maximum entropy is based on Bayesian probability theory. Maximum probability that an electron-density map is the true electron density is attained for the density $\{\rho_i\}$ that maximizes the function

$$Q\big[\{\rho_i\}\big] = \alpha S\big[\{\rho_i\}\big] - C_F\big[\{\rho_i\}\big]. \tag{4.8.19}$$

Notice that the Lagrange multiplier λ_F of equation (4.8.12) is replaced by $1/\alpha$ here. The Cambridge algorithm involves a double iteration very similar to the Gull–Daniell algorithm (Section 4.8.5.1). Initially, for a large but fixed value of α the maximum of $Q[\{\rho_i\}]$ is determined by iteration over $\{\rho_i\}$. The value of α is gradually decreased, and at each value of α a new estimate of $\{\rho_i\}$ is obtained by iterative search for the maximum of $Q[\{\rho_i\}]$. The double iteration is converged once the constraint equation (4.8.10) is fulfilled. Probability theory provides a value for $\chi^2_{\rm aim}$ based on the data; its value usually is smaller than one.

The success of the Cambridge algorithm is rooted in the special iterative procedure for finding the maximum of $Q[\{\rho_i\}]$ for each given value of α. Unlike the Sakata–Sato algorithm, the Cambridge algorithm fulfils the formal requirements of the MEM approach, for example leading to an MEM-optimized electron density that better obeys the criterion $\partial Q/\partial \rho_i = 0$ than the Sakata–Sato algorithm does (van Smaalen *et al.*, 2003). Nevertheless, the MEM-optimized electron-density map is not necessarily better than the one obtained with the Sakata–Sato algorithm.

4.8.5.4. *Two-channel MaxEnt method (Papoular & Gillon, 1990; Zheludev et al., 1995; Papoular et al., 1996)*

The MEM requires a map with strictly positive values, as is provided by the electron density. Maps with both positive and negative values can be written as the difference between two strictly positive maps. The entropy can now be defined as the sum of entropies according to equation (4.8.2) of these two strictly positive functions. The concept of two-channel entropy was first introduced for reconstruction of the magnetization density from polarized neutron scattering data, whereby the two directions of the spin are represented by the two maps (Papoular & Gillon, 1990). The same formalism was used to reconstruct the deformation electron density, which has both positive and negative values (Papoular *et al.*, 1996). The deformation density $\Delta\rho(\mathbf{r})$ is written as the difference between two positive functions, ρ^+ and ρ^-, representing the densities of accumulation and depletion of electrons as compared to the IAM, respectively:

$$\Delta\rho(\mathbf{r}) = \rho^+(\mathbf{r}) - \rho^-(\mathbf{r}). \tag{4.8.20}$$

The entropy of the difference density is then defined as the sum of the entropies of $\rho^+(\mathbf{r})$ and $\rho^-(\mathbf{r})$,

$$\begin{aligned} S_{\Delta\rho} &= S_{\rho^+} + S_{\rho^-} \\ &= -\sum_{i=1}^{N_{\rm pix}} \left[-\rho_i^+ + \rho_i^{(\rm prior)+} + \rho_i^+ \ln\left(\frac{\rho_i^+}{\rho_i^{(\rm prior)+}}\right)\right] \\ &\quad - \sum_{i=1}^{N_{\rm pix}} \left[-\rho_i^- + \rho_i^{(\rm prior)-} + \rho_i^- \ln\left(\frac{\rho_i^-}{\rho_i^{(\rm prior)-}}\right)\right]. \end{aligned} \tag{4.8.21}$$

This entropy is maximized to obtain the MEM-reconstructed difference density $\Delta\rho_{\rm MEM}$. The input data consist of the difference structure factors $\Delta F = F_{\rm obs} - F_{\rm model}$. Any of the algorithms for MEM calculations described above can be modified for two-channel entropy calculations. The advantage of this approach is that the dynamic range of the map $\Delta\rho(\mathbf{r})$ is much smaller than the dynamic range of the electron density itself. The disadvantage of this formalism is that it introduces additional freedom in the form of two values (ρ_i^+ and ρ_i^-) representing the value of the map at pixel i. As a result, the two-channel entropy can suppress fine details in the reconstructed difference density. This problem can be partially solved by decreasing the stopping value of the constraints. So far, the two-channel algorithm has been tested exclusively on single-crystal diffraction data.

4.8.5.5. *Valence-only MaxEnt method (Roversi et al., 1998)*

This method aims for an accurate electron-density study at the last stage of structural analysis. The refined structural parameters are used to create a core electron-density fragment, which then is considered to be known and is not included in the MaxEnt optimization. Only the valence electron density is modified. This method relies on very precise knowledge of the atomic displacement parameters (ADPs), which is often not available. Any error in the ADPs leads to negative regions in the valence density, which cannot be accounted for by the MEM. So far, the valence-only algorithm has been tested exclusively on simulated single-crystal X-ray diffraction data.

4.8.6. Constraints in the MEM based on the measured intensities from powder-diffraction data

4.8.6.1. *F and G constraints*

Integrated intensities of individual Bragg reflections can be determined by powder diffraction for resolved reflections as well as for reflections without too severe overlap, employing one of the decomposition techniques for powder-diffraction data. These reflections can be used to define an F constraint [equation (4.8.10)] and the MEM may be applied in exactly the same way as for single-crystal diffraction data (Section 4.8.4).

Fig. 4.8.4 presents an example of decomposition of the intensities of overlapping reflections into individual reflections by a Le Bail fit (without a structural model; see Chapter 3.5) and by a Rietveld refinement (with a structural model) for $K_2C_2O_4$ (Samy *et al.*, 2010; Dinnebier *et al.*, 2005). Careful consideration of the Rietveld and Le Bail plots shows strong differences between peak fitting at $2\theta = 37.7^\circ$. Two reflections at $2\theta = 37.7^\circ$ are fully overlapped, and the Le Bail fit assigns equal intensities to both reflections. The Rietveld refinement assigns all experimental intensity to one Bragg reflection and zero intensity to the other, because the calculated structure factor of the latter is zero.

A simple two-peaks example (taken from Takata, 2008) of the decomposition of intensities of partially overlapped reflections allows us to consider in detail the Rietveld and Le Bail decomposition methods. The calculated diffraction pattern does not provide an exact description of the data points in Fig. 4.8.5 owing to the incomplete structure model. The peak area is proportional to the square of the structure-factor amplitude and thus the problem is reduced to finding the peak area. The observed peak area is easy to evaluate for an isolated peak. The fundamental idea of the procedure for extraction of intensities of individual reflections from partially and completely overlapped reflections is simple: instead of using the integrated intensities from a powder-diffraction pattern (like in single-crystal analysis), the entire information content of a powder pattern available in step-scanned intensity data is subjected to refinement using a least-squares procedure.

The diffracted intensity at each data point is distributed over the contributing reflections according to the calculated intensities of these reflections at that point:

$$Y_i^{\rm obs}(2\theta_j) = \frac{Y^{\rm obs}(2\theta_j)\,Y_i^{\rm calc}(2\theta_j)}{\sum_{i=1}^{N} Y_i^{\rm calc}(2\theta_j)}, \qquad (4.8.22)$$

where $Y^{\rm obs}(2\theta_j)$ is the observed diffraction intensity at scattering angle $2\theta_j$, which is split into contributions $Y_i^{\rm obs}(2\theta_j)$ from $i = 1, \ldots, N$ reflections (Fig. 4.8.5*b*). $Y_i^{\rm calc}(2\theta_j)$ is the calculated intensity of the ith reflection at $2\theta_j$; its value depends on the structure-factor amplitude of reflection i as well as on the profile function and distance between $2\theta_j$ and $2\theta_{hkl}$ (Fig. 4.8.5*a*; Rietveld, 1967, 1969). The observed structure-factor amplitude, $|F_{\rm obs}(\mathbf{H}_i)|^2$, of reflection i is obtained by summation of $Y_i^{\rm obs}(2\theta_j)$ over all $2\theta_j$ [equation (4.8.22)]. In the case of Rietveld decomposition, the calculated structure factors of the model are used in equation (4.8.22) to decompose overlapping reflections into contributions of individual reflections. This procedure results in strong bias by the (incomplete) model of the intensities and phases of individual reflections. The Le Bail fit works without a structure model. All calculated structure-factor amplitudes are initially given unit value, and the values of the integrated intensities are determined iteratively. Bragg reflections of unequal intensity are obtained by using the profile functions. For fully overlapping peaks, the intensities are partitioned equally (Le Bail *et al.*, 1988).

The observed structure-factor amplitudes can be used in MEM calculations in combination with reflection phases from the structural model. The MEM-reconstructed electron density is not necessarily accurate, because any technique of decomposition results in structure-factor amplitudes of individual reflections of limited accuracy that are possibly biased by the model. These

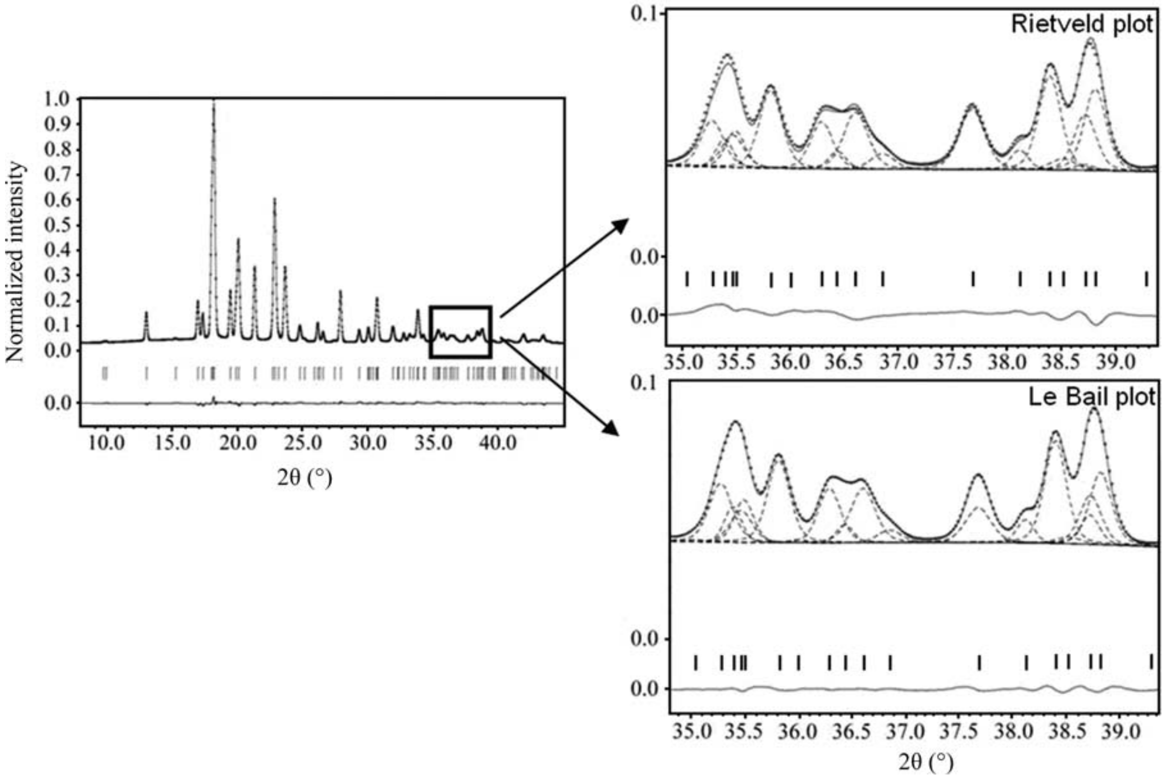

Figure 4.8.4

Dividing of the total intensity of the overlapping reflections into the contributions of individual reflections by Rietveld refinement (with a structural model) and by Le Bail fitting (without a structural model) for powder-diffraction data for $K_2C_2O_4$ (adapted from Samy *et al.*, 2010).

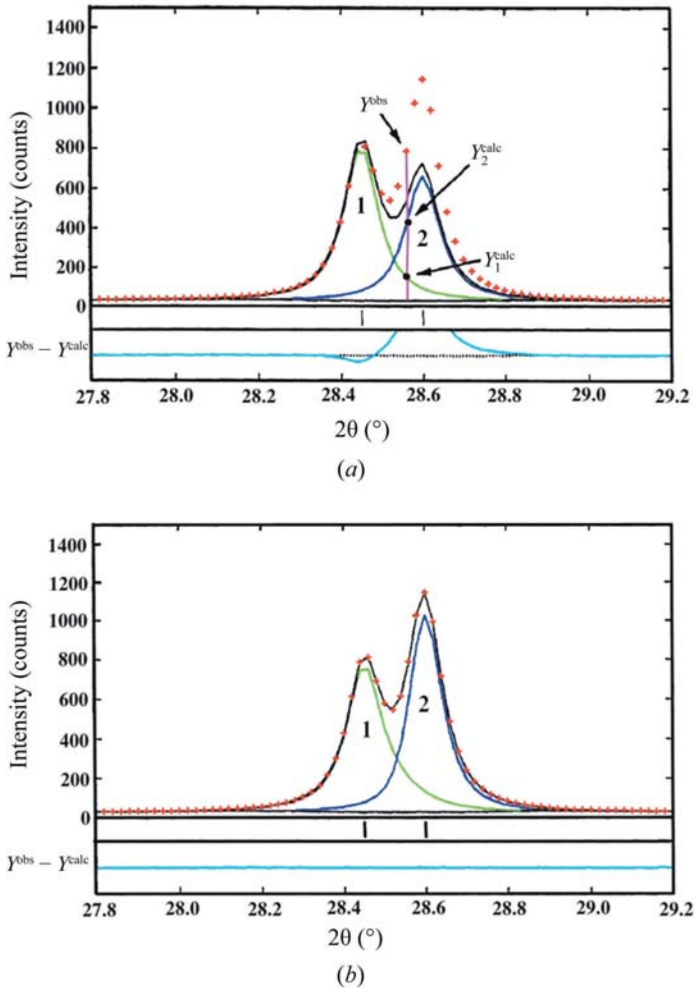

Figure 4.8.5
Observed intensity (points) as a function of the scattering angle, together with lines representing (*a*) the calculated intensity of the Rietveld refinement and (*b*) the intensities after decomposition according to equation (4.8.22) (from Takata, 2008).

uncertainties can be avoided by the use of so-called G constraints based on the integrated intensities of groups of overlapping reflections (Sakata *et al.*, 1990). G constraints can be easily incorporated into the Sakata–Sato algorithm, and are thus actively used in this algorithm.

G constraints are based on N_G groups of overlapping reflections. Group i has contributions of N_G^i reflections, resulting in a 'group amplitude' G^i equal to the square root of the integrated intensity and related to the structure-factor amplitudes through

$$G^i = \left[\sum_{j=1}^{N_G^i}\left(\frac{m_j}{\sum m_j}\left|F(\mathbf{H}_j)\right|^2\right)\right]^{1/2}, \qquad (4.8.23)$$

where m_j is the point-group multiplicity of reflection j. The summation runs over the symmetry-independent structure factors contributing to group i. The standard uncertainty of the group amplitude G_i follows as

$$\sigma(G^i) = \frac{1}{G^i}\left[\sum_{j=1}^{N_G^i}\left(\frac{m_j}{\sum m_j}\left|F(\mathbf{H}_j)\right|(\mathbf{H}_j)\right)^2\right]^{1/2}. \qquad (4.8.24)$$

The group amplitudes can be used in the G constraint in a similar way to the F constraint [equation (4.8.10)]:

$$C_G = -\chi^2_{\text{aim}}(G) + \frac{1}{N_G}\sum_{i=1}^{N_G} w_i\left(\frac{G^i_{\text{obs}} - G^i_{\text{MEM}}}{\sigma\left(G^i_{\text{obs}}\right)}\right)^2 = 0, \qquad (4.8.25)$$

where G^i_{obs} and $\sigma(G^i_{\text{obs}})$ are the group amplitude and standard uncertainty as obtained from the experiment, respectively, and G^i_{MEM} is computed from $F_{\text{MEM}}(\mathbf{H}_j)$ (Section 4.8.4) according to equation (4.8.23).

G constraints can be introduced into the MEM with aid of an additional Lagrange multiplier λ_G (see Section 4.8.4):

$$L = S - \lambda_N C_N - \lambda_F C_F - \lambda_G C_G. \qquad (4.8.26)$$

Experience has shown that a certain fraction of reflections must be available as F constraints in order for the MEM to converge to the correct electron-density distribution. Since the ratio of λ_F and λ_G is not known *a priori*, applications have used a single constraint with a single Lagrange multiplier λ_{FG} according to

$$L = S - \lambda_N C_N - \lambda_{FG} C_{FG} \qquad (4.8.27)$$

with the combined F and G constraint

$$C_{FG} = -\chi^2_{\text{aim}} + \frac{1}{N_{\text{all}}}\sum_{i=1}^{N_F} w_i\left(\frac{\left|F_{\text{obs}}(\mathbf{H}_i) - F_{\text{MEM}}(\mathbf{H}_i)\right|}{\sigma(\mathbf{H}_i)}\right)^2 + \frac{1}{N_{\text{all}}}\sum_{i=1}^{N_G} w_i\left(\frac{G^i_{\text{obs}} - G^i_{\text{MEM}}}{\sigma\left(G^i_{\text{obs}}\right)}\right)^2 = 0, \qquad (4.8.28)$$

where $N_{\text{all}} = N_F + N_G$ (Palatinus, 2003).

The formal solution of the MaxEnt equations then becomes [*cf.* equation (4.8.17)]

$$\rho_i = \frac{N_{\text{el}}N_{\text{pix}}}{V_{\text{UC}}}\rho_i^{\text{prior}}\exp\left[-\lambda_{FG}\left(\frac{\partial C_F}{\partial\rho_i} + \frac{\partial C_G}{\partial\rho_i}\right)\right] \times \left\{\sum_{i=1}^{N_{\text{pix}}}\rho_i^{\text{prior}}\exp\left[-\lambda_{FG}\left(\frac{\partial C_F}{\partial\rho_i} + \frac{\partial C_G}{\partial\rho_i}\right)\right]\right\}^{-1}. \qquad (4.8.29)$$

The implementation of G constraints in the Sakata–Sato algorithm is straightforward except for the computation of the derivative of the combined constraint, which is slightly more complicated than the calculation of the derivative of the F constraint.

4.8.6.2. *Constraints using 'partly phased' reflections for anomalous-scattering X-ray powder diffraction*

X-ray anomalous scattering from powders can be used for *ab initio* structure determination if at least two different data sets are available: one measured with a wavelength near the absorption edge of a chemical element contained in the sample and another measured with a wavelength far from the absorption edge. The corresponding Patterson map allows the localization of the resonant-scattering atoms. The phases of the resolved structure factors of centrosymmetric structures can be derived from this experiment. For noncentrosymmetric structures, two values remain for the phase φ_i of each reflection i. They can be written as $\varphi_i = \varphi_{0i} \pm \Delta_i$, where φ_{0i} and Δ_i are obtained from the experiment. This limited information from anomalous-scattering X-ray powder diffraction can be used in the MEM through the so-called A constraints for partly phased reflections (Burger & Prandl, 1999). Defining $A'^i = |F|\cos(\Delta_i)$ and $B'^i = |F||\sin(\Delta_i)|$, the A constraint is

$$C_A = -\chi^2_{\mathrm{aim}} + \frac{1}{N_A}\sum_{i=1}^{N_A}\left[\left(\frac{A'^i_{\mathrm{obs}} - A'^i_{\mathrm{MEM}}}{\sigma\left(A'^i_{\mathrm{obs}}\right)}\right)^2 + \left(\frac{B'^i_{\mathrm{obs}} - B'^i_{\mathrm{MEM}}}{\sigma\left(B'^i_{\mathrm{obs}}\right)}\right)^2\right]. \qquad (4.8.30)$$

4.8.6.3. *Prior-derived F constraints*

Experimentally, diffraction data are usually not available beyond $[\sin(\theta)/\lambda]_{\max}$ = 1.3 Å^{-1}. As discussed in Section 4.8.3, Fourier maps that are free from series-termination effects require all structure factors up to at least $[\sin(\theta)/\lambda]_{\max}$ = 6 Å^{-1}. Although much less severe, the MEM also suffers from series-termination effects if structure factors are incorporated of resolutions up to $[\sin(\theta)/\lambda]_{\max} \simeq 1.3$ Å^{-1}, even in cases where a procrystal prior is used. Since high-angle diffraction data are mainly determined by the core electrons, for which the procrystal prior is supposed to be a good estimate, it turns out that the calculated structure factors of the IAM are a better estimate for the high-order reflections than the value of zero that is implicit in using a resolution limit of 1.3 Å^{-1} or worse. Accordingly, the constraint in the MEM can be modified to include the so-called prior-derived F constraints (PDCs) based on calculated structure factors, $F_{\mathrm{prior}}(\mathbf{H}_i)$, of the prior structure model (Palatinus & van Smaalen, 2005):

$$\begin{aligned} C_{FG}^{\mathrm{PDC}} = {} & -\chi^2_{\mathrm{aim}} + \frac{1}{N_{\mathrm{all}}}\sum_{i=1}^{N_F} w_i\left(\frac{\left|F_{\mathrm{obs}}(\mathbf{H}_i) - F_{\mathrm{MEM}}(\mathbf{H}_i)\right|}{\sigma(\mathbf{H}_i)}\right)^2 \\ & + \frac{1}{N_{\mathrm{all}}}\sum_{i=1}^{N_G} w_i\left(\frac{G^i_{\mathrm{obs}} - G^i_{\mathrm{MEM}}}{\sigma\left(G^i_{\mathrm{obs}}\right)}\right)^2 \\ & + \frac{1}{N_{\mathrm{all}}}\sum_{i=1}^{N_{\mathrm{PDC}}} w_i\left(\frac{\left|F_{\mathrm{prior}}(\mathbf{H}_i) - F_{\mathrm{MEM}}(\mathbf{H}_i)\right|}{\sigma(\mathbf{H}_i)}\right)^2 = 0, \qquad (4.8.31) \end{aligned}$$

where the symbols have the same meaning as in equations (4.8.10) and (4.8.28), but $N_{\mathrm{all}} = N_F + N_G + N_{\mathrm{PDC}}$ and N_{PDC} is the number of reflections included in the PDC (third summation). The latter involve all reflections up to a high resolution of, for example, $[\sin(\theta)/\lambda]_{\max}$ = 2.5 Å^{-1}, which are not available in the experiment. Their standard uncertainties are made equal to the smallest standard uncertainty among the experimental data. While equation (4.8.31) is used for solving the MEM iterations [C_F is replaced by C_{FG}^{PDC} in equation (4.8.17)], the criterion for convergence is still based on constraints computed solely with the experimental data [equations (4.8.10) or (4.8.28)].

It has been shown for single-crystal diffraction data that a PDC with experimental data up to $[\sin(\theta)/\lambda]_{\max} \simeq 1.0$ Å^{-1} leads to good results. A single but unsuccessful application to powder X-ray diffraction data has been reported (Buchter *et al.*, 2011). However, the lack of success in that work might be related to the low data resolution of $[\sin(\theta)/\lambda]_{\max}$ = 0.6 Å^{-1} rather than to the use of powder-diffraction data instead of single-crystal diffraction data.

4.8.6.4. *Observed structure factors*

The structure factors for MEM calculations should be uniquely determined by the electron density. Anomalous scattering cannot be incorporated into this scheme, and experimental data have to be corrected for this effect. Furthermore, the precise scale of the observed structure factors and any extinction correction need to be known too. The MEM thus requires the availability of a structure refinement of reasonable quality, from which the magnitudes of these effects as well as the phases of the structure factors can be obtained to a good approximation. The refinement provides $F_{\mathrm{calc}}(\mathbf{H})$, which incorporate the effects of anomalous scattering as well as the scale factor (k_s) and a correction factor for extinction, (k_E).

The required corrections can be applied as follows (Bagautdinov *et al.*, 1998):

$$F^{\mathrm{elec}}_{\mathrm{obs}}(\mathbf{H}) = \frac{\left|F_{\mathrm{obs}}(\mathbf{H})\right|}{\left|F_{\mathrm{calc}}(\mathbf{H})\right|}\left[A^{\mathrm{elec}}_{\mathrm{calc}}(\mathbf{H}) + iB^{\mathrm{elec}}_{\mathrm{calc}}(\mathbf{H})\right], \qquad (4.8.32)$$

where $A^{\mathrm{elec}}_{\mathrm{calc}}(\mathbf{H})$ and $B^{\mathrm{elec}}_{\mathrm{calc}}(\mathbf{H})$ are the calculated real and imaginary parts of the structure factors without the contributions of anomalous scattering or extinction, *i.e.* they are the structure factors corresponding to the Fourier transform of the electron density of one unit cell.

4.8.7. Analysis of the electron-density distribution from powder-diffraction data

4.8.7.1. *Types of MEM-reconstructed electron-density distribution*

The principal application of the MEM to powder-diffraction data is the reconstruction of the electron (or nuclear) density distribution to investigate features not accounted for by a structure model or Fourier analysis. X-ray/neutron diffraction data carry information about the electron/nuclear density in the structure-factor amplitudes and phases extracted from the measured reflection intensities. This experimental information is used in the MEM *via* values for the observed structure factors $F_{\mathrm{obs}}(\mathbf{H})$ and their standard uncertainties $\sigma(\mathbf{H})$, and *via* the prior density distribution $\{\rho_i^{\mathrm{prior}}\}$ from Rietveld refinement.

The MEM can be applied to powder-diffraction data in several ways, which differ in the type of constraints, the way observed structure-factor amplitudes have been extracted from the data and the source of reflection phases (Fig. 4.8.6). The resulting density maps vary from completely biased by the structure model to model-free maps. A systematic investigation of the different maps has been carried out by Samy *et al.* (2010). Particularly noteworthy is the MEM electron-density map computed with F and G constraints with structure-factor amplitudes obtained by a LeBail fit and with phases from charge flipping. This type of map was first introduced by Samy *et al.* (2010), who showed that it provides a good description of the disorder in alkali-metal oxalates and carbonates. Following Samy *et al.* (2010), the different types of maps can be characterized as follows (Fig. 4.8.6).

(1) F_{calc}, φ^{calc}: the calculated structure factors (including phases), F_{calc}, are used as F_{obs} in the F constraint [equation (4.8.10)]. This MEM map is completely biased by the structure model, and should in principle reproduce it. Deviations from the model are usually found because of the limited resolution of the diffraction data and the resulting series-termination effects.

(2) F_{obs}, φ^{calc}: based on observed structure-factor amplitudes extracted from the data [equation (4.8.22)] with calculated structure factors from Rietveld refinement and phases calculated from the structure model. In the case of powder-diffraction data in particular, this MEM map is partially biased by the model, because calculated structure factors of the model are used to decompose overlapping reflections into contributions of individual reflections. This MEM map allows the localization of missing atoms in incomplete structure models, but it does not provide an accurate description of the electron- or nuclear-density distribution. The corresponding

maps also often contain weak noise (areas with positive electron density that do not correspond to any atom in the structure), especially when a flat prior is used.

(3) $F_{\rm obs} + G$, $\varphi^{\rm calc}$: based on the observed structure-factor amplitudes as in (2), but with F constraints for resolved reflections and G constraints for groups of overlapping reflections; phases are calculated from the structure model. The corresponding MEM map is less biased by the model than in (2). It not only allows localization of missing atoms in incomplete structure models, but also the accurate analysis of electron-density distributions provided a procrystal density is used. When the number of G constraints is not too large (less than 20% of the reflections take part in G constraints), a flat prior can be used, but the corresponding MEM map then will suffer from noise.

(4) $F_{\rm LeBail} + G$, $\varphi^{\rm calc}$: based on observed structure-factor amplitudes extracted from the data [equation (4.8.22)] by Le Bail fit, with F constraints for resolved reflections and G constraints for groups of overlapping reflections; phases are calculated from the structure model. This MEM map is even less biased by the model than (3). Le Bail decomposition provides amplitudes of structure factors disregarding any structural information, and while individual amplitudes of reflections in a group of overlapping reflections might not be accurate, an accurate value is obtained for the group amplitude [equation (4.8.23)]. Therefore, $F + G$ constraints are the only reasonable option. Additionally, $F_{\rm LeBail}$ should be corrected for anomalous scattering.

(5) $F_{\rm obs}$, $\varphi^{\rm CF}$: based on $F_{\rm obs}$ [see (2)] with reflection phases, $\varphi^{\rm CF}$, obtained by charge flipping with histogram matching (Baerlocher *et al.*, 2007). The main limiting factors for this MEM map are the complexity of the crystal structure and the quality of the powder-diffraction data. In general, the correct determination of the phases of all reflections (including weak reflections) becomes more difficult with increasing complexity of the crystal structure. Using phases $\varphi^{\rm CF}$ from charge flipping is the method of choice for disordered structures, since the corresponding disordered structural model from Rietveld refinement is usually affected by the correlations between many refined parameters and needs to be verified.

(6) $F_{\rm obs} + G$, $\varphi^{\rm CF}$: based on measured structure-factor amplitudes for resolved reflections $F_{\rm obs}$ from Rietveld refinement with G constraints for group amplitudes of overlapping reflections, and phases $\varphi^{\rm CF}$ from charge flipping with histogram matching. This type of MEM map is less biased than (5) and thus provides a more stringent test of the structure model. A procrystal density representing an (incomplete) structure model can be used.

(7) $F_{\rm LeBail} + G$, $\varphi^{\rm CF}$: based on $F_{\rm LeBail}$ [see (4)] with F constraints for resolved reflections and G constraints for groups of overlapping reflections, and phases $\varphi^{\rm CF}$ [see (5)]. This MEM

map is unbiased by the model, since both structure-factor amplitudes and phases are extracted from the diffraction data without any structural information. The resulting density distributions can be considered as almost completely *ab initio* density distributions. This is a very useful type of MEM map for disordered structures, because it avoids any possible inaccurate modelling of the disorder. This MEM map is limited by the complexity of the crystal structure and the quality of the powder-diffraction data.

4.8.7.2. *MEM-based improvement of the structure model from charge flipping*

Charge flipping provides phases for the measured reflections along with an electron density that is basically a Fourier map (Oszlányi & Sütő, 2004, 2005; Palatinus, 2004; Wu *et al.*, 2006; Palatinus & Chapuis, 2007; Baerlocher *et al.*, 2007; Palatinus, 2013). As discussed in Section 4.8.7.1, the reflection phases resulting from the charge-flipping procedure can be employed in the MEM for generating an MEM electron-density map that shows significantly more details than the Fourier map obtained directly by charge flipping. As shown by Samy *et al.* (2010), the MEM based on $F_{\rm LeBail} + G$ constraints and $\varphi^{\rm CF}$ reflection phases may thus provide an *ab initio* determination of the details of disorder in crystal structures.

Samy *et al.* (2010) investigated two compounds with structural disorder. A good fit to the diffraction data was obtained in Rietveld refinements of structure models with 24-fold disorder of the oxalate ion in α-$Rb_2C_2O_4$, and with eightfold disorder of the carbonate group in α-Rb_2CO_3 (Fig. 4.8.7). While the disorder of the oxalate anions involves rotations about an axis perpendicular to the principal axis as well as different conformations through rotations of the carboxyl groups, the carbonate group has no internal degree of freedom and exhibits only orientational disorder (Dinnebier *et al.*, 2005).

The MEM electron densities based on F constraints with $F_{\rm calc}$ [type (1) in Section 4.8.7.1] provide the electron density corresponding to the disorder models. The MEM with F constraints based on $F_{\rm obs}$ with $\varphi^{\rm calc}$ [type (2) in Section 4.8.7.1] leads to a similar density but with distinct differences that can be described as a smoother distribution of the densities of the anions (Fig. 4.8.7). Three more MEM density maps of decreasing model bias are presented in Fig. 4.8.7 (*cf.* Section 4.8.7.1), all of which have similar appearances. These MEM density maps show that the major features of the disorder in these two compounds have been captured by the respective structure models. More interestingly, the high degree of similarity between the MEM electron density based on $F_{\rm obs}$ with $\varphi^{\rm calc}$ [type (2)] and that based on $F_{\rm LeBail} + G$ constraints with $\varphi^{\rm CF}$ [type (7)] demonstrates that the latter method may be used for *ab initio* determination of structural disorder from powder-diffraction data (Samy *et al.*, 2010). Of course, this conclusion can be directly applied to single-crystal X-ray diffraction data as well.

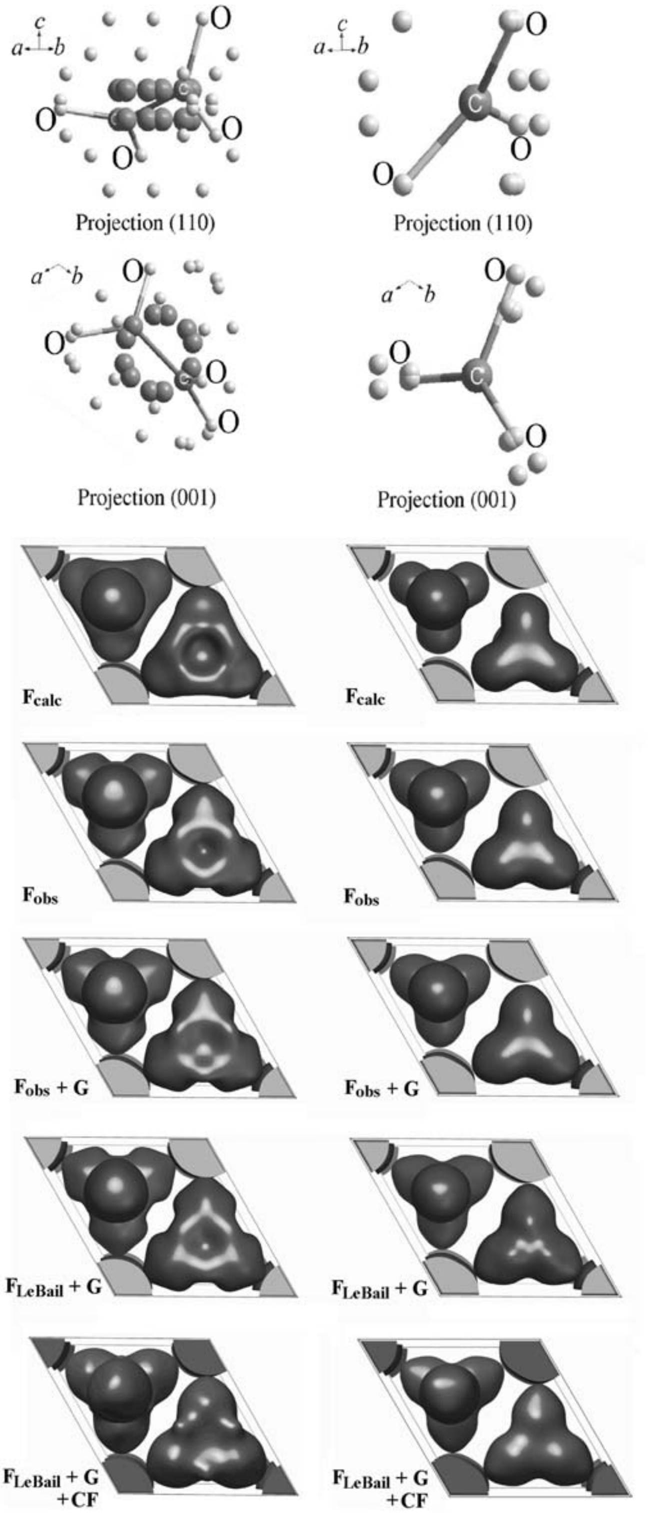

Figure 4.8.7

4.8.7.3. *Combination of MEM and Rietveld refinement (REMEDY cycle)*

The MEM/Rietveld method has been developed as a method called the REMEDY cycle for improving structure models determined from X-ray powder-diffraction data (Takata *et al.*, 1995). It involves the alternate application of Rietveld refinement of a structure model and MEM calculations based on $F_{\rm obs}$ and $\varphi^{\rm calc}$ [type (2) map in Section 4.8.7.1], while in each cycle the MEM electron density is employed to generate an improved structure model (Fig. 4.8.8). In general, any combination of structure-factor amplitudes and phases could be used for this iterative procedure [types (2)–(4) in Section 4.8.7.1], but applications have mainly been restricted to type (2) MEM calculations with flat prior densities (Takata, 2008), although type (3) ($F_{\rm obs} + G$, $\varphi^{\rm calc}$) and type (4) ($F_{\rm LeBail} + G$, $\varphi^{\rm calc}$) MEM calculations with procrystal density usually lead to better results (Magdysyuk *et al.*, 2012).

As described by Takata (2008), the MEM/Rietveld method requires an initial structure model to start the iterative procedure

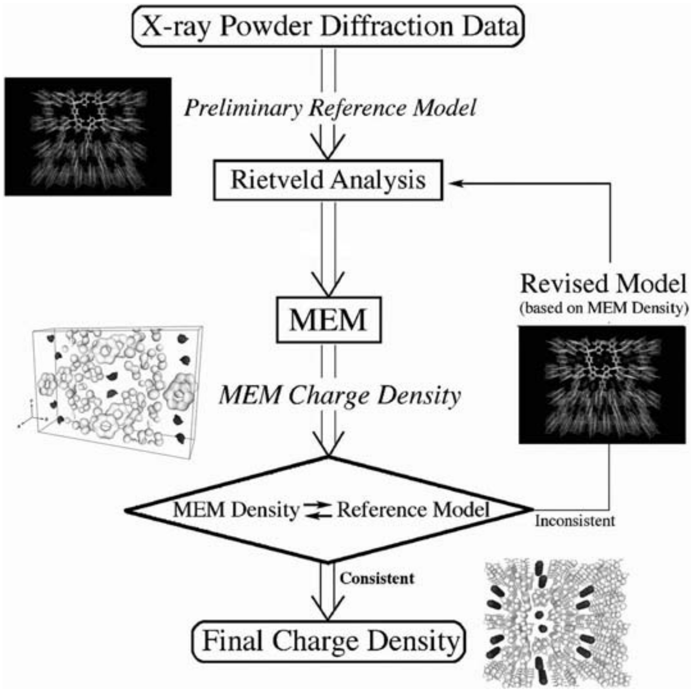

Figure 4.8.8

Flow chart of MEM/Rietveld method with structure refinement and MEM imaging of the charge density (adapted from Takata, 2008).

(Fig. 4.8.8). This model can be determined by any standard technique for structure solution from powder-diffraction data or it is known *a priori* (*e.g.* from similarities to related compounds). The initial model may be incomplete and the fit to the diffraction data attained with Rietveld refinement of the initial model may be poor. Based on this Rietveld refinement, $F_{\rm obs}$ amplitudes and $\varphi^{\rm calc}$ phases are obtained (Section 4.8.6.1), which are then used for the MEM calculations. The resulting MEM electron-density distribution allows for improvement of the structure model, *e.g.* by including newly located atoms. The improved model is then subjected to a second Rietveld refinement. The intensity repartitioning for overlapping reflections and phase assignment improves as the number of REMEDY cycles increases owing to improvements to the structure model and $F_{\rm calc}$, $\varphi^{\rm calc}$ values. In this way, MEM calculations and Rietveld refinement are alternately repeated (REMEDY cycles). Convergence is assumed if the R factors no longer decrease and no changes in the structural model can be detected.

One example of the successful application of the MEM/Rietveld method is the analysis of acetylene adsorption by a porous coordination polymer CPL-1 (Kubota *et al.*, 2006; Takata, 2008), which is shown in Fig. 4.8.9. Application of the MEM/Rietveld method has allowed the determination of small structural variations that depend on the filling fraction of acetylene molecules in the pores of the polymer (Takata, 2008).

The MEM/Rietveld method violates one of the principles of the MEM: strictly speaking, an iterative procedure, in which the result of the MEM is used as reference for the next cycle, is not allowed. On the other hand, one could argue that the improved structure model, as determined by application of the MEM, represents an independent new starting point for the Rietveld refinement and subsequent MEM calculations. In any case, the MEM/Rietveld method works, as demonstrated by many examples (Takata, 2008; Kato & Tanaka, 2016). The MEM/Rietveld method is more effective than Fourier synthesis for improving structural models owing to the higher signal-to-noise ratio of the former, as discussed elsewhere in this chapter.

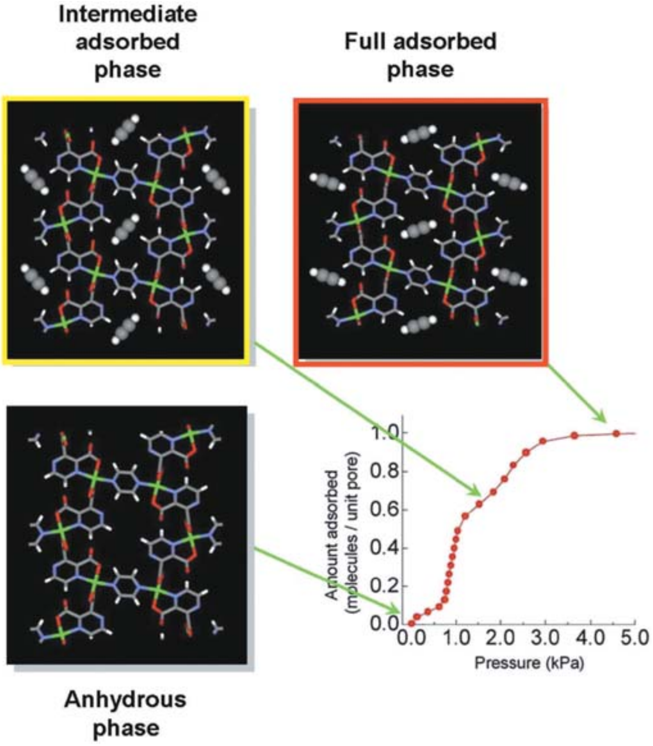

Figure 4.8.9

Acetylene adsorption isotherm and crystal structures of CPL-1 with adsorption of acetylene corresponding to the amount of adsorbed gas. Acetylene molecules are shown by the space-filling model; other molecules are shown as a wire model (from Takata, 2008).

The MEM/Rietveld method enables one to construct a detailed structure model on the basis of X-ray powder-diffraction data. In addition, at convergence and for diffraction data of sufficient resolution, the final MEM electron density may have the quality of showing features of chemical bonding (Kato & Tanaka, 2016; see Section 4.8.7.6).

4.8.7.4. *MEM-assisted structure solution by charge flipping*

As discussed in Section 4.8.7.2, reflection phases from charge flipping can be used for a complete *ab initio* determination of the electron density of ordered and disordered structures. The main limitation of charge flipping is the requirement of the availability of a complete data set up to a reasonable resolution (Palatinus *et al.*, 2007; Palatinus, 2013). If too many reflections are missing from the experiment, charge flipping will fail to solve the structure and the method of Section 4.8.7.2 cannot be applied.

An intrinsic property of the MEM is that it provides an estimate for the amplitudes and phases of the unmeasured structure factors (Sakata & Sato, 1990), thus the set of structure factors can be completed by MEM before applying the charge flipping for structure solution. This idea was used by Palatinus *et al.* (2007) to extrapolate the intensities of the missing reflections by optimizing the Patterson function, and subsequently use the computed structure factors together with experimentally measured reflections to enhance the ability of charge flipping to solve a crystal structure. The use of the MEM-optimized Patterson function was tested for the case of single-crystal diffraction data. In this way, it was possible to solve crystal structures from single-crystal X-ray diffraction data with approximately 50% coverage of reciprocal space. Although this method has not been tested for powder-diffraction data, it should be applicable to these data too.

Another way around the problem of incomplete data is the use of an approximate structure model for generating a non-random

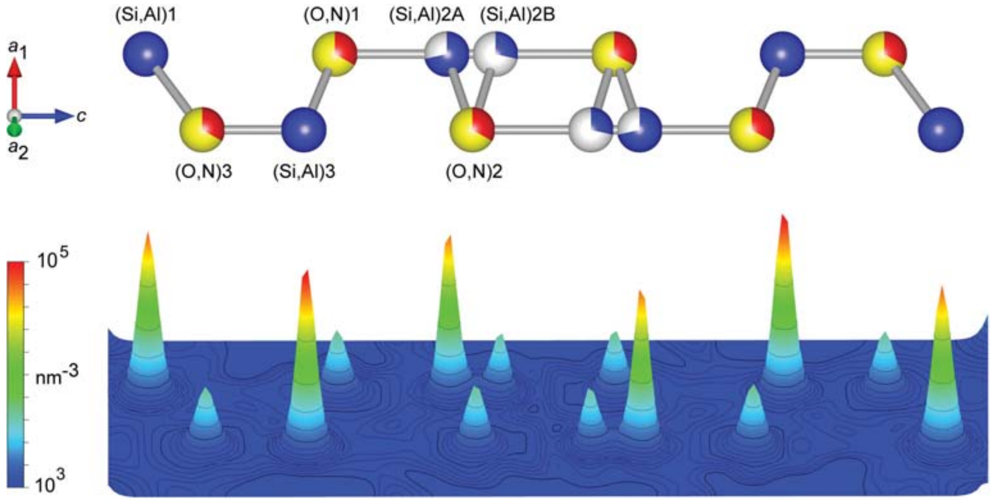

Figure 4.8.10
The top panel shows the (110) plane of the crystal structure of $SiAl_4O_2N_4$; red and yellow indicate fractional occupancies by oxygen and nitrogen, respectively; dark blue indicates the fractional occupancy of the (Si,Al)2A and (Si,Al)2B sites. The bottom panel gives a bird's-eye view of the MEM electron density on the (110) plane; (Si,Al)2A (fractional occupancy 0.72) clearly has more electrons than (Si,Al)2B (fractional occupancy 0.28). Reprinted from Banno *et al.* (2014), with permission from Elsevier. Corrected figure courtesy of Koichiro Fukuda.

set of starting phases for charge flipping (Šišak *et al.*, 2012). Since an approximate crystal-structure model is not necessarily available from external sources, it can be generated as the average of the structure models from the few best solutions of charge flipping applied to the incomplete data set. However, this model need not be close to the true model, because charge flipping applied to incomplete data may lead to a meaningless structure model that gives a good fit to the available data. Šišak *et al.* (2012) used the MEM to improve the set of starting phases of the approximate model, since the most reliable model will have the maximum value of the entropy of its electron density.

4.8.7.5. *Disorder and anharmonic atomic displacements*

Local maxima in the electron densities correspond to the positions of the atoms in ordered crystal structures. The MEM applied to diffraction data of partially ordered crystals leads to electron densities with local maxima of decreased magnitude for all partially occupied atomic sites. This feature has been nicely demonstrated in a series of studies on SiAlON compounds (Banno *et al.*, 2014). Fig. 4.8.10 shows part of the crystal structure with three independent (Si,Al) sites and three independent (O,N) sites. The site (Si,Al)2 is split into a pair of partially occupied sites with fractional occupancies of 0.72 for (Si,Al)2A and 0.28 for (Si,Al)2B. These unequal occupancies of the two sites of the split position are quantitatively reproduced in the MEM electron density (bottom part of Fig. 4.8.10). For the hydrogen-storage material KBH_4, an analysis by the MEM has revealed thermally activated orientational disorder of BH_4 groups (Bindzus *et al.*, 2015). The MEM combined with Rietveld refinements against X-ray powder-diffraction data has been used to locate extra-framework atoms in zeolites. This includes the determination of the locations of water molecules and potassium atoms in zeolite YNU-5 (Nakazawa *et al.*, 2017), the location of catalytically active Cu^{2+} in zeolite CHA (Andersen *et al.*, 2014) and absorbed water in faujasite (Perez *et al.*, 2017). Finally, the MEM has been used to determine the atomic distribution due to anharmonic displacements, including the identification of the diffusion pathways for Li^+-ion conduction in crystal structures or the absence thereof (Dietrich *et al.*, 2017; Monchak *et al.*, 2016). Employing the two-channel MEM with maps for atoms with negative and for atoms with positive scattering lengths, respectively, Monchak *et al.* (2016) have obtained a continuous volume of negative scattering density, demonstrating diffusion pathways for Li^+ ions in the superionic conductor $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ (Fig. 4.8.11).

Atomic positions are also accessible through the nuclear-weighted X-ray maximum entropy method (NXMEM) introduced by Christensen *et al.* (2015). NXMEM defines nuclear scattering factors with the atomic pseudo-form factor equal to the number of electrons of the atom. Calculated structure factors of a good structure model are employed for the transformation of observed structure factors towards observed electron-weighted nuclear structure factors (Christensen *et al.*, 2015) in a procedure similar to the procedure for correcting observed structure factors for anomalous diffraction, extinction and scaling (Bagautdinov *et al.*, 1998; see Section 4.8.6.4). In this way, model bias is introduced into the MEM. The MEM and NXMEM have been employed to elucidate disorder and anharmonic displacements of the metal atoms in thermoelectric PbS, PbTe and SnTe as well as CsCl (Christensen *et al.*, 2015; Kastbjerg *et al.*, 2013; Sist *et al.*, 2016, 2017).

4.8.7.6. *Accurate electron densities*

Initial applications of the MEM to single-crystal X-ray diffraction data have shown the importance of diffraction data sets being complete up to a resolution better than $[\sin(\theta)/\lambda]_{\max} = 1$ Å^{-1} if the determination of the electron density in chemical bonds is the goal (de Vries *et al.*, 1996; Takata & Sakata, 1996). These are the same requirements as the data have to fulfil for a multipole refinement (Gatti & Macchi, 2012). In X-ray powder diffraction, high-resolution data sets with $[\sin(\theta)/\lambda]_{\max} > 1.3$ Å^{-1} can be obtained with short-wavelength synchrotron radiation (Nishibori *et al.*, 2007; Momma *et al.*, 2013; Kato & Tanaka, 2016). Application of the MEM then may lead to electron densities that possess the quality of showing the reorganization of electron density within chemical bonds.

Integrated atomic charges can be determined from these MEM electron densities by topological analysis according to the quantum theory of atoms in molecules (QTAIM; Bader, 1990) of the experimental electron-density distribution. For the case of powder X-ray diffraction data for $LiBD_4$ this approach was successfully demonstrated by Buchter *et al.* (2011). Generation of accurate electron-density distributions may be impeded if too many reflections are available as *G* constraints, despite a formally high resolution of the diffraction data. This may happen in the case of heavy overlap of reflections, as it is an increasing problem for broad reflections and for structures of increasing complexity.

4.8.8. Extensions of the MEM

The principle of MaxEnt states that the most probable electron density is the one that maximizes the entropy [equation (4.8.2)], while fulfilling one or more constraints [*e.g.* the *F* constraint in equation (4.8.10)]. Straightforward application of the MaxEnt principle usually leads to noisy maps. Several extensions of the MEM have already been discussed in this chapter, all of which aim at a MEM that leads to a density distribution that is as informative as possible. They include the use of a non-uniform prior density [equation (4.8.2)], the use of prior-derived *F* constraints (Section 4.8.6.3), the use of static weights [equation (4.8.10)] and the selection of the point of convergence, $\chi^2_{\rm aim}$. The latter two aspects will be presented in more detail here. Finally, we will discuss the extension of the MEM to superspace for applications to aperiodic crystals (Section 4.8.8.3).

4.8.8.1. *Distribution of normalized residuals of the structure factors*

The experimental structure-factor amplitudes are not known exactly but deviate from their true values by an unknown amount. Assuming a Gaussian probability distribution for the difference between the measured and true values, the probability distribution is described by a single standard uncertainty σ_i or variance σ_i^2 for each structure-factor amplitude $|F(\mathbf{H}_i)|$.

For a sufficient number of independent reflections, one then expects a Gaussian distribution of the normalized residuals of the structure factors,

$$\frac{\Delta F(\mathbf{H}_i)}{\sigma(\mathbf{H}_i)} = \frac{F_{\rm obs}(\mathbf{H}_i) - F_{\rm MEM}(\mathbf{H}_i)}{\sigma(\mathbf{H}_i)}, \qquad (4.8.33)$$

if the $F_{\rm MEM}(\mathbf{H}_i)$ have been calculated from the MEM electron density. However, it was found (de Vries *et al.*, 1994; Jauch & Palmer, 1993; Palatinus & van Smaalen, 2002) that the distribution of the normalized residuals of the structure factors can deviate strongly from the Gaussian distribution. A few reflections (usually strong reflections at low angles) possess residuals of very large magnitudes, while the rest of the reflections are fitted almost exactly in order to fulfil the *F* constraint [equation (4.8.10) with $w_i = 1$ and $\chi^2_{\rm aim} = 1$]. The deviation from a Gaussian distribution of the residuals is reflected in the MEM electron density through the presence of non-physical features.

One possible solution to this problem was suggested by de Vries *et al.* (1994), who proposed so-called static weights, where weights are defined as proportional to some inverse integer power, $n = 2, 3, 4, \ldots$, of the length of the scattering vector [equation (4.8.10)]:

$$w_i = \frac{1}{|\mathbf{H}_i|^n}\left(\frac{1}{N_F}\sum_{i=1}^{N_F}\frac{1}{|\mathbf{H}_i|^n}\right)^{-1}. \qquad (4.8.34)$$

Both de Vries *et al.* (1994) and recent calculations on single-crystal X-ray diffraction by Hofmann *et al.* (2007) have shown $n = 4$ to be an optimal value. Another set of weights proposed by de Vries *et al.* (1994) is a weight proportional to an integer power of the structure-factor amplitude:

$$w_i = |F(\mathbf{H}_i)|^n\left(\frac{1}{N_F}\sum_{i=1}^{N_F}|F(\mathbf{H}_i)|^n\right)^{-1}. \qquad (4.8.35)$$

Static weights according to equation (4.8.34) are preferred for most applications. They ensure that the originally worst-fitting low-order reflections obtain a high weight in the modified *F* constraint, with the consequence of a much better approximation of the Gaussian distribution of the final distribution of residuals. Static weights according to equation (4.8.35) have been shown to lead to better results in the case of incommensurately modulated crystals (Section 4.8.8.3). This type of aperiodic crystals has many weak superlattice reflections including many appearing at low order, but which should be given small weights. Here, weights calculated according to (4.8.35) give high weights to the terms containing intense main reflections, most of which are of low order.

Another solution to the problem of a non-Gaussian distribution of residuals was proposed by Palatinus & van Smaalen (2002). They noted that the *F* constraint [equation (4.8.10)] is based on the second central moment of the distribution of $\Delta F(\mathbf{H})/\sigma(\mathbf{H})$. This allowed the introduction of the concept of generalized *F* constraints, or F_n constraints, which are based on the moment of order *n*:

$$\begin{aligned} C_{F_n} &= -\chi^2_{\rm aim} + \frac{1}{m_n({\rm Gauss})}\frac{1}{N_F}\sum_{i=1}^{N_F} w_i\left(\frac{|F_{\rm obs}(\mathbf{H}_i) - F_{\rm MEM}(\mathbf{H}_i)|}{\sigma(\mathbf{H}_i)}\right)^n \\ &= 0, \end{aligned} \qquad (4.8.36)$$

where $n = 2, 4, 6, \ldots$ is an even integer, and m_n(Gauss) is the value of the *n*th central moment of the Gaussian distribution. Several tests on selected examples showed that a generalized *F* constraint with $n = 4$ may lead to an improved distribution of residuals (Palatinus & van Smaalen, 2002).

4.8.8.2. *Stopping criterion*

The value of $\chi^2_{\rm aim}$ [equation (4.8.10)] does not influence the iterative procedure, since any constant in C_F drops out of its derivative with respect to any of the density parameters $\{\rho_i\}$ [equation (4.8.17)]. However, the value of $\chi^2_{\rm aim}$ determines the point of convergence through the criterion $C_F = 0$. It then directly gives the value of the sum of squares of reduced residuals [equations (4.8.10) and (4.8.33)]. Standard probability theory gives an expectation value of this sum of $\chi^2_{\rm aim} = 1$. Bayesian probability theory states that the model is biased towards the data, so that at convergence $\chi^2_{\rm aim} < 1$ (Gull & Skilling, 1999). These values not only assume a Gaussian distribution of the measurement errors in $F_{\rm obs}(\mathbf{H}_i)$, but they also assume that the estimated standard uncertainties $\sigma(\mathbf{H}_i)$ have been accurately obtained. This is not always the case. Straightforward application of the classical or Bayesian values of $\chi^2_{\rm aim}$ as a stopping criterion for the iterative procedure thus might lead to the fitting of noise in the data (when $\chi^2_{\rm aim}$ is too small) or to information in the data that is not fitted by the electron density (when $\chi^2_{\rm aim}$ is too large).

Based on these considerations, an empirical criterion for determination of the stopping criterion $\chi^2_{\rm aim}$ has been proposed (Hofmann *et al.*, 2007). This procedure involves a series of MEM calculations with different values of $\chi^2_{\rm aim}$. Visual inspection of the electron-density maps and the difference Fourier maps then allows the optimal value of $\chi^2_{\rm aim}$ to be determined. The difference Fourier map should contain features near atomic positions that are of similar magnitude to features outside bonds and atoms, thus showing them to be true noise. For the same $\chi^2_{\rm aim}$, the MEM electron-density map should show smooth isosurfaces and should be free from spurious maxima. Too-small values of $\chi^2_{\rm aim}$ violate the latter condition, while too-high values of $\chi^2_{\rm aim}$ give a difference Fourier map with clearly unfitted structure near the atoms. This procedure has worked well for several data sets. It could be shown that the optimal value of $\chi^2_{\rm aim}$ is related to the goodness of fit (GoF) of a multipole refinement using the same data by the relation $\chi^2_{\rm aim}$(optimum) = 0.68 × GoF (van Smaalen & Netzel, 2009).

4.8.8.3. *Generalization of MaxEnt algorithm to n dimensions (n > 3) and application to powder-diffraction data of aperiodic structures*

One aim of the application of the MEM in the field of superspace crystallography is to uncover the true modulations, and thus improve the structure model for aperiodic crystals (Papoular *et al.*, 1991; Steurer, 1991; Weber & Yamamoto, 1997; van Smaalen *et al.*, 2003; Palatinus & van Smaalen, 2004; Li *et al.*, 2011). Crystal structures of aperiodic crystals are described as periodic structures in (3 + d)-dimensional space, called superspace, where $n = 3 + d$ is the dimension of the space [*International Tables for Crystallography*, Volume C, Chapter 9.8 (Janssen *et al.*, 2006); van Smaalen, 2007]. Accordingly, aperiodic crystals are characterized by a generalized electron density $\rho_s(\mathbf{x}_s)$ in n-dimensional space. The MEM can be applied to the generalized electron density by the same formalism as described in this chapter. A discrete electron density is defined with $\rho_i = \rho_s(\mathbf{x}_i)$ where $\mathbf{x}_i$ are the coordinates of a grid of $N_{\rm pix} = N_1 \times \ldots \times N_{3+d}$ pixels over the superspace unit cell. Structure factors are the n-dimensional Fourier transform of $\rho_s(\mathbf{x}_s)$. With these two definitions, all equations of Sections 4.8.2–4.8.6 can directly be applied to superspace densities (van Smaalen *et al.*, 2003).

The MEM in superspace has only been applied to single-crystal X-ray diffraction data, but applications involving X-ray powder-diffraction data appear equally possible. It is actually a promising technique for structural analysis of powder-diffraction data of aperiodic crystals in those cases where only a limited number of the usually weak incommensurate superlattice reflections can be extracted from the powder-diffraction profile.

4.9. Structure validation

J. A. Kaduk

4.9.1. Introduction

Just as there is no single measure of the quality of a Rietveld refinement, no one factor indicates the quality of a crystal structure derived from diffraction data. Statistical (Toby, 2006) and graphical measures are important, but chemical reasonableness can carry even more weight (McCusker *et al.*, 1999; Kaduk, 2007*a*,*b*). Much chemical knowledge is incorporated into structure-validation programs such as *PLATON* (Spek, 2003, 2009), which is at the core of the *checkCIF* system (Helliwell *et al.*, 2006), but many judgements of the validity and quality of a structure depend on the experience and expertise of the user. Knowledge of molecular geometry can be incorporated into Rietveld refinements by including restraints (soft constraints) and constraints into the refinement. In this chapter, thought processes and tools which can be applied during and after refinement to assess structural validity are discussed.

4.9.2. Statistical measures (with contributions from B. H. Toby)

In a Rietveld refinement, we fit a model to data; it is the model which is refined, not the data. The Rietveld algorithm optimizes the model function to minimize the weighted sum of squared differences between the observed and calculated intensity values. The most straightforward measure of the quality of the fit is the weighted profile *R* factor,

$$R_{\rm wp}^2 = \frac{\sum_i w_i (y_{oi} - y_{ci})^2}{\sum_i w_i y_{oi}^2}, \qquad (4.9.1)$$

in which y_{oi} are the observed intensities (data points), y_{ci} are the data points calculated from the model and w_i are the weights. Generally,

$$w_i = \frac{1}{\sigma^2(y_{oi})}, \qquad (4.9.2)$$

in which $\sigma(y_{oi})$ is the standard uncertainty (Schwarzenbach *et al.*, 1995, 1996) for the intensity. Other weighting schemes can be used, but when the errors are purely statistical in nature, it can be proven (Prince, 2004; David, 2004) that the smallest uncertainties in the fitted parameters are obtained with this weighting scheme.

If we have an ideal model, one that accurately predicts the true value of each y_{oi}, the average value of $(y_{oi} - y_{ci})^2$ will be equal to $\sigma^2(y_{oi})$, and the expected value of $w_i(y_{oi} - y_{ci})^2$ is unity. The fit (and thus the residual) that one would obtain with this ideal model is the best possible one that can be obtained, provided that the weights are correct. This 'best possible $R_{\rm wp}$' is a very useful concept, and is called the expected *R* factor, $R_{\rm exp}$. Using *N* as the number of data points and *P* as the number of refined parameters (Young, 1993),

$$R_{\rm exp}^2 = \frac{N - P}{\sum_i w_i y_{oi}^2}. \qquad (4.9.3)$$

A related statistical concept is the statistical quantity 'reduced chi squared', χ^2 (Toby, 2006). This is defined (Young, 1993) as

$$\chi^2 = \frac{1}{N - P} \sum_i \frac{(y_{oi} - y_{ci})^2}{\sigma^2(y_{oi})}. \qquad (4.9.4)$$

A little algebra shows that χ^2 can also be determined from the expected and weighted profile *R* factors:

$$\chi^2 = \left(\frac{R_{\rm wp}}{R_{\rm exp}}\right)^2. \qquad (4.9.5)$$

The single-crystal literature often uses the term goodness of fit (*S*), which is defined by $S^2 = \chi^2$. In powder diffraction, the convention is to report χ^2 rather than *S*.

During the refinement process, χ^2 (and $R_{\rm wp}$) starts out large when the model is poor and decreases as the model fits the data better. Least-squares refinement should never cause χ^2 to increase, but increases do sometimes occur when parameters are correlated. A small increase followed by a drop to a lower value in subsequent cycles of refinement is not a cause for concern, but a large increase during a refinement cycle is a sign of a problem.

If at any point $\chi^2 < 1$, the weights are wrong because the standard uncertainties are overestimated. This situation commonly occurs when the intensities have been scaled before refinement, such as when the data have been collected using a variable-divergence slit (all Rietveld programs assume fixed-slit intensities) and the uncertainties have not been calculated correctly. The standard uncertainty of a y_{oi} value is generally calculated as the square root of the number of counts (not counts s^{-1} or other count rates) at that point, and sometimes includes an additional contribution. Estimation of standard uncertainties can be difficult for detectors that do not directly count photons, such as charge-coupled detectors or image plates. Data from two-dimensional detectors are often on an arbitrary scale, and thus the statistical measures are not meaningful in an absolute sense. There are techniques for placing intensities on an absolute scale (Suortti *et al.*, 1985; Klug & Alexander, 1974), but they are not often used in powder diffraction. Getting the weights right is important. I have seen cases in which the weights were calculated incorrectly; this effectively discards data, resulting in a distorted structural model and incorrect chemical conclusions derived from it.

When χ^2 is close to unity, the errors in the fit are dominated by the statistical errors in the data. There is no guarantee that the model is correct (there may be many models that produce equivalent fits), but the data are not sufficient to support a more complex model. Many correct refinements have $1 < \chi^2 < 3$ (or even higher; see below), but under some circumstances models obtained with $\chi^2 > 30$ may provide accurate crystallographic results, and there is no general rule on what value of χ^2 is low enough. As will be discussed later, even refinements with χ^2 close to unity can have significant problems (that is, can be wrong).

When $\chi^2 \gg 1$, several situations are possible:

(i) The model is reasonable, but the standard uncertainties are underestimated.

(ii) The model is incomplete and/or the data contain systematic errors.

Copyright © 2019 International Union of Crystallography

(iii) The model is wrong.

Many fine studies are published with $\chi^2 \gg 1$, but the reasons for the poor fit must be understood and discussed.

An important test of the fit when $\chi^2 \gg 1$ is to compare the residuals from the Rietveld refinement with those obtained from a Le Bail (2008) or Pawley (1981) fit, in which the peak intensities are optimized without the constraint of a structural model (see Chapter 3.5). If the crystallographic fit is as good as the structureless fit, then features of the data such as profile shapes or background are not being modelled correctly. More detailed analysis is required to understand whether these errors are affecting the integrated intensities and thus the crystallographic results. If the structureless fit is good but the Rietveld fit is not, there are likely to be systematic crystallographic problems with the model. Often these can be discerned by considering the chemical reasonableness of the model, but sometimes the real chemical system is more complex than can be described by a conventional crystallographic model (for example, it might contain stacking faults and other types of imperfections). However, systematic errors in the data, such as preferred orientation or (more problematically) poor grain sampling, can produce a pattern that cannot be fitted well by a reasonable model.

Having a χ^2 value that is far from unity has a significant implication when interpreting the results from many modern Rietveld programs (Toby, 2006). The least-squares minimization allows the statistical uncertainty in the observations to be propagated to derive uncertainties in the refined parameters. These values are derived from the variance–covariance matrix, but these estimates are accurate only when $\chi^2 \simeq 1$ (Prince, 2004). Many (but not all, and not necessarily for all variables) Rietveld programs multiply the apparent standard uncertainties by the slope of the normal probability plot (discussed below in Section 4.9.3) to arrive at 'more accurate' estimates of the uncertainties. If the source of the error has a negligible correlation with the parameter in question (such as profile-shape errors and atomic coordinates), the 'corrected' uncertainty may be worse than the true uncertainty. On the other hand, if the systematic error is correlated with the parameter (such as intensity errors from beam spillover or a too-thin flat-plate specimen, which will correlate with the atomic displacement coefficients), the correction may not be large enough.

Most modern Rietveld programs compute other residuals, most of which I do not find useful in distinguishing bad refinements from good ones. Commonly calculated is the unweighted profile R factor,

$$R_p = \sum_i |y_{oi} - y_{ci}| / \sum_i y_{oi}. \qquad (4.9.6)$$

Since $R_{\rm wp}$ is the quantity minimized in the Rietveld refinement, and the weights are important, I do not find this quantity particularly useful. Some programs calculate $R_{\rm wp}$ both for the whole pattern and with the background subtracted. The background-subtracted version can occasionally be useful for assessing the quality of the fit to the peak intensities.

Single-crystal refinement residuals are based on the observed and calculated structure-factor amplitudes $F_o(hkl)$ and $F_c(hkl)$. While the $F_c(hkl)$ are computed directly from the structural model in a Rietveld refinement, the $F_o(hkl)$ are not directly measured because of the overlap of reflections in the powder pattern. One of the several great insights in the development of the Rietveld method (Rietveld, 1969) was the mechanism for estimating $F_o(hkl)$ by partitioning observed intensities according to the $F_c(hkl)$ values. The better the model, the better these estimates become. Using the extracted $F_o(hkl)$ and $F_c(hkl)$, approximations to the normal unweighted single-crystal R factors can be calculated (Young, 1993):

$$R(F) = \frac{\sum_{hkl} |F_o(hkl) - F_c(hkl)|}{\sum_{hkl} F_o(hkl)},$$
$$R(F^2) = \frac{\sum_{hkl} |F_o^2(hkl) - F_c^2(hkl)|}{\sum_{hkl} F_o^2(hkl)}. \qquad (4.9.7)$$

Since the $F_o(hkl)$ values are biased by the model, these residuals tend to be smaller than would be derived from a single-crystal data set, but they are useful for comparisons. The label $R_{\rm Bragg}$ is used in the Rietveld literature to refer to reflection-intensity-based residuals, but the term is ambiguous and is used to mean both $R(F)$ and $R(F^2)$. The best practice is to report both quantities so that there is no ambiguity.

There are differences of opinion on the utility of these various residuals, mainly arising from how they are computed. The easiest way to achieve a low χ^2 is to collect poor (noisy) data. The statistical errors in the data then swamp any errors in the model. A Rietveld refinement using noisy data will tend to have a low χ^2 but a high $R_{\rm wp}$. A similar situation arises when the background makes up a significant portion of the intensity, such as when a highly fluorescent specimen is measured. Counting for longer times increases the statistical precision of a diffraction measurement. As the total number of counts in the pattern increases, the $R_{\rm exp}$ decreases. Collecting better data will thus often increase the difference between $R_{\rm exp}$ and $R_{\rm wp}$ (although decreasing both of them), resulting in an increase in χ^2. Likewise, improved instrumental resolution is a good thing; it decreases the degree of peak overlap, resulting in more accurate integrated intensities and thus more accurate structural information. However, improved signal to noise and resolution often make imperfections in the model (particularly in the profile shapes) more obvious, resulting in increased refinement residuals. Synchrotron data are significantly better than laboratory patterns in both signal to noise and resolution, so we can often expect to see higher residuals from refinements using synchrotron data.

Statistical measures such as the F-test [see Volume C, Chapter 8.4 (Prince & Spiegelman, 2004)] are appropriate for comparing two different models compared with the same data, but are of little use in comparing one refinement with another (based on different data sets but assuming similar instrument configurations). With experience, each user develops a sense of what is an appropriate range for residuals for his/her types of problems and data. Whatever residual is used, the sources of the discrepancies in the fits must be understood and discussed in the report of the Rietveld refinement.

4.9.3. Graphical measures (with contributions from B. H. Toby and J. K. Stalick)

The statistical quality measures discussed in Section 4.9.2 provide overall measures of the quality of the Rietveld fit. Through graphical inspection of the discrepancies between the observed and calculated patterns, we can determine the nature of the disagreements, decide whether they are significant and how to adjust the model to minimize them, and judge whether any remaining systematic errors are likely to bias the fitted parameters. A good principle in carrying out a Rietveld refinement is 'deal with the sources of the largest errors first'. The best way to determine the origins of the greatest discrepancies in the fit is

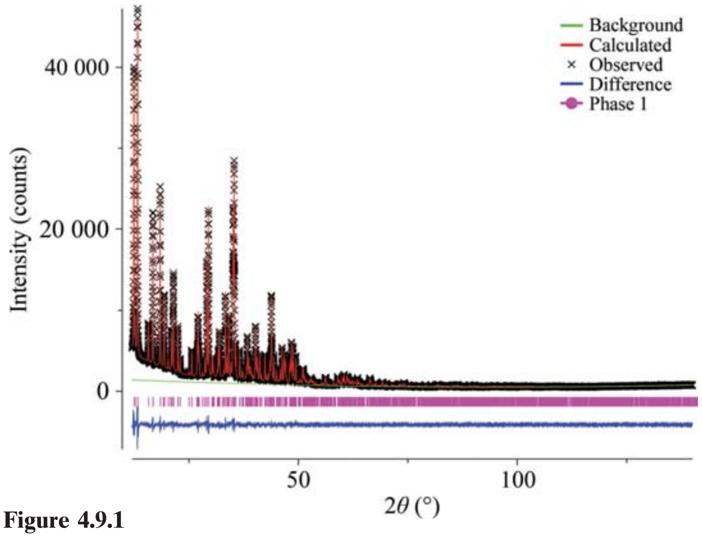

Figure 4.9.1
A 'Rietveld' plot from the refinement of calcium tartrate tetrahydrate. The observed data points are indicated by the black × symbols, the calculated pattern is represented by the red curve and the difference pattern (observed − calculated) is shown on the same vertical scale by the blue curve. The vertical tick marks indicate the reflection positions and the green curve is the background function.

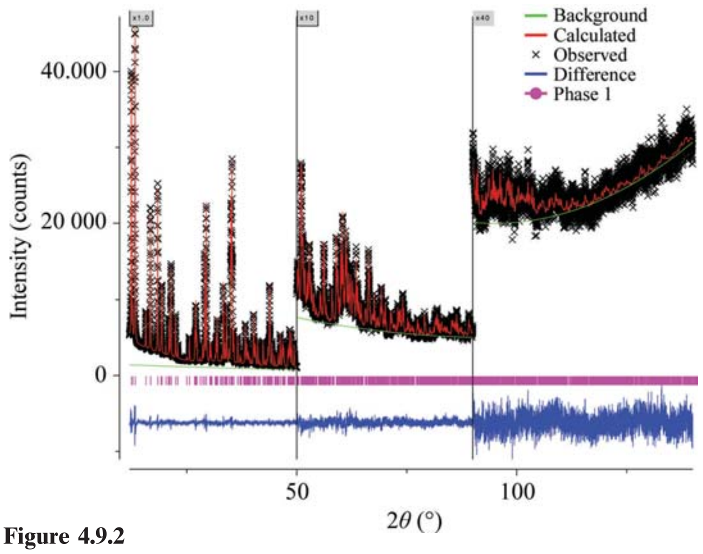

Figure 4.9.2
The calcium tartrate tetrahydrate Rietveld plot of Fig. 4.9.1 but with a variable vertical scale. The region from 50 to 90° has been multiplied by a factor of ten and the region above 90° by a factor of 40. Such changes in scale make it easier to judge the quality of the fit of the weaker peaks.

graphical examination of the observed and computed patterns. Detailed discussion of the physics and mathematics that give rise to various kinds of errors takes place in Chapters 3.1–3.3 of this volume. In this chapter, we concentrate on empirical advice.

Graphical inspection requires plotting the diffraction data on a range of scales and in a variety of formats. When evaluating one's own work this is not difficult, since Rietveld packages include plotting programs for this task. When reviewing published work this task is more difficult, since static figures in a paper cannot provide enough necessary detail. The incorporation of 'advanced figures' can facilitate evaluation enormously. Allowing reviewers and readers the ability to carry out graphical analysis of Rietveld results was one of the motivations for extending the CIF format to allow the exchange of observed and computed powder diffraction data (Toby, 2005). Many Rietveld packages allow the export of results in CIF. From these CIF files, utilities such as the *pdCIFplot* program (Toby, 2003) can be used for graphical inspection of the fits.

Although statistical measures can be discussed in abstract terms, graphical measures require looking at real plots. For this discussion, we will use the Rietveld refinement of the structure of calcium tartrate tetrahydrate (Kaduk, 2007*a*). The specimen was the sediment from the bottom of a wine bottle, and the pattern was collected on a Bruker D8 Advance diffractometer equipped with a VÅNTEC-1 position-sensitive detector (supplementary files kadu937.gsas and d8v3.prm). The initial structural model was taken from Hawthorne *et al.* (1982). The final residuals were $R_{\rm wp} = 0.0454$, reduced $\chi^2 = 3.336$, $R(F) = 0.0711$ and $R(F^2) = 0.0707$.

Rietveld results are most commonly displayed in a more-or-less standard format, generally referred to as the 'Rietveld plot' (Fig. 4.9.1). This type of plot displays the observed diffraction data as individual points, with the calculated pattern superimposed as a continuous line. The plot has vertical tick marks indicating the positions of the reflections. Also typically displayed is a difference plot (observed − calculated), generally on the same vertical scale as the observed and calculated plots. The difference curve tends to overaccentuate discrepancies in the most intense peaks, for which large deviations may be within the statistically expected levels. For this reason, it is preferable to plot intensities normalized by their uncertainties, $I/\sigma(I)$, which is sometimes referred to as a normalized Rietveld plot. In this mode, the plotted magnitudes of differences correspond directly to their contribution to $R_{\rm wp}$ and χ^2, and thus the influence that the discrepancies have on the fit. Having said this, it should be noted that the eye is not very good at integrating. A discrepancy of a few points at the top of a peak seems to be more significant than a small error in the background that extends over hundreds of points. The latter can have a much larger influence on χ^2. For this reason, the cumulative χ^2 plot, which will be introduced later, is useful for showing the true influence of discrepancies.

Although the static Rietveld plot generally found in a publication is useful for seeing the 'big picture', there is considerable detail that can only be seen when the information is viewed at several magnification scales. Thus, this plot is much more useful when it is 'live' (*i.e.* when it is possible to zoom in on details). More subtle features can then be discerned. To overcome the disadvantages of a static plot, a good practice is to vary the vertical scale in a publication figure to permit easier examination of the weak peaks (Fig. 4.9.2). Alternative ways of re-normalizing the plot to obtain greater sensitivity to the weak features are the (observed − calculated)/σ or 'error' plot (Fig. 4.9.3), the

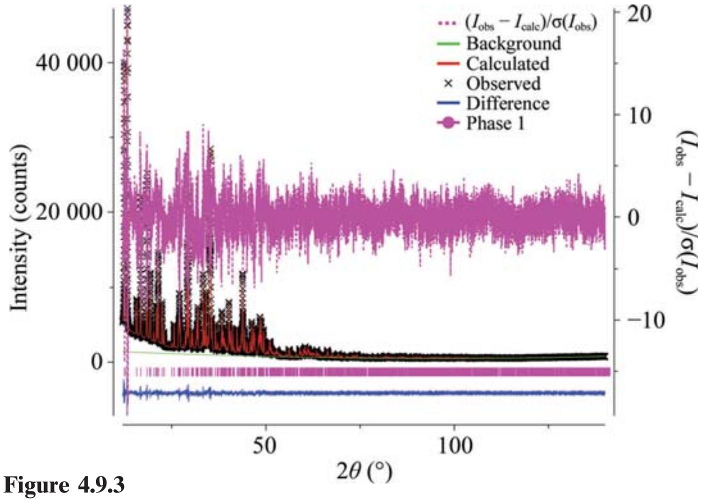

Figure 4.9.3
The calcium tartrate tetrahydrate Rietveld plot of Fig. 4.9.1 with an 'error' plot superimposed. The magenta curve (using the right-hand vertical scale) plots $(I_{\rm obs} - I_{\rm calc})/\sigma(I_{\rm obs})$ for each data point.

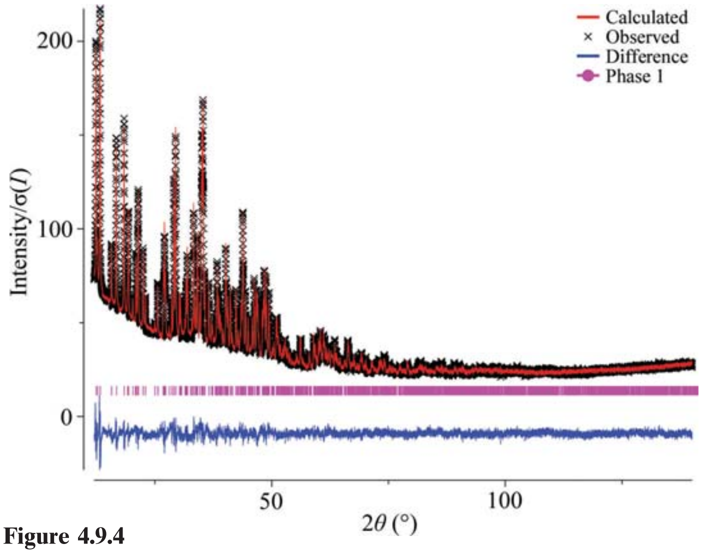

Figure 4.9.4

normalized Rietveld plot $I/\sigma(I)$ (Fig. 4.9.4) and the weighted Rietveld plot (Fig. 4.9.5). The weighted Rietveld plot is not commonly used, but I find it helpful because it is closer to the function that is minimized in the least-squares refinement. Such weighted plots also provide a vivid demonstration that the weak high-angle peaks are just as important to the least-squares refinement as the strong low-angle peaks (Figs. 4.9.6*a* and 4.9.6*b*; supplementary files kadu1536.gsas and iitd26.prm).

The cumulative χ^2 plot (Fig. 4.9.7; David, 2004) has advantages for highlighting the largest errors in the Rietveld fit. This function is simply the running average of the $[(\text{obs} - \text{cal})/\sigma]^2$ values. For an ideal fit, all points will be fitted with an average discrepancy of σ, so the cumulative χ^2 plot approximates a straight line with a slope of unity. For a non-ideal fit, regions that are poorly fitted will be highlighted by a sudden increase in the cumulative χ^2 values. The steps in Fig. 4.9.7 indicate (on zoomed examination) that the asymmetry of the strong low-angle peaks is not modelled particularly well. The integration contained in this type of plot highlights regions where smaller discrepancies over an extended range of the data degrade the fit. Smaller but extended discrepancies are much harder to discern in other types of plots. It is useful to review the reflection indices associated with an individual tick mark, as this simplifies the diagnosis of preferred orientation and anisotropic broadening.

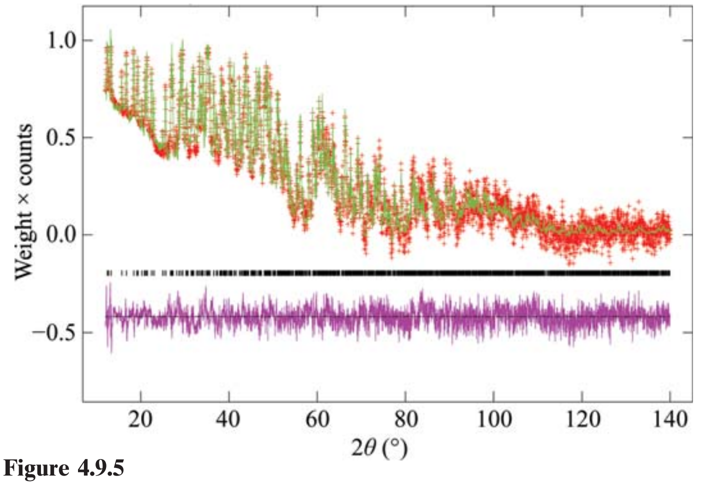

Figure 4.9.5
A weighted Rietveld plot for calcium tartrate tetrahydrate. The observed and calculated intensities are multiplied by the least-squares weights $1/\sigma^2(I_{\rm obs})$.

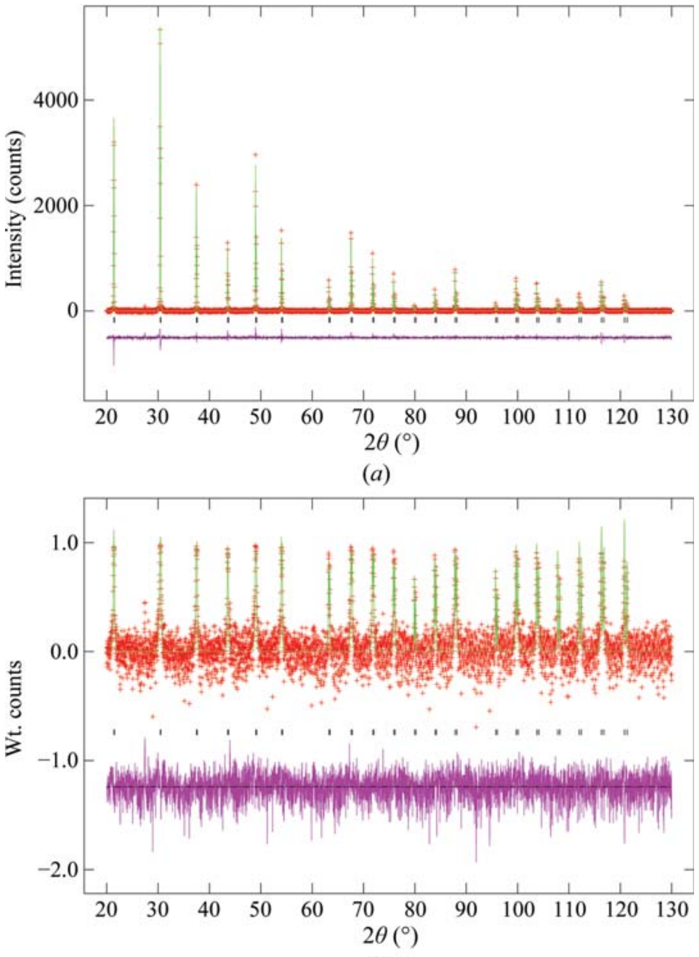

Figure 4.9.6
(*a*) A Rietveld plot from a refinement of NIST SRM 660a, $\rm LaB_6$. (*b*) The equivalent weighted Rietveld plot, making it clear that weak peaks are just as important as strong peaks.

The normal probability plot (Fig. 4.9.8) is useful for detecting systematic errors in the fit. To make this plot, the individual data points are sorted by $(\text{obs} - \text{cal})/\sigma$ and compared with the frequency of errors expected from a normal distribution. An ideal normal probability plot has a slope of unity and an intercept of zero. The example plot in Fig. 4.9.8 has a slope of 1.4928 and an intercept of 0.0296 (for the default region $\pm 2\sigma$). The slope of the normal probability plot is used internally in some least-squares programs to multiply the estimated standard uncertainties

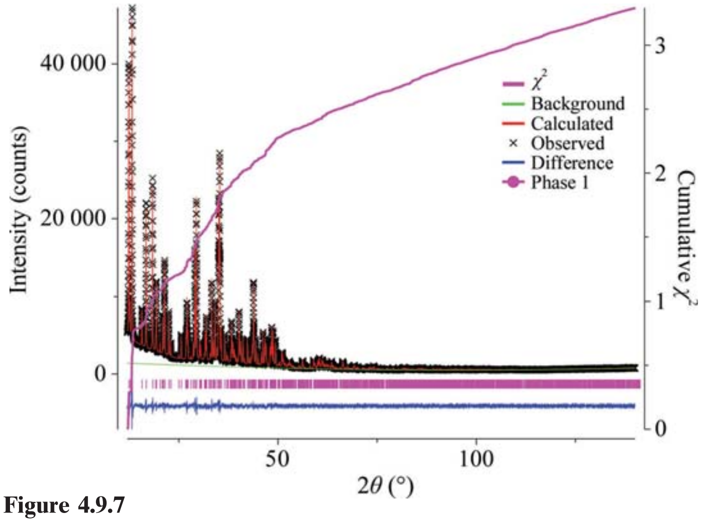

Figure 4.9.7

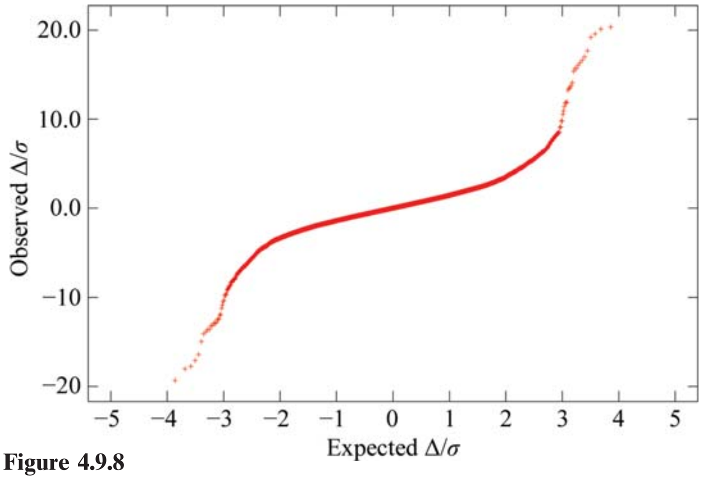

Figure 4.9.8
A normal probability plot from the refinement of calcium tartrate tetrahydrate.

obtained from the variance–covariance matrix to obtain a better estimate of the true uncertainties. An intercept far from zero suggests the presence of systematic errors, either in the data or the model.

The plots shown so far have been from the end of the refinement. It is also valuable to examine these plots periodically throughout the refinement to indicate which variables need to be considered next in the refinement. Examining the normal Rietveld plot at high vertical magnification, or the normalized (Fig. 4.9.9) or weighted (Fig. 4.9.10) plots, provides a check on the quality of the background fit. Away from the peaks, the calculated pattern should pass through the middle of the data points. The background should obviously not lie above the data points. The fits in Figs. 4.9.9 and 4.9.10 (after refinement of a scale factor and a three-term shifted Chebyshev polynomial background function) show that the background fitting needs to be improved. Additional background terms were added (up to nine) and the fit improved. For this case I ultimately chose to use a three-term shifted Chebyshev background function along with a diffuse scattering function to model the contributions of an apparently small amount of amorphous material in this sample. Display of the background function (shown in green in Figs. 4.9.1, 4.9.2, 4.9.3 and 4.9.7) is very helpful in assessing the quality of the fit.

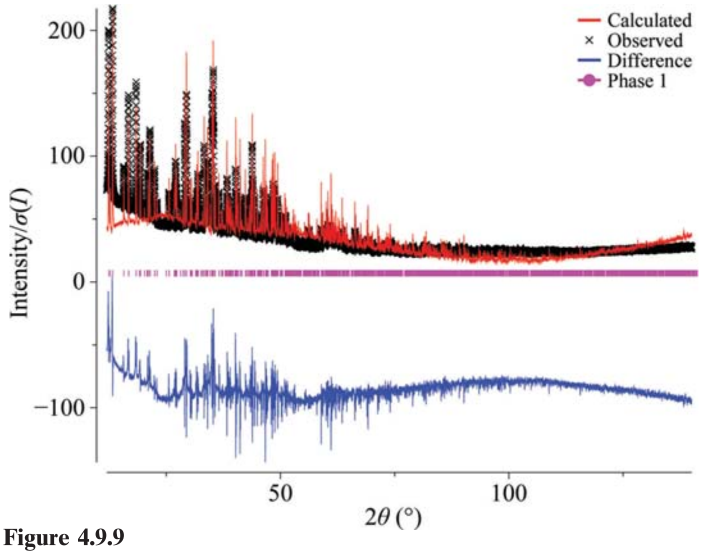

Figure 4.9.9
A Rietveld plot of calcium tartrate tetrahydrate after refinement of a phase fraction and a three-term shifted Chebyshev background function. The difference plot shows that a better background function is needed.

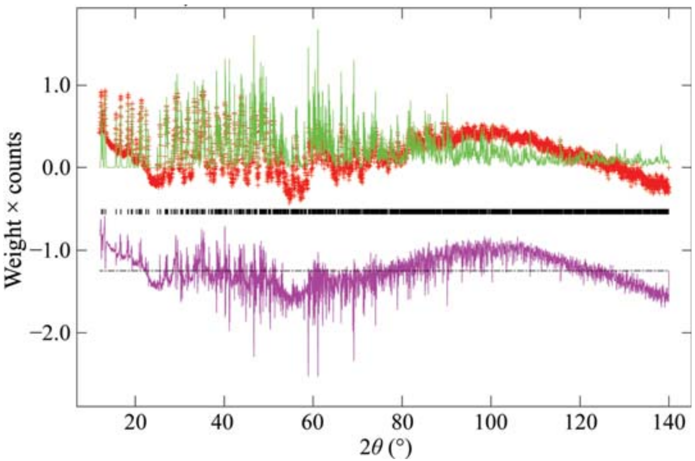

Figure 4.9.10
A weighted Rietveld plot of calcium tartrate tetrahydrate after refinement of a phase fraction and a three-term shifted Chebyshev background function. The difference plot shows that a better background function is needed.

A poorly fitted background most commonly affects the profile shape (especially the description of the peak tails), but can also affect the phase scaling factors and thus the quantitative analysis. This is particularly true for minor phases. When the background refines to a level that is too high and the profiles of the weak peaks become too wide, the phase fractions and thus the concentrations of minor phases will be over-represented. When the background is poorly fitted at high Q [where $Q = (2\pi)/d$], this same effect causes atomic displacement parameters to be overestimated, since higher-Q reflection intensities are undercounted. The influence of the background misfitting depends on the type of study, but usually does not affect the fractional atomic coordinates greatly. Crystallite size/strain analysis is often highly background dependent. In the current example, the background and diffuse scattering coefficients are highly correlated with each other, but are relatively independent of the structural and profile parameters.

It is highly advantageous to examine the computed background, which is best performed at high magnification with the background plotted against the observed data without normalization for uncertainty (which would cause the background to jump irregularly). Backgrounds from well crystallized samples in standard mountings are slowly varying and require only a few terms to fit well. This may not be true when special sample cells are used. Some programs include a $1/\sin 2\theta$ term, which describes air scattering well. A moderately common error is to use too many background terms in an attempt to fit medium-frequency features in the data. Such features can arise from amorphous components (which are better described using a diffuse scattering function) or the overlap of poorly modelled peak tails in clusters of peaks. Such fits point to deficiencies in the crystallographic and/or profile models. Attempting to fit such effects with more background terms can lead to serious errors in the structural model.

However, when too few terms are used the background function is not able to fit the observed changes in background with Q, leading to systematic errors in peak intensities and thus the crystal structure. A best practice is to use a small number of background terms in the initial stages of a refinement and to examine the fit graphically at regular intervals. In the final stages of refinement one can add more terms to see whether the fit is improved and (if so) that the changes in the background curve better match the observed background. It is also wise to check

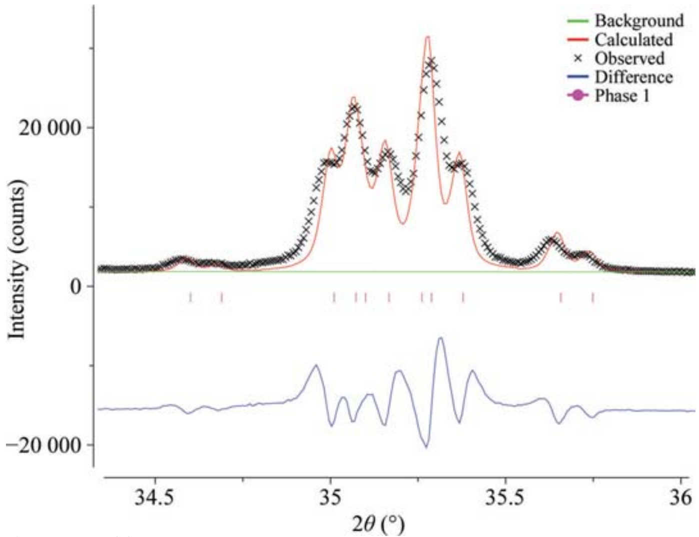

Figure 4.9.11
A small region of the calcium tartrate tetrahydrate Rietveld plot early in the refinement. The calculated peaks are not in the right places, so the conclusion was that the lattice parameters and the specimen displacement coefficient needed to be refined.

whether the structural model is altered by such changes to the background function.

The process of carrying out a Rietveld refinement requires continuous intimate interaction with the raw data, mainly through graphical tools. After the first few cycles of refinement (scale factor and three background terms), close examination of small regions of the pattern (Fig. 4.9.11) indicated that the peaks were not in the correct places. The main controls over the positions are the lattice parameters and the specimen displacement coefficient, so these were added to the refinement. Once the agreement of the calculated and observed peak positions was good (Fig. 4.9.12), it was clear that the calculated peak widths were too narrow. The appearance of the peaks is Lorenztian (Cauchy), suggesting that Lorentzian size and/or strain coefficients should be added to the refinement. The peak widths differ in this small region, suggesting that the broadening is anisotropic. Such anisotropy can arise from size and/or strain effects. In this case, the treatment of anisotropic strain broadening described by Stephens (1999) was used. (See also Chapters 5.1 and 5.2.)

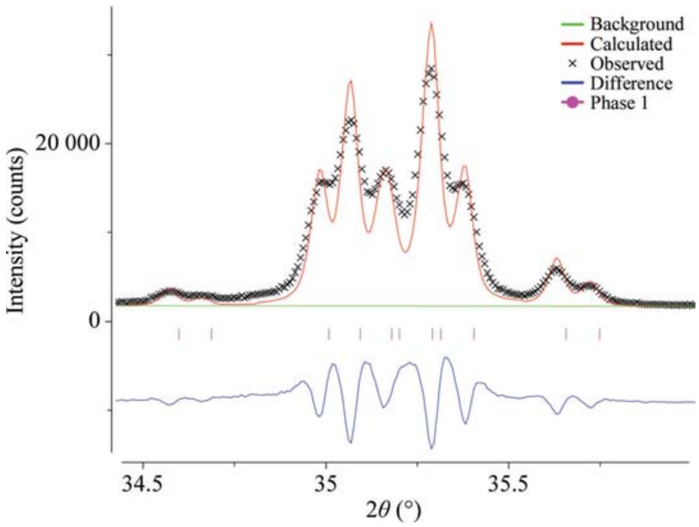

Figure 4.9.12
The same 34.5–36° region of the pattern of calcium tartrate tetrahydrate after refinement of the cell parameters and specimen displacement. The peak positions are now correct, but the profile coefficients need to be refined.

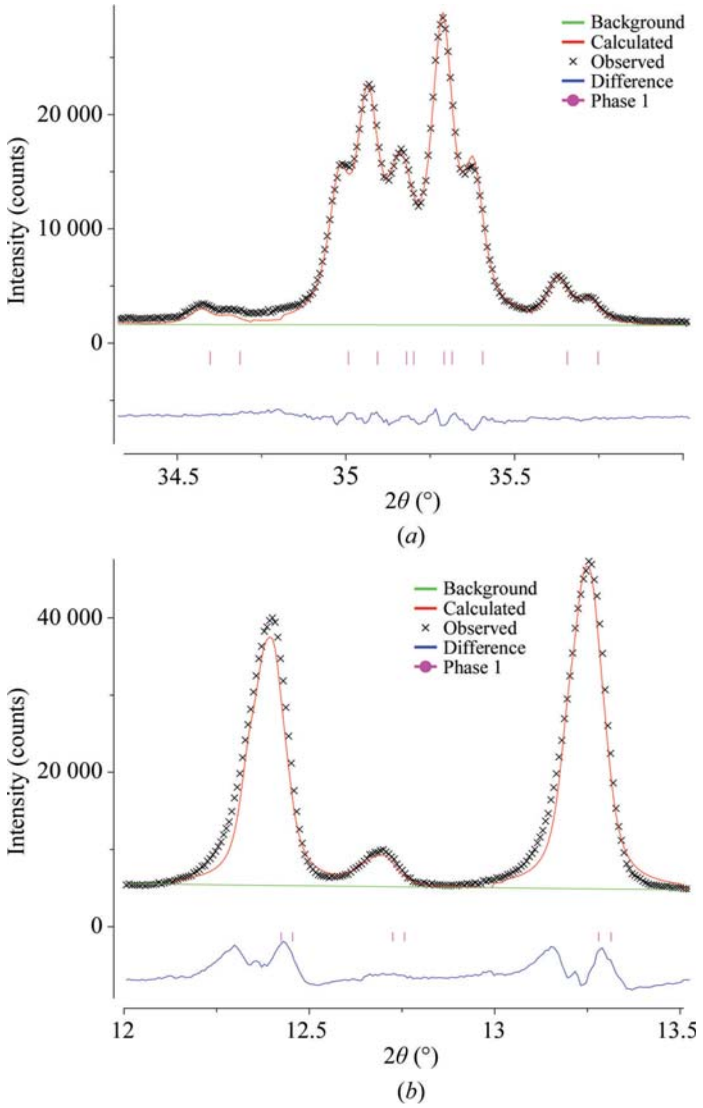

Figure 4.9.13
(*a*) The 34.5–36° region of the calcium tartrate tetrahydrate pattern after refinement of profile coefficients. The effects of the 1% peak cutoff can be seen on the peak tails. (*b*) The 12–13.5° low-angle region of the calcium tartrate tetrahydrate pattern. The profile asymmetry is not modelled well, suggesting that an asymmetry coefficient needs to be refined.

Once more cycles of refinement had been carried out, close examination of individual regions provided clear direction on how to improve the fit. Although the fit in the higher-angle regions was much better (Fig. 4.9.13*a*), the asymmetry of the low-angle peaks was not described correctly (Fig. 4.9.13*b*). The asymmetry of low-angle (and high-angle, but this is rarely observed) peaks arises mainly from instrumental effects, and results from axial divergence and flat-specimen contributions to the convolutions that determine profile shapes. Calcium tartrate tetrahydrate has fairly modest X-ray absorption, so we might expect an additional contribution to the asymmetry from transparency effects. Thus, one of the Finger–Cox–Jephcoat (Finger *et al.*, 1994; van Laar & Yelon, 1984) asymmetry parameters was added to the refinement.

An additional effect can be seen in Fig. 4.9.13(*b*), most clearly at $2\theta \simeq 13°$. All Rietveld codes limit the number of data points to which a reflection contributes (to save computer time). From the unit-cell and correction terms, the reflection position is known. Using this position and the profile shape, the data points to which this reflection contributes can be determined out to some limit. The limit is variously defined in terms of some fraction of the

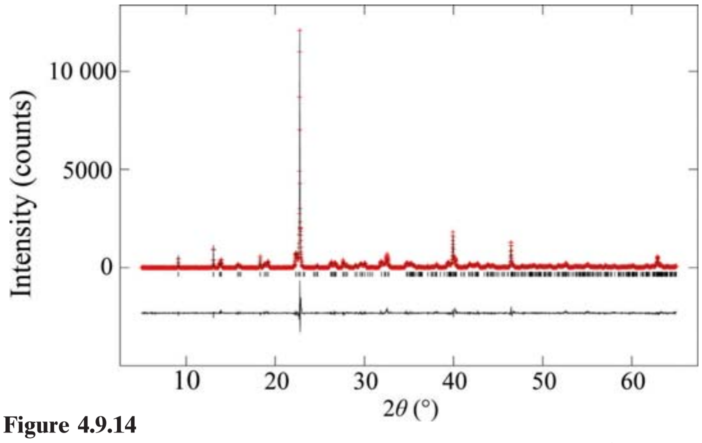

Figure 4.9.14
A full-scale Rietveld plot from the refinement of $Ba_3CaSb_2O_9$ (Rowda *et al.*, 2008) using synchrotron radiation before the impurity phases were identified and included in the refinement. The reduced χ^2 at this stage was 3.857.

maximum intensity or some multiple of the full width at half maximum (FWHM). In this case, each peak was assumed to contribute to data points down to 1% of the peak intensity; outside this range the peak contribution was zero. The result is an incomplete description of the tails of the strong peaks. To correct this, the peak cutoff was lowered to 0.5% of the peak intensity.

Additional types of deficiencies in the model can be determined by very close graphical inspection of the fit. Particularly important are observed peaks that are not accounted for by the model. The most common causes of such peaks are impurity phases and an incorrect cell/symmetry. Although the initial full-scale Rietveld plot (data) of the refinement of the 6H perovskite $Ba_3CaSb_2O_9$ (Rowda *et al.*, 2008) using synchrotron data appeared to be acceptable (Fig. 4.9.14), closer examination at zoomed scales (Fig. 4.9.15) revealed the presence of additional peaks. Some of these were resolved peaks, but others were shoulders on the strongest peaks. Searches for these peaks in the Powder Diffraction File indicated the presence of three impurity phases. Attempts to fit the multiphase data using a single-phase model resulted in structural distortions, which were eliminated by using a more complete model.

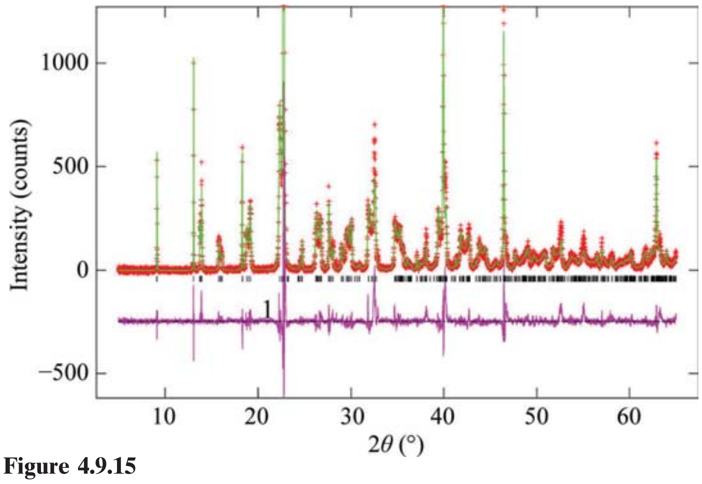

Figure 4.9.15
The plot of Fig. 4.9.14, zoomed in to the region under 1000 counts. The presence of impurity peaks is clear.

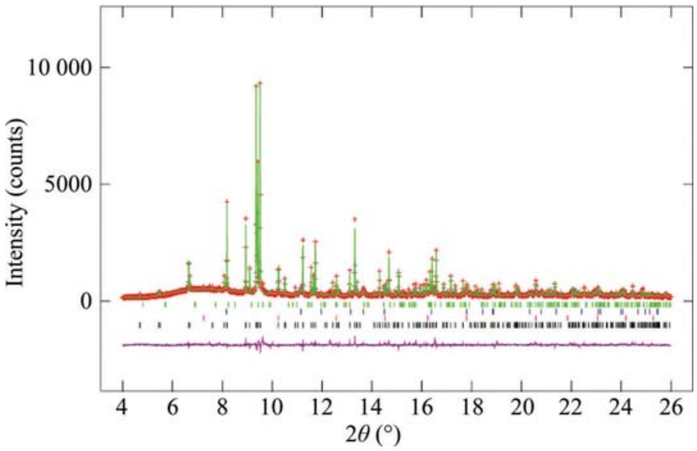

Figure 4.9.16
Full scale Rietveld plot of $(Ba_{1.25}Sr_{0.75})TiO_4$.

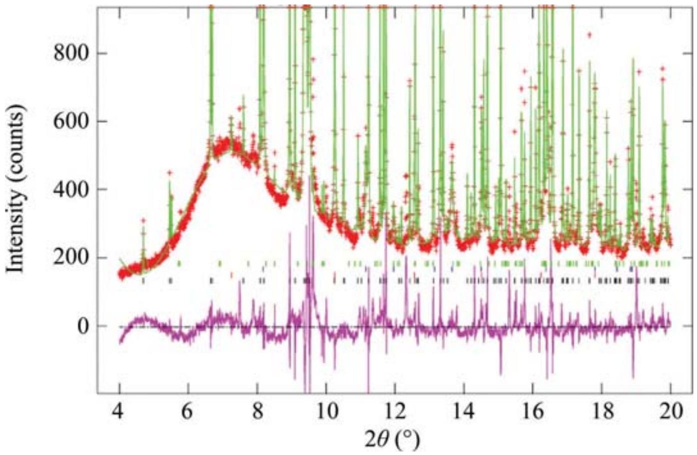

Figure 4.9.17
A portion of the plot of Fig. 4.9.16 zoomed in to the region under 1000 counts. Several weak peaks that are not accounted for by the current model are clear.

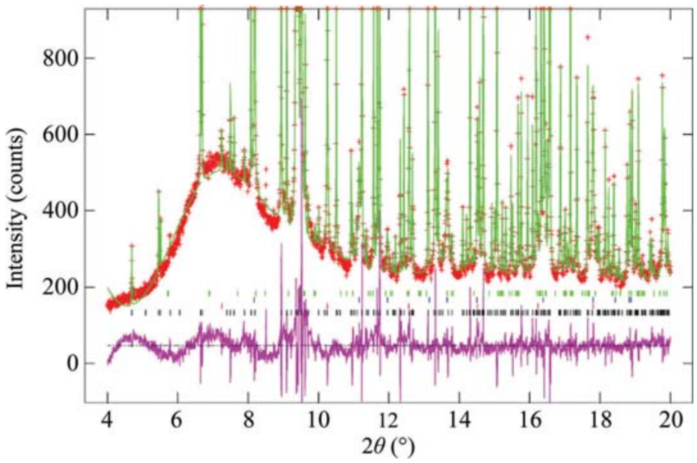

Figure 4.9.18
A portion of the Rietveld plot of $(Ba_{1.25}Sr_{0.75})TiO_4$ after the correct unit cell and structure had been identified. The new cell accounts for all of the weak peaks in Fig. 4.9.17.

The initial full-scale Rietveld plot (supplementary files ba2180.gsas and id100602.prm) of the refinement of the structure of $(Ba_{1.25}Sr_{0.75})TiO_4$ in *Pnma* with a = 7.48904 (3), b = 6.03638 (3), c = 10.32873 (5) Å and V = 466.928 (4) Å^3 appeared to be acceptable at full scale (Fig. 4.9.16), but closer examination (Fig. 4.9.17) showed the presence of extra peaks even after impurities had been identified. These peaks did not correspond to any known or chemically reasonable isostructural phase. They were added one at a time to the strong low-angle peaks as input to *DICVOL91* (Boultif & Louër, 1991), which repeatedly suggested the same primitive orthorhombic unit cell with $a = 2a$. Lattice matching led to the identification of a lowered symmetry $Pna2_1$ model that accounted for these weak peaks (Fig. 4.9.18)

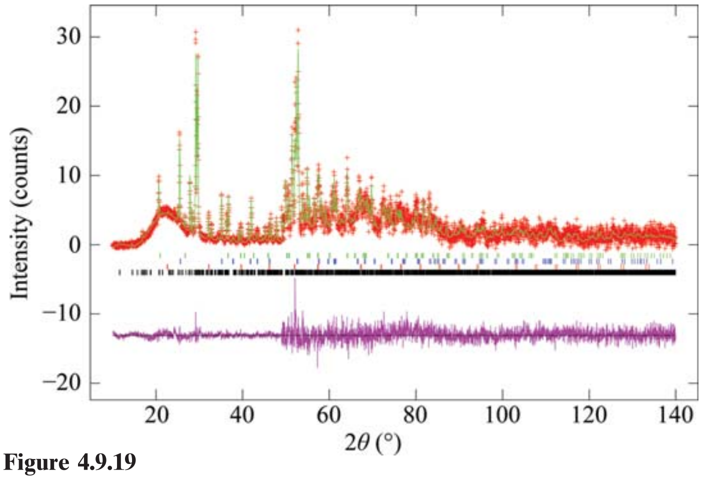

Figure 4.9.19
A Rietveld plot of $(Ba_{1.5}Sr_{0.5})TiO_4$ early in the refinement, with an incorrect unit cell for the major phase.

and was chemically reasonable. When confronted with a model that does not index a significant number of weak peaks (especially at low angles), it is often worthwhile to plot the reflection positions for the cell volume doubled in various ways (axis doubling as well as $2^{1/2} \times 2^{1/2}$ expansions of pairs of axes) to see whether these peaks can be explained by a subtle change of the symmetry.

The opposite problem, where a structural model is of too low symmetry, can also be encountered. As an example, initial refinement (supplementary files wong224.gsas and padv.prm) of the structure of $(Ba_{1.5}Sr_{0.5})TiO_4$ in $P2_1nb$ with $a = 6.0634$ (2), $b = 22.6066$ (9), $c = 10.4040$ (4) Å (as it was supposed to be isostructural to Ba_2TiO_4) yielded a reasonably good fit (Fig. 4.9.19), but there were chemically unreasonable features of the structure, and the cell predicted too many low-angle peaks which were unobserved (Fig. 4.9.20). Searches for extra symmetry yielded an aristotype having a cell with one third of the volume; this simpler model was more reasonable and yielded a better refinement.

The presence of a small number of unfitted peaks usually has only minor effects on the Rietveld refinement of the parameters of the major phase(s), particularly if the impurity peaks do not overlap those of the major phase significantly. Nonetheless, when a Rietveld analysis is completed, an important measure of quality is the fit of all of the peaks in the pattern. Often when the source of the problem becomes known, the problem turns out to be more profound than originally realized. The impurity phase may have large peaks which overlap those of the major phase(s) and the fit becomes skewed in trying to account for the spurious intensity. Exclusion of isolated peaks does not address this in any meaningful way, since the more serious problem of overlapping peaks is unresolved. Better results will be obtained when the impurity phase is included in the model (using a Le Bail or Pawley fit of the indexed impurity pattern) than by excluding the regions surrounding the impurity peaks.

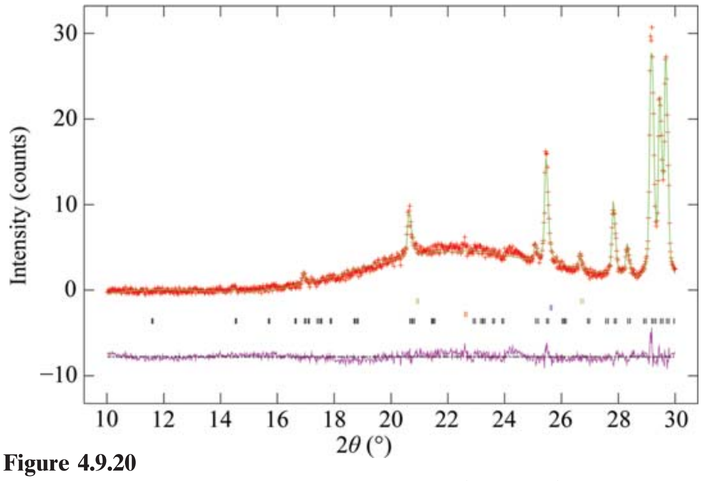

Figure 4.9.20
The low-angle portion of the Rietveld plot of $(Ba_{1.5}Sr_{0.5})TiO_4$, showing that the unit cell predicts many peaks which are not observed. The true unit cell had one-third of the volume of the cell used here.

In distinct contrast to the previous situation is the presence of calculated peaks that are not observed in the experimental pattern. No matter how small, this can only mean that the model structure is incorrect. One such example is the determination of the structure of '$BaCuO_2$', which was reported several times in the literature; unfortunately, in all cases there were calculated peaks with no observed intensity. This material (when prepared in air) was later found to contain carbonate ions (Aranda & Attfield, 1993).

4.9.4. Chemical reasonableness

Although statistical and graphical measures of the quality of the fit are important, the chemical reasonableness of the resulting structure carries even more weight (McCusker *et al.*, 1999). What do we mean by 'chemical reasonableness'? This is shorthand for saying that (with more than a million crystal structures determined) we have a good idea of normal values for bond distances, angles and other features of molecular geometry for most chemical systems. Structures refined by the Rietveld method should fall within these normal ranges. A proposal of remarkable geometry should be supported by more evidence than a routine Rietveld refinement. Chemical knowledge can be used in structure solution, refinement and analysis of results.

Our chemical knowledge is summarized in different ways for different classes of compounds. The repository of organic and organometallic crystal structures is the Cambridge Structural Database (CSD; Groom *et al*., 2016). We can perform our own analysis of any desired structural parameter using the tools in *ConQuest* and *Mercury* (Sykes *et al.*, 2011), or use the pre-created databases of intramolecular (Mogul; Bruno *et al.*, 2004) and intermolecular (GOLD) interactions supplied with the CSD. Inorganic crystal structures are archived in the PDF-4+/Linus Pauling File (Pearson's Crystal Data; Villars *et al.*, 1998; ICDD, 2012), the Inorganic Crystal Structure Database (Hellenbrandt, 2004) and CRYSTMET (White *et al.*, 2002). Our knowledge of inorganic bond distances is conveniently summarized in the bond-valence formalism (Brown & Altermatt, 1985; Brown, 1996, 2002) and tables of ionic radii (Shannon & Prewitt, 1969). Pearson's Crystal Data contains information about the distribution of interatomic distances between any pair of atom types, and similar histograms of interatomic distances derived from the Inorganic Crystal Structure Database are contained in the Build/Connectivity menu of the *Diamond* visualization software (Crystal Impact, 2013).

Ultimately, even though Rietveld refinements use powder diffraction data, we are still performing crystallography. Structure validation uses the same principles as those used for single-crystal studies, perhaps modified to account for the lower information content of powder data compared with single-crystal data.

et al., 2005) has been described in Barr *et al.* (2007). We can anticipate the development of additional statistical tools to make the job of structure validation easier. This section includes several examples of more traditional attempts to assess the quality of organic crystal structures.

4.9.4.1.1. *Calcium tartrate tetrahydrate*

The crystal structure of calcium tartrate tetrahydrate has been reported four times (Ambady, 1968; Hawthorne *et al.*, 1982; Boese & Heinemann, 1993; Kaduk, 2007*a*). The Rietveld refinement in Kaduk (2007*a*) provides a good test of the structural accuracy and precision that can be achieved using powder data.

Tartrate (Fig. 4.9.21) is a common anion and more than 400 crystal structures that contain it have been reported. The geometry of a tartrate ion is easily analysed using *Mercury* (Sykes *et al.*, 2011). For bond distances and angles (Tables 4.9.1 and 4.9.2), histograms (Figs. 4.9.22 and 4.9.23) and descriptive statistics are obtained. The standard uncertainty on a bond is typically 0.02 Å and that on a bond angle is 2°. The bonds and angles are quite well defined. Since the atom numbering is arbitrary, it is useful to group the distances, angles and torsions by topologically equivalent quantities. For torsion angles, averages are not as useful, but polar histograms (Fig. 4.9.24) are valuable for analysing the multimodal distributions of torsion angles.

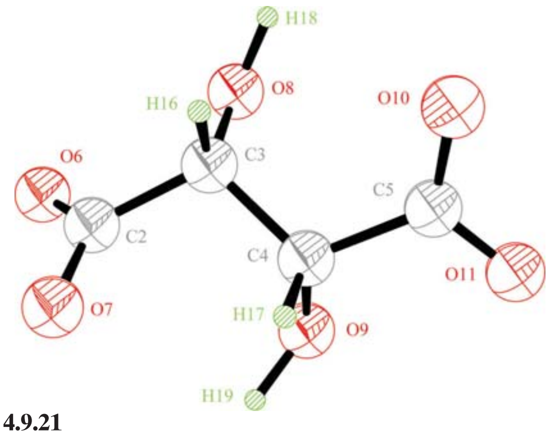

Figure 4.9.21
The structure of a tartrate anion.

This chemical information about bond distances and angles was incorporated into the refinement by the use of restraints. The restraints are treated as additional observations in the least-squares refinement; they are additional data items and the refinement will also attempt to minimize the weighted difference between the restraint target value and the value derived from the structure. I generally use the average from the Mogul/*Mercury* analysis as the restraint target value and use the standard deviation of the distribution as the uncertainty for the target value, sometimes modified by my experience with a particular

A *Mercury* polar histogram of the O8—C3—C4—O9 torsion angles in tartrate anions.

chemical system. The impact of each restraint is dictated by the restraint weighting factor divided by the square of the uncertainty.

Often a high weighting factor is used early in the refinement (a factor which may be as large as 1–2 orders of magnitude greater than the number of data points in the powder pattern), so that fitting to the restraints is as significant as fitting the data. As the refinement progresses the restraint weighting is gradually decreased. The best practice is for the restraint weights to be small (or even better, zero) in the final refinement; we want the results to be dominated by the data and not by our prior knowledge. There is currently some debate among crystallographers as to how the restraint weights should be documented. I prefer to report the fraction of the total χ^2 which is contributed by the restraints. For this calcium tartrate refinement, the restraint contribution was 1.1%.

There is often not sufficient information in an X-ray powder pattern to refine individual atomic displacement coefficients (informally called thermal parameters), and only with exceptional data can anisotropic displacement coefficients be refined successfully (and then only for the high-Z atoms). With less-than-ideal data, it is common to need to decrease the number of refined parameters. One good way to do this is to group $U_{\rm iso}$ values by similarity of environment or topology. A common isotropic displacement coefficient was refined for the tartrate C atoms, another for the tartrate O atoms and another for the O atoms of the four water molecules. The $U_{\rm iso}$ of each H atom was constrained to be 1.3 times that of the atom to which it is attached; this is essentially the riding model that is often used in single-crystal refinements.

The CSD does not currently report displacement coefficients, although they are being archived for incorporation into future releases of the database. We are thus faced with the problem of defining the initial values for $U_{\rm iso}$, and what to expect as reasonable values. For a known structure such as this one we can consult the original papers for the values (if they were reported at all). It might be necessary to consult deposited supplementary material. With experience, one can generally make reasonable guesses for the initial $U_{\rm iso}$. For this refinement, I used 0.02 Å^2 for calcium, 0.03 Å^2 for carbon and oxygen and 0.039 Å^2 for hydrogen. In refinements using X-ray powder data (especially laboratory data) it may be necessary to fix the $U_{\rm iso}$ values of at least some atoms (especially lighter atoms) to reasonable values. Sometimes the data do not support the refinement of displacement coefficients, especially if the angular range is limited. The $U_{\rm iso}$ values are often highly correlated with other parameters; for example, those of heavy atoms are correlated with the scale factor of the phase. Likewise, in refinements using data sets with extensive peak overlap at high angles there may be no clear information on the background intensity level. In this case, placing the background at different levels will change the refined $U_{\rm iso}$ values. In such a case, I may set the $U_{\rm iso}$ values to expected values and refine the background coefficients once. In subsequent refinements the $U_{\rm iso}$ values are refined. $U_{\rm iso}$ has no physical meaning if negative, but a value that is negative by less than 2–3 standard uncertainties is not significantly different from zero. One aspect of chemical reasonableness is to confirm that the $U_{\rm iso}$ values lie within the expected ranges; spurious values are likely to indicate quality problems with the data or the fit. Very large values indicate that too much scattering density is being placed at a site; it could be that an atom is not present at that location, that the site is disordered or that the site had a significant vacancy concentration. $U_{\rm iso}$ values of less than 2–3 standard uncertainties below zero can indicate that not enough scattering density is being placed on the site, perhaps because the wrong atom type has been assigned or perhaps because other areas of the structure are disordered, causing the scale factor to refine to a value that is too small. Many sources of experimental error, such as unmodelled preferred orientation, can give rise to very large or small $U_{\rm iso}$ values.

Another measure of reasonableness is the difference Fourier map. This electron-density map is calculated using the difference between the observed and calculated structure-factor amplitudes and the phases calculated from the current structure model. For X-rays, positive peaks indicate electron density which is 'in' the data but not yet in the model. Negative peaks (holes) indicate places where the model includes too much electron density. For neutrons, peaks indicate extra or missing scattering density; while most atoms have a positive scattering factor, a negative peak can represent too much of a positive atom or not enough of a negative atom. Difference maps calculated using powder data tend to be flatter than single-crystal difference maps because the F_o values for overlapping reflections are partitioned according to the F_c values and are thus biased by the model. Nevertheless, they are useful for locating missing atoms and assessing whether atom types have been assigned correctly. For such a 'complete' organic structure, the difference map should be flat, say to ± 1.0 e Å^{-3}. Difference maps for inorganic structures may exhibit larger peaks and holes, especially at special positions. Atoms at special positions often contribute to only some classes of reflections. Intensity errors at such reflections become relatively more important in the calculation of electron density at special positions.

Using high-quality powder data, it is sometimes (perhaps less than half of the time) possible to locate H atoms in the difference map, but it is rarely possible to refine their positions using X-ray powder data. When knowledge of the H-atom positions is an object of the structural study, neutron diffraction is the better technique, but samples with more than 10–25% of the atoms in the unit cell as H will usually require at least partial deuteration. The H-atom positions in calcium tartrate tetrahydrate were derived by a quantum-chemical geometry optimization with density functional theory (DFT) using *CASTEP* (Segall *et al.*, 2002) based on the refined heavy-atom positions and using the fixed experimental unit cell. For the final Rietveld refinement, the H atoms were fixed at their optimized positions and the heavy atoms were refined. In the absence of such a quantum calculation, it may be necessary to fix the H atoms at reasonable locations. It is always advisable to include the H atoms, even if their positions are only approximate. I have found that better residuals and more reasonable structures are obtained. At the very least, more accurate quantitative phase analyses are obtained. In this calcium tartrate tetrahydrate example, an excellent refinement was obtained (Kaduk, 2007*a*). The largest peak and hole in the difference Fourier map were 0.56 e Å^{-3} (1.22 Å from C5) and -0.51 e Å^{-3} (1.56 Å from O11), respectively.

Comparison of a refined structure with the universe of known organic crystal structures is most easily performed by reading the CIF into *Mercury* and executing *CSD System/Mogul Geometry Check*. In this case, most of the bond distances and angles, and all of the torsion angles, were found to be 'not unusual (enough hits)', indicating that they fall within the normally expected ranges. Three bond distances (C2—O6, C3—C4 and C5—O11) were found to be 'unusual (enough hits)'. The C3—C4 distance of 1.559 (4) Å is only 1.7 e.s.d.'s from the Mogul average of 1.524 (21) Å for this bond. Likewise, the C2—O6 and C5—O11 distances of 1.230 (4) and 1.287 (4) Å differ by 1.0 and 1.8 e.s.d.'s from the average carboxylate distance of 1.25 (2) Å indicated by Mogul. The two angles O7—C2—C3 and O11—C5—C4 of 113.9 (4) and 114.8 (4)° differ from the Mogul average value of 117.2 (20)° by 1.6 and 1.2 e.s.d.'s, respectively. The default *Geometry Check* tolerances are quite small, and all of these quantities lie well within the normal distribution of topologically equivalent parameters.

The Ca atom is eight-coordinate and its coordination is irregular. The Ca—O bond distances range from 2.35 to 2.53 Å, with an average of 2.45 (6) Å. The *Mercury CSD System/Mogul Geometry Check* indicated that there were 'not enough hits' for the Ca—O bonds, but a manual analysis of CaO_8 coordination spheres in the CSD (using *ConQuest*) indicated an average Ca—O distance of 2.48 Å. The Ca—O distance expected from the bond-valence formalism is also 2.48 Å. The sum of the Ca—O bond valences is 2.22, showing that the Ca atom is 'crowded'. The Mulliken overlap populations from the quantum calculation show that the bonds have significant covalent character.

A prominent feature of this (and many) crystal structures is hydrogen bonding. Analysis of the hydrogen-bond network is always a part of structure validation. Because the H-atom positions obtained from an X-ray Rietveld refinement are often not very accurate or precise, I tend to rely on analysis of the result from a DFT optimization of the refined crystal structure. *Mercury* provides a *Calculate/Graph Sets* tool for analysing the topology of hydrogen bonds, but its results often need to be corrected manually.

A good rule of thumb is that every hydrogen bond that can form does form. The presence or absence of expected hydrogen-bond patterns thus serves as a valuable check on the reasonableness of a structure, especially from an *ab initio* solution using powder data and before refinement. Both hydroxyl groups of the tartrate act as donors in very strong hydrogen bonds: O8—H18 to a solvated water molecule and O9—H19 to a coordinated carboxylate O atom. O9 also acts as an acceptor from a coordinated water molecule O12, but O8 does not act as an acceptor. Additional strong hydrogen bonds occur between the water molecules. Several weak hydrogen bonds also seem to be present, including ones that involve the two CH groups. The large amount of energy gained by the formation of these hydrogen bonds helps to explain the high bond-valence sum for calcium and the relatively high density of this compound (1.844 g cm^{-3}). The average density of compounds in the CSD containing only Ca, C, H and O atoms is 1.52 (40) g cm^{-3}.

It is instructive to compare the results from the Rietveld and previous single-crystal studies with respect to the accuracy and precision of the chemically interesting derived quantities. The lattice parameters are more precise and (I believe) more accurate than those of the single-crystal studies. The average relative precision of the lattice parameters derived from powder data in 2006 was 5×10^{-6}. The average relative precision of the single-crystal lattice parameters from 1968 is 2×10^{-3}, and the precision of those from 1982 and 1993 is 2×10^{-4}. The improvement in the single-crystal precision reflects improvements in instrumentation. Because powder diffractometers are optimized for resolution (single-crystal instruments can depend on the spatial resolution generated by the specimen), the lattice parameters from a Rietveld refinement will generally be more precise and accurate than those derived from a single-crystal data set. The use of area detectors in modern single-crystal work has resulted in improved precision of lattice parameters compared with these (they are determined using the positions of all of the reflections), but there is still a reason to carry out combined refinements using powder and single-crystal data sets. The improved precision of the lattice parameters from the powder data will propagate into improved precision of bond distances and angles, and thus more chemical insight. A difficulty is that today most single-crystal data sets are collected at low temperatures, while most powder data are collected under ambient conditions. The difference in temperature means that the lattice parameters will differ significantly. To carry out a combined refinement, the data sets need to be collected under the same conditions. All three single-crystal data sets were collected at room temperature, but the lattice parameters vary significantly. These differences may represent sample-to-sample variations, differences in the actual ambient temperatures or something as simple as a different value of the X-ray wavelength. The 1968 values were derived from photographic data, so it is easy to imagine that they might be systematically different from the diffractometer values. The powder values are closest to the 1982 determination.

To assess the accuracy of the Rietveld-derived bond distances, consider the two single-crystal determinations from 1982 and 1993. The apparent standard uncertainty of a C—C or C—O bond distance is 0.004 Å. The average standard uncertainty of the single-crystal bond distances is ~0.002 Å. As we might expect, the powder values are less precise than those obtained from single-crystal data. The powder bond distances differ by an average of 0.02 (2) Å from the single-crystal distances, and there is no systematic trend in the differences. The differences average three standard uncertainties but are well within the standard uncertainties of the Mogul-derived distributions. Although less precise, the powder-derived bond distances are accurate enough to answer most chemical questions (Kaduk & Partenheimer, 1997). The standard uncertainty of a Ca—O bond is ~0.005 Å, compared with 0.007 Å for the single-crystal distances; some bonds exhibit more variation than others between the two single-crystal determinations. There are no systematic differences between the individual powder and single-crystal Ca—O distances, and the average Ca—O distances are the same in all determinations.

The average difference between the powder and single-crystal bond angles is only 1.6 (11)°. The agreement among chemically equivalent angles is excellent, and all angles fall within the normal ranges indicated by Mogul. The average difference between the powder and single-crystal torsion angles is 1.3 (11)°. The agreement between the (unrestrained) torsions and the single-crystal values is excellent. Both the powder and single-crystal values fall within the normal ranges obtained from Mogul.

Deciding whether the displacement coefficients (thermal parameters) are reasonable can be a challenge, because the CSD does not currently include them (although they are now being archived and will be incorporated into the CSD in the future). Sometimes the displacement coefficients are included in the original publication, but more and more often they are relegated to supplementary material.

Displacement coefficients from Rietveld refinements often have a bad reputation, because they are often 'too low' or even negative (physically unreasonable). If the various systematic intensity errors at low angles (such as beam spillover and surface roughness) are minimized or modelled (or both), reasonable displacement coefficients can be obtained from Rietveld refinements.

The average $U_{\rm iso}$ value for Ca from the single-crystal refinements is 0.014 Å^2, compared with the value of 0.045 Å^2 from the Rietveld refinement. The average single-crystal values for the tartrate C atoms, tartrate O atoms and water O atoms are 0.017, 0.022 and 0.042 Å^2, respectively, compared with 0.041, 0.045 and 0.073 Å^2 from the Rietveld refinement. In this refinement, the $U_{\rm iso}$ values are actually larger than the single-crystal values. This was a powder specimen, so we might expect more disorder (static, dynamic or both) than in a carefully prepared single crystal. The refined $U_{\rm iso}$ values seem reasonable and increase confidence in the quality of the refinement. The U values in organic compounds generally vary smoothly with location in the molecule. *checkCIF* is particularly good at comparing the displacement coefficients of neighbouring atoms and generating alerts when one of them is unusual. Such anomalous U values are sometimes a sign of a misidentified atom.

Submitting a powder CIF to *checkCIF* often generates many pages of alerts, many of which do not represent real problems. In the future *checkCIF* will be improved to present alerts that are more appropriate to the type of study, but at present it is necessary for the author and editor to ‘filter’ these alerts. Submitting the CIF for this calcium tartrate tetrahydrate example yielded level-A alerts about isotropic non-H atoms in the major residue. Such alerts are expected, since we do not expect to refine anisotropic displacement coefficients using powder data. Many level-A alerts were generated about suspect O—H bonds. Since the H-atom positions were generated from a DFT calculation, the O—H distances are longer than those expected for the artificially shortened distances expected from a crystallographic refinement (Churchill, 1973). There were many level-C alerts about senseless standard uncertainties on interatomic distances involving H atoms. These are expected because the H-atom positions were not refined. There was a level-B alert that no absolute configuration information was given, and a level-C alert about a missing Flack parameter. Since the hkl and $\bar{h}\,\bar{k}\,\bar{l}$ reflections necessary to determine the absolute configuration always exactly overlap in a powder pattern, it is impossible to determine the absolute configuration using powder data! (*Note*: this test has since been disabled for powder CIFs.) There were a few level-G alerts, but these were either easily fixed or irrelevant for powder data.

4.9.4.1.2. *Guaifenesin*

The crystal structure of guaifenesin [3-(2-methoxyphenoxy)-1,2-propanediol; Fig. 4.9.25], a common expectorant, was first solved using synchrotron powder data (Kaduk, 2004; supplementary files guaifenesin.gsas and id101003.prm, CSD code PANKUL01). Almost simultaneously, the structure was solved using single-crystal data (Wang *et al.*, 2005; CSD code PANKUL) and then again later (Bredikhin *et al.*, 2009; CSD code PANKUL02). These three determinations under ambient conditions (along with the DFT-optimized structure) provide an excellent test of the quality that can be obtained using powder techniques.

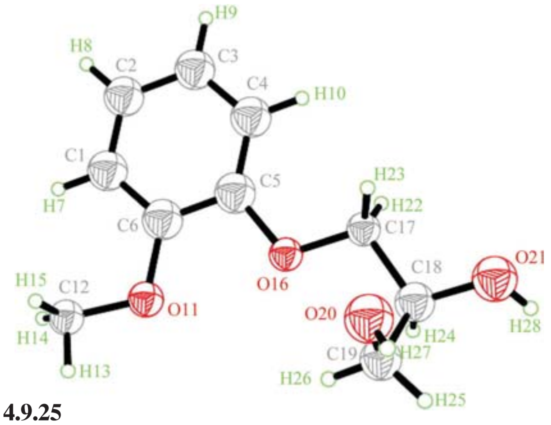

Figure 4.9.25
Refined molecular structure of guaifenesin.

Considering what is chemically reasonable can be important in the structure-solution process. It can make the task easier and save the crystallographer from reporting a wrong structure. The initial attempt to solve the structure using Monte Carlo simulated-annealing techniques used five torsion angles. A retrospective analysis of torsion angles in the CSD showed that the torsion angles involving the phenyl–oxygen bonds had very narrow distributions around 180°. These two torsions could have been fixed during the structure solution, making the problem smaller. In the CSD, the three torsion angles in the propyl side chain exhibit the normal *trans*/±*gauche* trimodal distributions. The structure could have been solved using $3 \times 3 \times 3 = 27$ rigid molecules instead of allowing the torsion angles to vary continuously. It is always worth carrying out such an analysis before structure solution, rather than after.

The initial model yielded a reasonable fit to the powder pattern, but the torsion angles were very far from the expected values. The $U_{\rm iso}$ value of the benzene-ring C atoms was much smaller than expected, while those of the side-chain heavy atoms became unreasonably large. Clearly this model was incorrect. These clues led me to consider other structural models, including different conformations of the propyl side chain. Eventually, a successful and much more reasonable model was derived.

Many common organic fragments are essentially rigid, and so can be described as rigid bodies in the Rietveld refinement. There is really no need to refine all of the structural parameters of a benzene ring. However, care must be taken when deciding whether to treat a fragment of a structure as a rigid body because some fragments (such as aromatic carboxylic acids; Kaduk *et al.*, 1998) are much more flexible than chemists commonly believe.

The final refinement of 56 variables using 8213 observations yielded the residuals $R_{\rm wp} = 0.1092$, $R_p = 0.0856$, $\chi^2 = 1.643$, $R(F) = 0.0931$ and $R(F^2) = 0.1179$. The refinement included a C_6H_4 rigid body and restraints on all of the bond distances and angles; the torsion angles were unrestrained. The restraints contributed 1.5% to the final χ^2. Several of the H atoms could be located in a difference Fourier map calculated without the H atoms. The largest peak and hole in the final difference Fourier map were 0.25 and −0.23 e Å^{-3}, respectively.

The *Mercury Mogul Geometry Check* output indicated that almost all of the bond distances and angles, and all of the torsion angles, fell within normal ranges. Only the C5—O16 and C6—O11 distances of 1.438 (1) and 1.438 (1) Å, respectively, were noted as ‘unusual (enough hits)’ (Figs. 4.9.26 and 4.9.27). These distances were subjected to restraints of 1.44 (1) Å. The Mogul averages for these distances are 1.371 (20) and 1.367 (16) Å, respectively. The angles C12—O11—C6 and C17—O16—C5 of 113.7 (3) and 114.1 (3)°, respectively, were noted as unusual (Figs. 4.9.28 and 4.9.29). These angles were subjected to restraints of 115 (3)°, and the Mogul averages are 117.6 (15) and 117.9 (19)°, respectively. The position of one of the torsion angles in the Mogul distribution is illustrated in Fig. 4.9.30. Changing these restraints to 1.37 (1) Å and 118 (3)°, as would be expected from Mogul, removed the geometry-check alerts. The statistical residuals were essentially unchanged. This serves as a good lesson that reasonable values should be used for geometrical restraints.

The *checkCIF* output contained many alerts about suspect bonds involving H atoms. Since the H atoms were reported in positions from the DFT calculation, the C/O—H bonds are longer than the crystallographically expected ones, and this alert

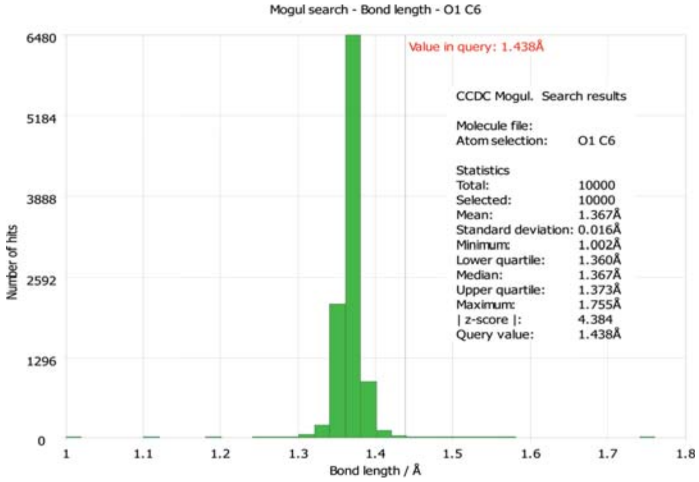

Figure 4.9.26

is normal. *checkCIF* calculates different (and higher) standard uncertainties on the bond distances and angles. This difference is expected, as all of these quantities were subject to rigid-body constraints or restraints. It is best practice to report which geometrical quantities were subject to restraints, so that their significance can be evaluated by the reader.

A density-functional geometry optimization (with the unit-cell parameters fixed at the experimental values) using *Crystal09* (Dovesi *et al.*, 2005, 2009) resulted in a structure with no Mogul geometry check alerts. Examining the optimized structure using *checkCIF* resulted in no significant alerts.

Mogul geometry checks of the two single-crystal structures revealed no unusual geometrical features. The average differences between the bond distances, bond angles and torsion angles in these two structures are 0.004 (3) Å, 0.3 (2)° and 0.4 (3)°, respectively, and the differences are random. These two structures can be considered identical for all practical purposes. The average differences between the Rietveld and PANKUL02 bond distances, bond angles and torsion angles are 0.014 (9) Å, 1.0 (11)° and 1.7 (11)°, respectively, and the differences are random. The accuracy of the molecular geometry from the Rietveld refinement is good enough for most chemical purposes.

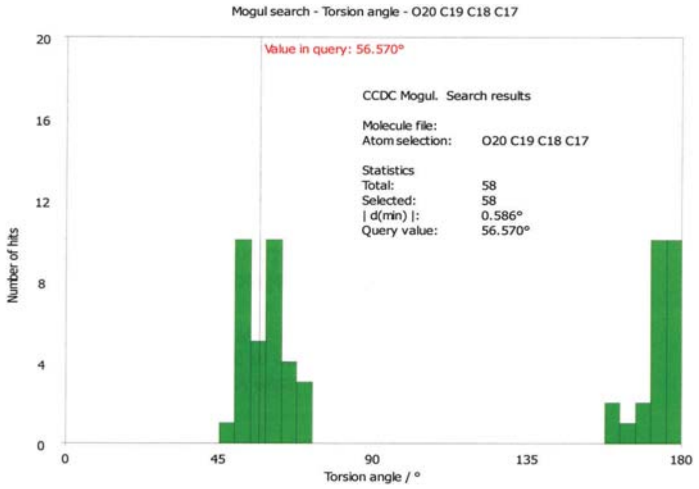

Figure 4.9.30
A *Mogul Geometry Check* histogram of the O20—C19—C18—C17 torsion angle in guaifenesin, showing its position in the histogram of equivalent angles.

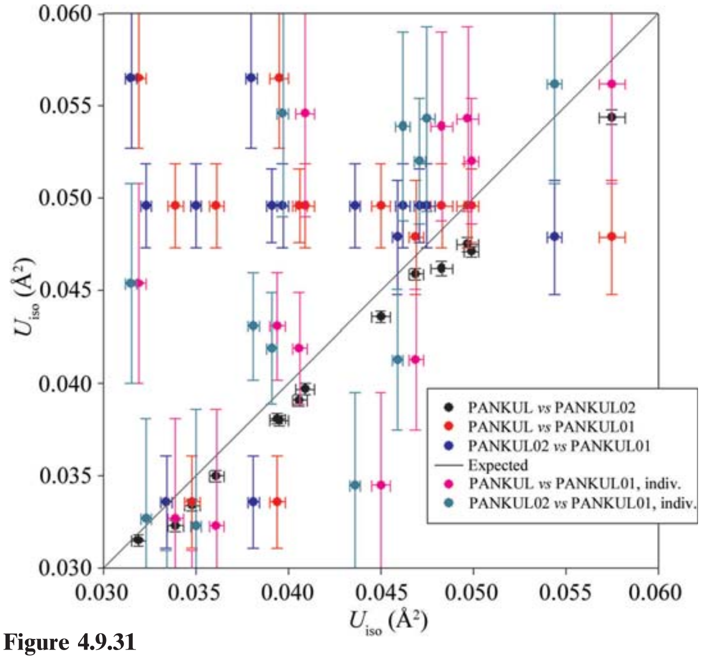

Figure 4.9.31
Comparison of the isotropic displacement coefficients for the powder (PANKUL01) and two single-crystal (PANKUL and PANKUL02) structures of guaifenesin.

Overlaying the DFT-optimized molecule with the Rietveld results yielded an r.m.s. difference in atom positions of 0.0345 Å. By far the largest differences were for the H atoms, as expected.

The *Mercury Calculate/Molecule Overlap* tool makes it easy to calculate the root-mean-square deviations between atomic positions in molecules. The r.m.s. differences between the powder structure PANKUL01 and the single-crystal structures PANKUL and PANKUL02 are 0.0392 Å (maximum 0.0603 Å) and 0.0434 Å (maximum 0.0755 Å), respectively. Visual overlays of the structures make them appear very similar. Changing the phenyl ether restraints to more reasonable values decreased these r.m.s. deviations to 0.0329 and 0.0348 Å, respectively.

The isotropic displacement coefficients of the C and O atoms from the Rietveld refinement are in good agreement with those determined from single-crystal data (Fig. 4.9.31), but their precision is nearly an order of magnitude worse. The main differences arise from the use of constraints on the U_{iso} values of the C atoms in the phenyl ring and in the propyl side chain in the Rietveld refinement. The agreement between the Rietveld and single-crystal U_{iso} values becomes better when they are allowed to refine individually. The agreement between the U_{iso} values in the two single-crystal refinements is excellent. With good powder data, we can reasonably expect accurate U_{iso} values from a Rietveld refinement, and obtaining such reasonable U_{iso} values is a good measure of the quality of the data and refinement.

When assessing the reasonableness of a structure or comparing structures, it is always worth examining the crystal structure as well as the molecular structure. The *Mercury Calculate/Structure Overlay* tool facilitates such comparisons. Although the heavy-atom positions in the two single-crystal structures of guaifenesin are identical, the positions of the hydroxyl protons differ (Fig. 4.9.32). The topology of the hydrogen-bond network is the same in both structures, but the locations of the protons in the hydrogen bonds (closer to one O atom or the other) differs. It is not clear what this difference means, although the structures are chiral. The hydroxyl proton positions of the Rietveld structure are the same as those in PANKUL02. Because the hydroxyl protons were located in a difference Fourier map and were confirmed by a DFT calculation, I believe that the PANKUL01/PANKUL02 hydroxyl groups are correct.

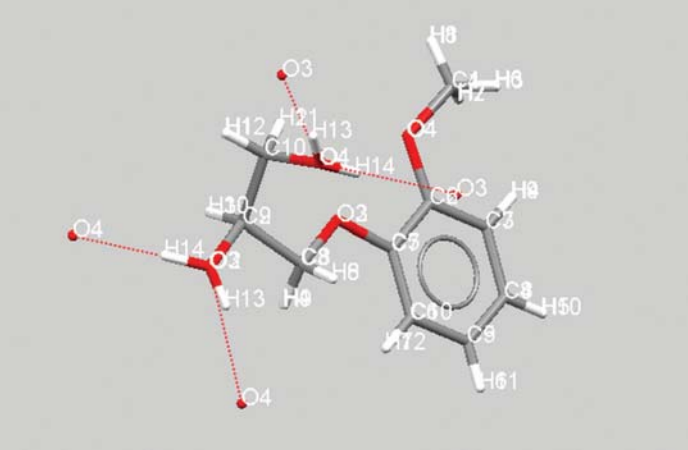

Figure 4.9.32
Mercury overlay of the two single-crystal structures (PANKUL and PANKUL02) of guaifenesin, showing the differences in the positions of the hydroxyl protons.

4.9.4.1.3. *Cobalt(II) acetate tetrahydrate,* $Co(C_2H_3O_2)_2(H_2O)_4$

The crystal structure of cobalt(II) acetate tetrahydrate was refined using single-crystal (the crystal was selected from the reagent used to generate the powder), laboratory and synchrotron X-ray powder data under ambient conditions using the same sample (Kaduk & Partenheimer, 1997; Kaduk, 1998). Refinements were carried out using individual data sets and in combination.

In the comparison of the various refinements, it is useful to compare bond distances and angles (Table 4.9.3), the root-mean-square deviations of the atoms (Table 4.9.4) and the displacement coefficients (Table 4.9.5). In this analysis, we will consider the *SHELXL* single-crystal refinement as the reference.

In the refinement using laboratory powder data, it was not possible to locate or refine the H-atom positions. They were fixed at the single-crystal locations with a common isotropic displacement coefficient. Restraints were desirable and necessary to obtain convergence, and their weight was decreased as the refinement progressed. It proved possible to distinguish the C—O and C═O bonds in the acetate ligand. The standard uncertainties on the bond distances were ~0.01 Å, compared with 0.001–0.002 Å in the single-crystal refinement. The average difference in the bond distances was 0.02 Å and that in the O···O distances was 0.08 Å. The average difference on the bond angles was 3° and the average r.m.s. displacement of the atoms was 0.07 Å.

The Co atom could be refined anisotropically using synchrotron data, and no restraints were necessary for stable refinement. It was still necessary to fix the H atoms at calculated positions. The standard uncertainties on the bond distances were ~0.005 Å. The standard uncertainties on the angles were ~0.2°, compared with 0.1° in the single-crystal refinements. The average differences in the bond distances, angles and O···O distances were 0.02 Å, 0.9° and 0.04 Å, respectively. The r.m.s. difference in the positions of the heavy atoms was 0.03 Å. The refinement using synchrotron powder data yielded excellent accuracy, with about half the precision of a single-crystal refinement.

In the joint refinement using two powder data sets, the Co atom was refined anisotropically and the remaining heavy atoms

could be refined with individual isotropic displacement coefficients. Attempts to refine the C and O atoms anisotropically led to some non-positive-definite U tensors. The H-atom positions could be refined, subject to restraints. The $U_{\rm iso}$ values for the H atoms did not refine to reasonable values, so they were fixed at 0.06 Å^2. The accuracy and precision of the structural parameters were similar to those of the synchrotron refinement. Joint refinement using multiple powder data sets permitted the refinement of more structural parameters with good accuracy.

4.9.4.2. *Inorganic compounds*

The CSD and its associated software provide many tools which facilitate the validation of organic structures. The tools in the inorganic structural databases are not as well developed, so assessment of chemical reasonableness can be more indirect.

4.9.4.2.1. *The bond-valence method*

As crystallographic techniques developed, it became clear that there was a relationship between the length of a bond and its strength [see Brown (2002) and references therein]. We can consider the atomic valence V_i (the absolute value of the oxidation state) of the atom i in a crystal structure to be the sum of the individual bond valences,

$$V_i = \sum_j S_{ij}, \qquad (4.9.8)$$

and that the bond valence between atoms i and j is approximated by the two-parameter expression

$$S_{ij} = \exp\left(\frac{r_0 - r_{ij}}{B}\right), \qquad (4.9.9)$$

in which r_{ij} is the distance between atoms i and j, and r_0 and B are parameters that are chosen to ensure good agreement between the sums of bond valences and the atomic valences (formal charges or oxidation states) in a large number of well determined crystal structures. For many bond types, B is close to 0.37 Å. Brese & O'Keeffe (1991) determined these parameters for a large number of cation–anion pairs, and a current set of bond-valence parameters are maintained at http://www.ccp14.ac.uk/ccp/web-mirrors/i_d_brown/bond_valence_param by I. David Brown. Workers on a specific subset of compounds often determine more precise bond-valence parameters for their particular system (for examples, see Sidey, 2010, 2012; Krivovichev & Brown, 2001; Locock & Burns, 2004). It is frequently useful to incorporate the expected values for the bond distances in a particular cation–anion coordination sphere into Rietveld refinements as restraints.

4.9.4.2.2. *Hexaaquairon(II) tetrafluoroborate, [Fe(H$_2$O)$_6$](BF$_4$)$_2$*

A deposit (Kaduk, 2007*b*) isolated from a linear α-olefins plant (which used a BF$_3$ catalyst) yielded a nearly white crystalline powder when washed with methanol (supplementary files bagh09.gsas and d8v3.prm). The solid was moisture sensitive, so was protected from the atmosphere by a Kapton film attached to the sample holder with silicone grease.

The pattern could be indexed (*ITO12*; Visser, 1969) with a primitive orthorhombic unit cell with a = 7.686, b = 13.286, c = 5.376 Å and V = 548.95 Å^3. The cell accounted for 17 of the first 20 peaks (three weak peaks were unindexed), with a figure of merit of 34.4. This figure of merit is high enough that we can believe that there is some truth to the unit cell. The *ITO* output suggested that 'the cell is probably hexagonal, with a = 15.34 and c = 5.38 Å'. *ITO*'s suggestions of higher symmetry (based on the reduced form of the unit cell; Mighell &

Rodgers, 1980; Stalick & Mighell, 1986) are correct often enough that they need to be taken seriously, but in this case the program was wrong.

Searching for matches to the reduced cells of both the orthorhombic and hexagonal unit cells in the ICSD using default tolerances yielded no hits. Widening the tolerances yielded what eventually turned out to be the correct structure model, but the actual process was more convoluted (Kaduk, 2007*b*). Similar searches for matches to the reduced cells in the NIST Crystal Data Identification File (Mighell & Himes, 1986) yielded a number of divalent-metal perchlorate and tetrafluoroborate hexahydrates, most of which were from the same paper (Moss *et al.*, 1961). The lattice constants were determined using a 9 cm diameter Debye–Scherrer camera, so it was uncertain whether the cells were hexagonal or pseudo-hexagonal, but I could be reasonably sure that the compound that I isolated was $Fe(BH_4)_2(H_2O)_6$.

$Fe(BH_4)_2(H_2O)_6$ was present in the Powder Diffraction File as entry 00-021-0427, and was reported to crystallize in $Pmn2_1$ with $a = 7.71$, $b = 13.54$, $c = 5.42$ Å: essentially the same cell as determined by *ITO*. The pattern did not look similar to the observed pattern (Fig. 4.9.33), but it is not a high-quality pattern, consistent with its 'blank' quality mark. The PDF entry lists $Mg(ClO_4)_2(H_2O)_6$ (West, 1935) as the prototype structure.

In the refinement, restraints of 2.12 (2) Å were applied to the Fe—O bonds. An analysis of all 59 $Fe^{2+}O_6$ coordination spheres in the CSD suggested a value of 2.10 (6) Å, and bond-valence calculations yielded 2.16 Å. In early refinements the BF_4 groups were modelled as rigid bodies, but in the final refinement the rigid bodies were replaced by restraints of 1.42 (1) Å on the B—F

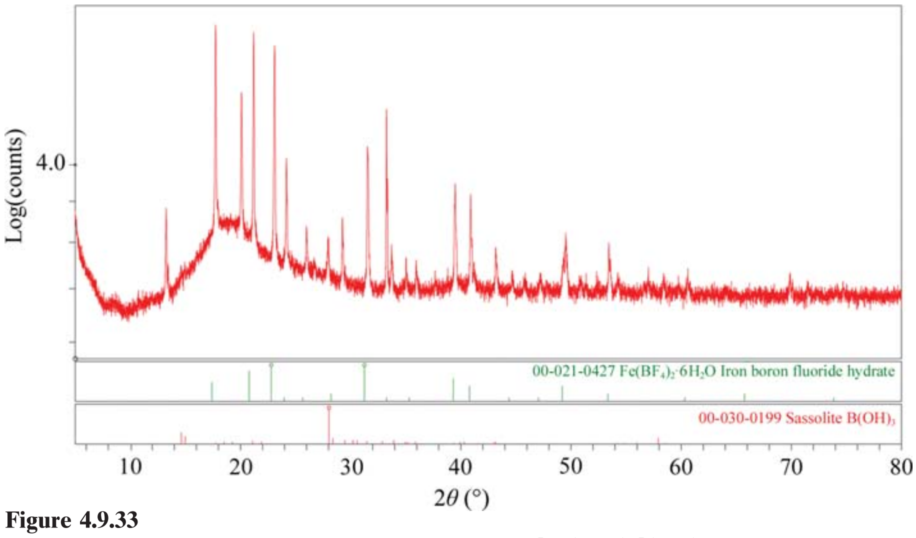

Figure 4.9.33

Comparison of the experimental powder pattern of $[Fe(H_2O)_6](BF_4)_2$ and the PDF entry 00-021-0427 reported for this compound. Sassolite was present as an impurity in the sample.

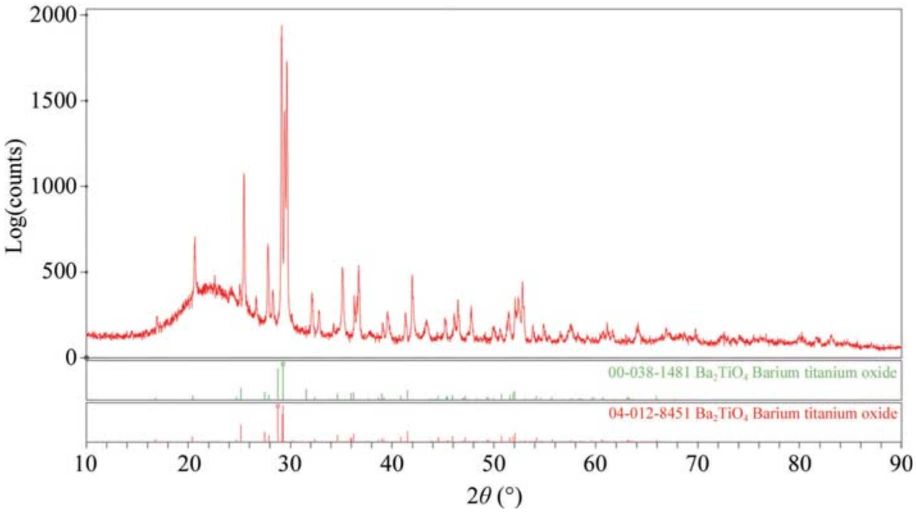

Figure 4.9.34

The observed pattern of $(Ba_{1.5}Sr_{0.5})TiO_4$ compared with the experimental and calculated PDF entries for Ba_2TiO_4. The sample had been blended with amorphous silica for grinding in a micronizing mill.

bond distances, along with F—B—F angle restraints. Analysis of 5546 hits for BF_4^- in the CSD suggested 1.36 (6) Å, bond-valence calculations suggested 1.39 Å, *International Tables for Crystallography* indicated 1.37 (7) Å and an analysis of tetrafluoroborates in the ICSD indicated 1.37 (3) Å. Since BF_4 anions are often disordered, exhibit large thermal motion (both of which lengthen the apparent bond distance) or both, I chose a larger value for the restraint.

The refinement yielded a geometrically reasonable structure. The $U_{\rm iso}$ values of the Fe and O atoms were 0.037 (2) and 0.056 (3) $Å^2$, respectively; these are higher than we might expect for an inorganic structure, but within the normal ranges. The $U_{\rm iso}$ values of the atoms in the two independent BF_4^- groups were uncomfortably large at 0.158 (6) and 0.092 (5) $Å^2$.

Most chemists know that, as a tetrahedral group, the tetrafluoroborate ion is often disordered statically or dynamically in crystal structures. We might therefore expect the $U_{\rm iso}$ values for the atoms in this group to be large, but how large is unreasonably large? Because BF_4^- is often the disordered counterion to a more chemically interesting cationic complex, there are fewer well defined structures of the BF_4^- ion than one might expect. Of the 67 structures of BF_4^- ions in the 2006/2 release of the CSD, 28% had missing displacement coefficients. For low-temperature (<200 K) structures the $U_{\rm iso}$ values for BF_4^- lie mainly in the range 0.02–0.06 $Å^2$, but some are as large as 0.12–0.16 $Å^2$. In room-temperature structures they are larger, generally ranging from 0.03 to 0.07 $Å^2$, but some are much higher. Checking the primary papers for the BF_4^- structures in the CSD suggested that the values of 0.16 and 0.09 $Å^2$ were not exceptionally high and thus were chemically reasonable.

The measurements of the physical properties of this compound and other divalent-metal tetrafluoroborates show that they all melt within 5 K of room temperature. Examination of the reported structures of compounds close to their melting points showed that the $U_{\rm iso}$ values of 0.16 and 0.09 $Å^2$ are not at all unreasonable for a structure determined within 5 K of the melting point. A knowledge of chemical reasonableness played a role at almost every point in the solution and refinement of the crystal structure of $Fe(BF_4)_2(H_2O)_6$, and shows how such knowledge contributed to the success of a Rietveld refinement.

4.9.4.2.3. *$(Ba_{1.5}Sr_{0.5})TiO_4$*

As part of a study aimed at understanding the details of the crystallography and crystal chemistry of the intermediate members of the $(Ba_{2-x}Ti_x)TiO_4$ solid-solution series (Kaduk, 2007*b*), a powder pattern (Fig. 4.9.34) was obtained that showed that $Ba_{1.5}Sr_{0.5}TiO_4$ (kindly supplied by W. Wong-Ng, NIST) was isostructural to orthorhombic Ba_2TiO_4 (supplementary files wong224.gsas and d8v3.prm). Orthorhombic β'-Ba_2TiO_4 crystallizes in $P2_1nb$, with a = 6.107 (1), b = 22.952 (4), c = 10.540 (2) Å (Günter & Jameson, 1984). The coordinates from Günter & Jameson (1984) were used as the initial structural model. The refined lattice parameters of $Ba_{1.5}Sr_{0.5}TiO_4$ were a = 6.0634 (2), b = 22.6606 (9), c = 10.4040 (4) Å. The refinement appeared to be excellent (Fig. 4.9.35). The residuals were $R_{\rm wp} = 0.1090$, $R_p = 0.0838$, $\chi^2 = 1.345$ and $R(F^2) = 0.1199$, but I was convinced that the structure was wrong.

The refinement of the atomic coordinates and other variables never converged, even with a damping factor of 9 (applying only one tenth of the calculated shift to the coordinates in each least-squares cycle). A refinement that does not converge is a sure sign that something is wrong with the model, the data or both. The stoichiometry derived from the fractional occupancies of the Ba/Sr sites was wrong. The difference between the 56 electrons of Ba and the 38 electrons of Sr is large enough that we should expect to get the fractional occupancies right, even when using laboratory X-ray data. The standard uncertainties of the fractional coordinates were exceptionally high, in the third decimal place for the cations and the second decimal place for the O atoms, and were higher than is reasonable. The $U_{\rm iso}$ value of the O atoms did not refine to a reasonable value, but this is not unusual in the presence of heavy atoms using X-ray data.

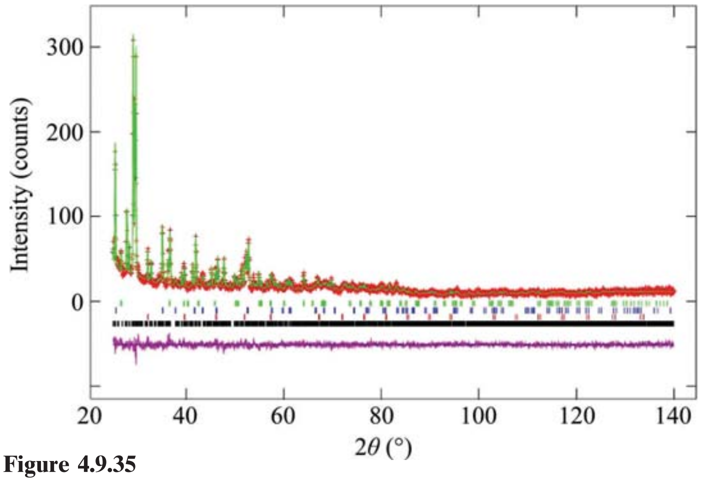

Figure 4.9.35
A Rietveld plot from an incorrect refinement of the structure of $(Ba_{1.5}Sr_{0.5})TiO_4$. The residuals were R_{wp} = 0.1090, R_p = 0.0838, χ^2 = 1.345 and $R(F^2)$ = 0.1199.

This combination of problems is often associated with wrong symmetry. The *MISSYM* program of the *NRCVAX* system (Le Page, 1987; this functionality is now incorporated into *checkCIF* and *PLATON* as *ADDSYM*) suggested the presence of a centre of symmetry at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ and thus that the space group was really *Pmnb*. This has the consequence that the six Ba/Sr sites, the three Ti sites and six of the O atoms are located on a mirror plane rather than a general position. Attempting to refine a structure in a space group with a symmetry that is too low can yield the symptoms observed here.

The appropriate atoms were moved manually to the special positions and the space group was changed. The resulting refinement was nearly as good as the first, with R_{wp} = 0.1011, R_p = 0.0851, χ^2 = 1.370 and $R(F^2)$ = 0.1424, but used only 61 variables instead of 85. (The Occam's razor principle of fewer variables is better is a good guide.) This refinement never converged; the shifts of the atom coordinates alternated between positive and negative, and never went to zero. The refined Ba/Sr composition was $Ba_{1.3}Sr_{0.7}$; closer to the known $Ba_{1.5}Sr_{0.5}$, but still disappointing. The U_{iso} values for the heavy atoms fell within normal ranges, but it was still not possible to refine the U_{iso} values for the O atoms. The standard uncertainties on the fractional coordinates were still too large: 0.001–0.004 for the heavy atoms and 0.003–0.012 for the O atoms. The most worrying feature was that many low-angle peaks were predicted for this fairly large unit cell, but were not observed. These would all have to be unobserved because of low intensity, rather that extinct by symmetry. This idea is built into the definition of the Smith–Snyder figure of merit for indexing (Smith & Snyder, 1979); a smaller unit cell which accounts for all of the peaks is favoured over a larger cell.

Another application of *MISSYM* (with larger than the default tolerances) suggested the presence of additional translational symmetry, with the translation vector $0, \frac{1}{3}, 0$. At this point I finally looked at the structure, and realized that β'-Ba_2TiO_4 was clearly a superstructure with its *b* axis three times that of a smaller unit cell. On searching for matches to the $a, \frac{1}{3}b, c$ cell in the NIST Crystal Data Identification File, I discovered that $(Ba_{1.5}Sr_{0.5})TiO_4$ is actually isostructural to K_2SO_4 and that I had been using a unit cell three times too large.

Restarting the refinement with coordinates based on those of K_2SO_4, I obtained an excellent refinement. The residuals were R_{wp} = 0.1115, R_p = 0.0864, χ^2 = 1.396 and $R(F^2)$ = 0.1565 and the model was chemically reasonable. The refinement of only 32 variables yielded a composition $Ba_{1.58}Sr_{0.42}$, which is acceptably close to the expected stoichiometry of $Ba_{1.5}Sr_{0.5}$. The U_{iso} value for Ba/Sr was 0.017 (1) Å^2, which is reasonable for a site occupied by disordered large cations. The U_{iso} value for Ti was a reasonable 0.013 (3) Å^2 and the U_{iso} value for the O atoms refined to 0.054 (7) Å^2; this is perhaps a little high for a ceramic, but the O atoms are bonded to Ba/Sr atoms which are disordered. The standard uncertainties on the Ba/Sr, Ti and O fractional coordinates were ∼0.0004, 0.0011 and 0.00*n*, respectively, which are about what I would expect for such a system. The interatomic distances (subject to restraints) and the O—Ti—O angles (free) were reasonable. All of the statistical, graphical and chemical measures suggested that the structure was (finally) correct.

4.9.4.2.4. *$(Ba_{1.25}Sr_{0.75})TiO_4$*

Another compound in the $(Ba_{2-x}Sr_x)TiO_4$ series was $(Ba_{1.25}Sr_{0.75})TiO_4$ (also kindly supplied by W. Wong-Ng, NIST). Given the trouble that was encountered with $(Ba_{1.5}Sr_{0.5})TiO_4$, synchrotron data were collected on the MR-CAT ID10 beamline at APS from a rotating capillary specimen using a wavelength of 0.4959 Å (supplementary files ba2180.gsas, wong224.gsas, id100602.prm and d8v3.prm). Starting from the $(Ba_{1.5}Sr_{0.5})TiO_4$ model yielded a reasonable refinement (49 variables): *Pnma*, *a* = 7.48904 (3), *b* = 6.03638 (3), *c* = 10.32873 (5) Å, *V* = 466.928 (4) Å^3, R_{wp} = 0.0847, R_p = 0.0621, χ^2 = 2.625. The refined stoichiometry was $Ba_{1.13}Sr_{0.87}TiO_4$. The U_{iso} values for Ba/Sr, Ti and O were 0.0245 (5), 0.0240 (16) and 0.066 (3) Å^2, respectively. The U_{iso} values for Ti and (notably) the O seemed a little too high, especially given the very good synchrotron data.

A full-scale Rietveld plot (Fig. 4.9.16) looked good, but an enlargement of the pattern (Fig. 4.9.17) revealed the presence of a number of weak peaks that were not accounted for by the model. Searches for the peaks (manually picked from the difference plot) against the Powder Diffraction File showed that they did not correspond to any known phase or to a new composition isostructural to a known phase. To test the hypothesis that the peaks were part of the pattern of the major phase, I added them one at a time to the strong peaks used to index the pattern using *DICVOL91* (Boultif & Louër, 1991). A feature of *DICVOL91* (and one that was overcome in later versions) was that it allowed no unindexed lines; this proved to be a useful feature for this problem. No matter which weak line I added, the program came up with the same primitive orthorhombic unit cell: *a* = 14.9760, *b* = 10.3177, *c* = 6.03666 Å, *V* = 932.77 Å^3. The *a* axis was twice what I had been using; this compound crystallized in a 2× supercell of the original cell. A search for matches to the reduced cell in the ICSD (with larger than default tolerances) yielded $(NH_4)_2BeF_4$, which crystallizes in Pna_12 (Srivastava *et al.*, 1999), the coordinates of which were used as the basis for a new refinement.

In addition to distance and angle restraints, chemical composition restraints were used in the refinement. Each of the four Ba/Sr sites was assumed to be fully occupied by a mixture of Ba and Sr. The restraint was that the unit cell contained 10.0 (3) Ba atoms and 6.0 (3) Sr atoms. Two of the sites were occupied mainly by Ba and the other two by Sr (Kaduk, 2007*b*). A major objective of the study was to determine how the Ba/Sr site occupancies changed as the overall composition varied.

A refinement of this model (90 variables) using combined synchrotron and laboratory patterns yielded an excellent refinement: R_{wp} = 0.0621, R_p = 0.0477, χ^2 = 1.561 and $R(F^2)$ = 0.0726. The largest peak and hole in the difference Fourier map were +1.75 and −2.15 e Å^{-3}, respectively. The refined lattice parameters were a = 14.97814 (5), b = 6.03634 (2), c = 6.03634 (2) Å and the space group was $Pna2_1$. *MISSYM* suggested that a centre of symmetry was present, but refinements in *Pnam* yielded poorer residuals and chemically less reasonable geometry; in this case the suggested extra symmetry was only approximate. The refined composition of the major phase was $Ba_{1.30}Sr_{0.70}TiO_4$, which was in good agreement with the expected formula. The $U_{\rm iso}$ values for Ba/Sr, Ti and O were 0.0141 (3), 0.0166 (11) and 0.0267 (20) Å^2, respectively, which were much more reasonable for a hard ceramic such as this. In this refinement, chemical reasonableness was important at almost every step in obtaining the correct structure.

4.9.4.2.5. *Mullite, $Al_{4.85}Si_{1.18}O_{9.77}$*

The refinement of a mullite supplied by Kyanite Mining Company (supplementary files kadu1286.gsas, kadu1328.gsas and d8v3.prm) provided a good example of many of the difficulties which can be involved in Rietveld refinement of an inorganic material (Kaduk, 2009). Several different approaches were used to validate the structure both during and after refinement.

A significant hurdle in beginning a Rietveld refinement can be deciding which structural model to use. The pattern of the major mullite phase was matched about equally well by several PDF entries. The PDF editors have extended the quality-mark system used for experimental patterns to calculated patterns and the structures from which they were derived. (The details of the quality-mark system are discussed in Chapter 3.7 of this volume.) The quality marks include * (no warning found during data evaluation), I (minor warning), B (significant warning), O (major warning), P (structure assigned by the editor based on a prototype) and H (hypothetical structure). I chose to begin the refinement with the coordinates from the 'star' quality pattern 01-074-4143 (Li *et al.*, 2004).

The mullite structure contains one fully occupied octahedral Al site and two partially occupied tetrahedral sites. Before refinement of the atom coordinates, the interatomic distances and angles were calculated, so that decisions could be made about how to incorporate chemical knowledge into the refinement. The octahedral Al1 was bonded to two O5 atoms at 1.90 Å and four O6 atoms at 2.04 Å. The tetrahedral Al2/Si3 was bonded to one O5 atom at 1.66 Å, two O6 atoms at 1.67 Å and one O7 atom at 1.67 Å. The tetrahedral Al4 was bonded to one O5 atom at 1.69 Å, two O6 atoms at 1.86 Å and one O8 atom at 1.48 Å. Based on experience and the bond-valence formalism (Brown, 2002), we know that 1.90 (2) Å is a reasonable value for an octahedral Al—O distance, 1.61 (2) Å is reasonable for a tetrahedral Si—O distance and 1.74 (2) Å is reasonable for a tetrahedral Al—O distance. The octahedral Al1 and tetrahedral Al4 sites could be confidently assigned as completely Al, but the composition of the Al2/Si3 site was not yet known. The current bond distance of 1.67 (2) Å was used in the initial restraint.

After refining the atom coordinates, the average Al2/Si3—O distance was 1.696 Å. Interpolating between the ideal tetrahedral Si—O and Al—O distances yielded an Al:Si ratio of 0.66:0.33. A constraint was set up to keep the Al:Si ratio at 2:1, but the total site occupancy was refined. Among potential refined parameters was the anisotropic size-broadening coefficient ptec. Refining this term rationally requires specifying (and thus knowing) a unique direction for the anisotropic broadening. Using *Mercury* to calculate the Bravais–Friedel–Donnay–Harker (BFDH) morphology (Bravais, 1866; Friedel, 1907; Donnay & Harker, 1937) expected from the crystal structure is often a good way of identifying the unique axis if it is not obvious from the symmetry.

The final refinement yielded the residuals $R_{\rm wp}$ = 0.0481, R_p = 0.0377, χ^2 = 1.533, $R(F)$ = 0.0183 and $R(F^2)$ = 0.0365. The restraints contributed 0.7% of the final χ^2. The largest peak and hole in the difference Fourier map were +0.33 (1.44 Å from two Al1 sites) and −0.38 e Å^{-3} (0.68 Å from Al1), respectively, so the map was acceptably flat. The slope and intercept of the normal probability plot were 1.141 and 0.0276, showing that any systematic errors were small.

The sample consisted of a mixture of phases, including 7.6 (1) wt% amorphous material (glass). In the absence of amorphous material, the bulk chemical analysis calculated from the phase concentrations and compositions can be compared with the measured bulk analysis for a valuable internal consistency check. In this case, such analysis would have to include an analysis of the glass in an electron microscope.

From the refined structural parameters, the composition of the mullite was calculated as $Al_{4.85}Si_{1.18}O_{9.77}$. The (unconstrained) sum of the positive charges in the unit cell was +19.28 and the sum of the negative charges was −19.54. The agreement was to ~1% of stoichiometric, which I considered acceptable. The ratio of the Al2 and Si3 occupancies was constrained, but the sum of the occupancies of Al2, Si3 and Al4 was not and was 1.008. As expected, either site 2/3 or 4 was occupied, but not both simultaneously (they are too close to each other).

The bond-valence sums were close to the expected values for Al1 (2.96), Al4 (2.94) and the O atoms (1.90, 2.10 and 1.96), but not for Al2/Si3. The differences from the expected values of 3 and 4 help to rationalize the multiple and partial occupancy of this site. The agreement of the bond-valence sums with their expected values is another way of saying that the bond distances fall within the normal ranges. The average deviation of the bond angles at the highly occupied metal sites was 2.2 (35)° and 7.2 (33)° for the less-occupied Al4 site.

The displacement coefficients of the atoms in mullite [Al/Si = 0.00932 (2), O = 0.0081 (4) Å^2], quartz [0.0156 (5) Å^2] and a silicon internal standard [0.0087 (5) Å^2] were quite reasonable for such rigid inorganic phases. With a large angular range of data and careful specimen preparation it is possible to obtain reasonable displacement coefficients even using laboratory X-ray powder data.

The refined mullite lattice parameters (space group *Pbam*) were a = 7.54718 (12), b = 7.70054 (12), c = 2.88546 (4) Å. A search of the ICSD for structures having reduced-cell parameters within 0.03 Å of these values yielded 24 aluminosilicate mullites. In almost all of these refinements the occupation of Al at the Al2 site was fixed at 1/2 and the Si occupancy was refined. This sample seemed to be a typical and chemically reasonable mullite, which is slightly richer in Al than average. The a lattice parameter corresponded to ~75 wt% Al_2O_3 and the cell volume to ~25% wt% SiO_2 according to the correlations in Deer *et al.* (1982). The refined composition is close to these values, providing another validation of the structure.

4.9.4.2.6. *6H perovskite $Ba_3CaSb_2O_9$*

The intial model for the crystal structure of the hexagonal 6H perovskite $Ba_3CaSb_2O_9$ determined using synchrotron powder data (Rowda *et al.*, 2008; discussed above in Section 4.9.3) had two worrying features. The two crystallographically independent Ba atoms had very different $U_{\rm iso}$ values: 0.0080 (9) and 0.0221 (9) Å^2. The angles around the octahedral Ca and Sb

Table 4.9.6

Average bond distances and angles from 26 experimental determinations of α-quartz compared with average values from 20 determinations in the ICSD

Parameter	Average experimental value	Average value from ICSD
Si—O (Å)	1.602 (12)	1.619 (12)
	1.595 (12)	1.599 (12)
O—Si—O (°)	110.83 (46)	111.15 (45)
	108.60 (18)	108.98 (32)
	108.67 (60)	108.27 (201)
	109.38 (74)	
Si—O—Si (°)	143.78 (60)	143.59 (45)

cations were very different from the expected 90/180°; normally these octahedra are quite rigid. These unusual structural features prompted an examination of the Rietveld plot, which led to the identification of 10.6 wt% face-centred cubic perovskite Ba_2CaSbO_6, 0.5 wt% CaO and 0.3 wt% BaO. Incorporating these impurity phases into the Rietveld refinement resulted in Ba U_{iso} values of 0.0239 (5) and 0.0228 (4) Å,^{2} and almost ideal octahedral geometry of the calcium and antimony cations. In the absence of the impurity phases, the model for the major phase had distorted to obtain the best fit to the powder pattern.

4.9.4.2.7. *Quartz*

As part of a study of cation-site occupancies in zeolite Y as a function of ion exchange (Kaduk, 2005), the structure of an α-quartz internal standard was refined 26 times using synchrotron powder data. From an individual Rietveld refinement, the standard uncertainties of the quartz lattice parameters were typically 0.00003 and 0.00004 Å for *a* and *c*, respectively. The averages of the 26 values were 4.9138 (8) and 5.4054 (4) Å at 300 K. The distributions corresponded reasonably to normal distributions. The standard uncertainty of an individual measurement of *a* was underestimated by a factor of 30 and that of *c* by a factor of 10 compared with those obtained by a true sampling of the population. To assess the accuracy (rather than the precision) of these results, the average values from 20 high-quality determinations from the ICSD were computed: a = 4.9130 (33) and c = 5.4037 (30) Å. The experimental values differed from these best values by less than one standard uncertainty.

The quantities of interest to a chemist, the bond distances and angles, were likewise accurate (Table 4.9.6). These results demonstrate that we can reasonably expect to measure bond distances to an accuracy of ~0.01 Å and angles to ~0.5° in favourable cases using powder data. This is a lower accuracy than is commonly supposed, but is sufficient for most chemical purposes.

4.9.5. Working by analogy

Lattice matching (reduced-cell searches) and comparison of formula types can be powerful and complementary techniques for phase identification and confirmation. Indeed, many thousands of structures have been assigned by the editors of Pearson's Crystal Data (Villars *et al.*, 1998) using just such 'prototyping' techniques. Searching for unit-cell and/or formula analogues can help to confirm the chemical reasonableness of a model and save the effort of *ab initio* structure determination.

The powder pattern of $Ba_5Zn_4Er_8O_{21}$ (supplementary files icdd124.gsas and padv.prm; now included in the Powder Diffraction File as entry 00-049-0598) could be indexed on body-centred tetragonal, end-centred orthorhombic and *C*-centred monoclinic unit cells with about the same high figures of merit. Searches for the formula type A4B5C8X21 in the ICSD and PDF showed that all examples of this formula crystallize in *I*4/*m*. The tetragonal cell was thus chosen, and a successful refinement was obtained in this space group.

Among the crystalline phases present in a black tar isolated from a pump seal in a refinery was PDF entry 00-022-0006, $Al_4H_2(SO_4)_7(H_2O)_{24}$ (supplementary file pak03.gsas). The crystal structure had not been reported, so a model had to be found in order to carry out a quantitative phase analysis by the Rietveld method. A search of the ICSD for the formula type A4B7X52 yielded only one hit, $Cr_4H_2(SO_4)_7(H_2O)_{24}$ (PDF entry 01-072-0981). Although the powder patterns did not resemble each other very well, the similarity of the metal charges and sizes, the common sulfate anions and the number of water molecules suggested that the two compounds might be isostructural. The Cr structure proved to be a suitable model for the Al compound (Kaduk, 2002).

Although it was easy to identify several iron oxides and hydrous oxides in a corrosion deposit from a pilot plant reactor that used a triflic acid catalyst, the major phase did not match any pattern in the Powder Diffraction File. The pattern (supplementary files simp08.gsas and padv.prm) of the major phase could be indexed in a *C*-centred orthorhombic unit cell with a = 18.6415 (14), b = 6.9291 (5), c = 6.5938 (5) Å. A reduced-cell search in the CSD yielded the hit $V^{2+}(CF_3SO_3)_2(H_2O)_6$, which proved to be a suitable isostructural model for Rietveld refinement (Kaduk, 1999).

Sometimes the process of lattice matching can be more convoluted. The pattern of a calcium salt of trimellitic acid (supplementary files barn133.gsas and d8v3.prm) could be indexed in a triclinic unit cell with a = 6.9419 (2), b = 7.0404 (2), c = 10.4125 (3) Å, α = 86.884 (3), β = 82.418 (2), γ = 69.531 (1)°. A reduced-cell search in the CSD (using a 3% tolerance on the volume) yielded (among others) the hit EKUNON, a cadmium salt of trimellitic acid, $Cd(HC_9H_3O_6)(H_2O)$. Substituting calcium for cadmium in the EKUNON structure model did not yield a good Rietveld refinement. The structure was then solved *ab initio*. Comparing the two structures showed that the chemical change had altered the relative magnitudes of the *a* and *b* axes. The compounds do turn out to be isostructural, but the interchange of the axes prevented success in the initial refinement.

4.9.6. Structure validation in general

The history of structure validation has focused on quantities derived from the fractional coordinates (distances, angles and torsions), but has on occasion extended to examination of the displacement coefficients (Harlow, 1996) and to the correction of space-group errors (Marsh, 1984, 1986, 1988, 1995, 1997, 1999, 2002, 2004; Marsh & Bernal, 1995; Marsh & Herbstein, 1983, 1988; Marsh *et al.*, 2002; Marsh & Schomaker, 1979, 1980, 1981; Baur & Kassner, 1992; Baur & Tillmanns, 1986; Herbstein, 1997; Herbstein & Marsh, 1982, 1998; Schomaker & Marsh, 1979).

Structures deposited in the Protein Data Bank are checked for the agreement of bond lengths and angles with standard values (Westbrook *et al.*, 2003). Validation of protein structures includes determining whether the backbone torsion angles φ and ψ in each residue lie in regions of a plot of φ against ψ that have favourable energy (Ramachandran *et al.*, 1963).

Much recent effort has been directed at the validation of protein structures. The set of tools included in *MolProbity*

(Lovell *et al.*, 2003; Davis *et al.*, 2007; Chen *et al.*, 2010) is noteworthy. Since protein refinements, like Rietveld refinements, ultimately suffer from a lack of data, validation tools have been developed (Zucker *et al.*, 2010) for protein structures in which the translation/libration/screw formalism has been used to model a large set of atoms acting as a rigid body.

The first steps towards the validation of protein structures were taken in the early 1990s (Richards, 1988; Brändén & Jones, 1990; Jones *et al.*, 1991; Laskowski *et al.*, 1993). The rapid growth in the number of structures deposited in the Protein Data Bank (Berman *et al.*, 2000) has permitted the development of more sophisticated tools for validation. These tools are summarized in the report of the X-ray Validation Task Force (VTF; Read *et al.*, 2011). Although the VTF states that the criteria are not necessarily applicable for the evaluation of structures derived from powder data, the report contains many ideas that are useful in general. The tools include evaluation of bond distances and angles, planarities and chiralities. The assumption that distributions of bond distances and angles are Gaussian is not necessarily true. Assessment of the protein backbone conformation involves analysis of torsion angles, and these are also important for validating side-chain conformations. It is crucial to include the H atoms so that all atom contacts can be evaluated. Analysis of underpacking and hydrogen bonds are also key parts of validation. The tools for structure-factor and electron-density validation and Wilson plots are not as relevant to powder structures, but should not be ignored.

Rietveld refinements often incorporate prior knowledge in the form of restraints and constraints. The quality of the resulting structure model will only be as good as the quality of the prior knowledge, which should be checked. It can be the case that what we think we know is not true. A correct structure model should permit the prediction of some parameters or properties that were not used in the refinement. If the model can successfully predict information that was not incorporated into the model, our confidence in the model is increased (Kleywegt, 2009).

Most constraints and restraints involve intramolecular quantities, but we should not neglect intermolecular features when validating a structure. There should be no bad contacts between atoms that are not covalently bonded, including H atoms. We can take clues from macromolecular crystallography, and expect that hydrophobic portions of molecules will pack together, hydrogen bonds will form, and positively and negatively charged regions of molecules will be close to each other.

A common way of testing the reasonableness of nonbonded contacts is to perform a conformational analysis of the molecule. Such conformational analyses tend to be performed *in vacuo*. This environment tends to result in more compact conformations than are typically observed in the solid state (see Taylor, 2011 and references therein) and so must be used with caution. For accurate comparison of nonbonded H–H distances, the bonded $X{-}H$ distances determined using X-ray diffraction need to be normalized (*Mercury Edit/Normalise Hydrogens*) to account for the artificially short distances derived in an X-ray experiment. Analysis of a large number of well determined structures in the CSD had yielded good values for the minimum expected nonbonded distances for a number of atom–atom pairs [see Table 2 in Taylor (2011)]. A statistical analysis of hydrogen bonds in the CSD has led to the logit hydrogen-bonding propensity (LHP) model (Galek *et al.*, 2007), which is useful in identifying and analysing likely and unusual hydrogen-bonding patterns.

The structure determination of 2,2-aziridinedicarboxamide (Podsiadło *et al.*, 2007) demonstrated the fact that that powder patterns can be insensitive to significant structural variations, and that geometrical tests can be crucial to determining the correct structure.

Table 4.9.7
R.m.s. differences Δ (Å) between the non-H atoms in experimental and DFT-optimized crystal structures of the citrate group in group-1 citrate salts

Cations	Reference	Experiment	R.m.s. Δ (Å)
H_3	CITRAC10	Single crystal	0.030†

† *Mercury* molecule overlay. ‡ Manual measurement in *Materials Studio*. § *Mercury* structure overlay. ¶ *CASTEP* geometry optimization.

A particularly powerful way of validating a crystal structure is to compare the experimental model with the results of a dispersion-corrected density-functional calculation (van de Streek & Neumann, 2010, 2014). Normal DFT calculations can also be used with a fixed unit cell. The r.m.s. deviation between the non-H-atom positions in the experimental and optimized structures is a good measure of the correctness of the experimental structure. Such calculations are useful for evaluating potential disorder, examining space-group ambiguities, correcting atom-type assignments and locating H atoms.

As part of a systematic study of group-1 citrate salts (Rammohan & Kaduk, 2018), the structures of known and new salts were optimized (using cells fixed at the experimental values) using DFT calculations. The r.m.s. deviation for the new powder structures was 0.22 Å (Table 4.9.7), while the r.m.s. deviation for the single-crystal structures was only 0.08 Å. (The single-crystal structure of trilithium citrate was excluded from the calculation of the average because the H atoms were not located in the original report and we could expect difficulty in determining the position of the light Li atom using X-ray data.) The accuracy of the powder structures does not seem to be as high as that of the single-crystal structures.

The deposition of raw data will make validation easier in the future.

4.9.7. *CheckCIF/PLATON*

The current state of the art for automated structure validation of small-molecule crystal structures is implemented in the *checkCIF/PLATON* web utility (https://checkcif.iucr.org/, http://journals.iucr.org/services/cif/checking/checkfull.html; Spek, 2009). Its use is required for all small-molecule structures published in IUCr journals, and is required or recommended by many other journals. Since most published crystal structures are determined using single-crystal data, the suite is geared to them. Powder crystallography is still crystallography (although performed with less information), so many of the tests are also applicable to powder structures. Some are not, however, and users submitting powder structures to *checkCIF* should be prepared to deal with some alerts which are not applicable.

Validation issues are divided into four categories:

(i) missing or inconsistent data,
(ii) indicators that the structure model may be wrong or deficient,
(iii) indicators that the quality of the results may be low,
(iv) cosmetic improvements, queries and suggestions.

The validation software assigns one of four severity levels (A, B, C or G) to detected issues. Level-A alerts indicate that there may be a serious problem, which should be resolved unless there is a scientifically acceptable explanation. Level-G alerts are general information and not necessarily errors. They indicate something unexpected, and can still point to serious problems that could not be analysed in detail on the basis of the available data. Currently, more than 460 validation tests have been implemented. Most tests result in a one-line message. Each test is associated with documentation explaining the problem, together with possible options to address it (http://journals.iucr.org/services/cif/datavalidation.html).

Most problems can be analysed and resolved using just the data available in the CIF. However, reflection data (as a structure-factor file, F_o/F_c in CIF format) are sometimes necessary. The listing of structure factors derived from a Rietveld refinement is less useful, so deposition of the raw powder data is required when submitting a powder structure to IUCr journals.

Of the more than 460 tests performed by *CheckCIF*/*PLATON*, some common and/or useful alerts for authors and editors deserve comment.

CELLV02. This checks that the standard uncertainty (s.u.) reported in the CIF (and generated by the Rietveld program) matches that calculated from the standard uncertainties on the lattice parameters reported in the CIF. Sometimes the difference is the result of rounding errors, but in other cases the difference is significant. Apparently Rietveld programs sometimes do not calculate this quantity correctly. A level-A alert is issued when the difference is more than 8 s.u.'s, a level-B alert when the difference is more than 4 s.u.'s and a level-C alert if the difference is more than 2 s.u.'s.

CELLZ01. This tests that the cell contents calculated from `_chemical_formula_sum` and `_cell_formula_units_Z` matches those calculated from the atom sites present in the `_atom_site_list` and the `_symmetry_information`. This is a surprisingly common alert, but is easily corrected by manual editing of the CIF generated by the Rietveld program

DENSD01. A related alert resulting from the error in molecular weight. Level-A, -B and -C alerts are issued if the ratio of the submitted crystal density and that calculated from the formula fall outside the ranges 0.90–1.10, 0.95–1.05 and 0.99–1.01, respectively.

FORMU01. Similarly, differences between the reported and calculated molecular weights can result in this alert concerning the `_chemical_formula_sum` and `_chemical_formula_moiety`.

PLAT080. A least-squares refinement converges when the shift/error value for each refined parameter is close to zero (within the tolerance established for convergence criteria). This test warns the user that the refinement has not converged. Because of correlations among parameters, it is never good practice to report results from a refinement that has not converged.

PLAT091 and **PLAT092**. These indicate that no wavelength was found in the CIF, and that the specified wavelength was not copper, molybdebum or silver radiation. (Valid alternatives are 'neutron' and 'synchrotron'.) When no wavelength is specified in the CIF, *checkCIF* defaults to molybdenum. For most powder experiments this is not appropriate, so it is wise for the user to manually edit the CIF to include the correct wavelength. Since the CIF is intended to be an archive of the experiment, in the long run it is worth including the correct wavelength.

PLAT094, **PLAT097** and **PLAT098**. These test for a report of the maximum and minimum densities in a difference Fourier map. Although not commonly reported (and generally smaller than expected from a single-crystal study because of the model bias of the $F_{\rm obs}$ values) they can be another useful measure of the quality of the refinement. I recommend their inclusion in the results of a powder study. Both the ratio of the maximum to the minimum densities and the absolute values can give clues about errors in the model (such as wrongly assigned atoms or systematic errors in the intensities).

PLAT110–115. These key tests examine the model for the presence of additional symmetry by the application of *ADDSYM*. Although a model too low in symmetry cannot generally be refined using powder data (the refinement tends to oscillate or diverge), these tests can be valuable in identifying the problem. Test 115 looks for the presence of noncrystallographic centres of symmetry and can be useful in identifying the presence of pseudosymmetry.

PLAT128–129. These test for nonstandard monoclinic settings and space-group names, respectively. Although some programs only know about standard settings, there may be valid scientific reasons for choosing a nonstandard space-group setting, particularly when the rules for defining the conventional or reduced cell conflict with a standard space-group setting. These alerts serve to indicate that some discussion of the choice of space group is warranted.

PLAT150–152. An alert is generated when the reported standard uncertainty on the cell volume differs from that calculated using the s.u.'s on the cell dimensions, or if the s.u. is not included at all. Some software packages do not calculate the s.u. on the cell volume correctly. The correct formula is given in Nardelli (1983).

PLAT155–158. These alerts concern low-symmetry unit cells. The convention for a (primitive triclinic) Niggli reduced cell is that $a < b < c$. There are two types of reduced unit cells: type 1, in which all angles are $<90^\circ$, and type 2, in which all angles are $\geq 90^\circ$. Mixed unit cells should not be reported. Unless there are special scientific reasons, the structure is best reported with reference to the reduced unit cell. The IUCr convention is that monoclinic cells should have $\beta > 90^\circ$, even though a cell with $\beta < 90^\circ$ could strictly speaking be considered correct.

PLAT161–163. These alerts indicate that standard uncertainties are missing on at least one x, y or z coordinate. Such alerts are common when some coordinates (such as those of H atoms or an atom fixed to define the origin) are fixed in the refinement. These alerts call for some discussion.

PLAT198. The temperature of the diffraction experiment (in K) should always be specified, even if it is ambient. Omission of the temperature is common, even in variable-temperature studies.

PLAT203–209 and **PLAT211–216**. These alerts concern anisotropic displacement coefficients. Since it is unusual to refine ADPs using powder data, the user can expect alerts about isotropic non-H atoms in the main residue. Even when using isotropic displacement coefficients, they should be positive. Tests for unusually shaped (prolate or oblate) ellipsoids are not generally relevant for powder structures unless ADPs have been refined.

PLAT220–221. These tests examine the isotropic equivalent displacement coefficients and so are directly relevant to powder structures. A larger than normal range of $U_{\rm iso}$ values can indicate that atoms have been incorrectly identified. The common practice of grouping $U_{\rm iso}$ values may reduce the usefulness of these tests.

PLAT230–234. These apply the Hirshfeld rigid-body test (Hirshfeld, 1976) to different classes of bonds. The idea behind these tests is that the most important intramolecular vibrational modes are generally torsional or angle-deformation modes. In comparison, bond-stretching modes have smaller amplitudes. Thus, we expect that bonds are relatively rigid and that the atoms at each end of the bond should have the same mean-square amplitudes of vibration along the bond. The displacement ellipsoids are then analysed to obtain the vibration amplitudes along each bond. When the two atoms have very different amplitudes, it can be a sign that something is wrong with the model.

PLAT241–244. We expect that an atom will have a similar displacement coefficient to its neighbours and to atoms in similar chemical environments. When the U value of an atom is unusually high or low compared with those of its neighbours, it is a sign that the model needs to be examined.

PLAT306–309. These test for unusual bonding of single atoms. Isolated O atoms are most likely to represent water molecules. It may be possible to locate the H atoms around these O atoms in a difference Fourier map, but the chances are less than 50:50. It is generally possible, however, to place the H atoms at least approximately by an analysis of O–X distances and deduce potential hydrogen-bonding patterns. Isolated metal atoms are generally a sign of misidentification of a halogen. Singly bonded metal atoms are very rare and are also a sign of a misidentified atom. An O atom that makes only a single bond is probably a sign of a missing H atom.

PLAT310. This test identifies very short contacts between atoms, which only become apparent after the application of symmetry to the asymmetric unit. It is a good reminder that as crystallographers we should examine not just intramolecular interactions but also intermolecular properties.

PLAT312–321. These tests flag unusual features of the local environment of C, N and O atoms, including the geometry and the number of attached H atoms. One of these alerts can be a sign of a misidentified atom.

PLAT330–332. These examine the C—C distances and the range of distances in phenyl rings. Since phenyl groups in Rietveld refinements are often described as rigid bodies, these tests may not be so useful.

PLAT340–342. These test the precision of the C—C bonds in structures with various sorts of heavy atoms. Since we can expect less precision using powder data, it is not unusual to encounter such alerts. They are still worth investigating.

PLAT350–374. These test whether many sorts of bonds are longer or shorter than normal. While (with the lower accuracy and precision of powder structures) we can expect occasional experimental values to lie on the tails of the normal distributions, true outliers are a sign that something is wrong with the model.

PLAT410–417. These test short H$\cdots$H contacts. Even though the H atoms are often placed in calculated positions, bad contacts suggest that there is something wrong with the structure model.

PLAT420–482. These examine real and potential hydrogen bonds. Generally, the presence of donors without acceptors or acceptors without donors is a sign that something is wrong. The geometrical criteria used in these tests are from Jeffrey (1997).

PLAT601–606. These tests examine any voids present in the structure. Except for nanoporous materials such as zeolites and metal–organic frameworks, we do not expect real crystals to contain empty space. Some voids may represent disordered solvent molecules, but others may represent real errors in the model. A paper reporting a structure with significant void volume should discuss the issue.

PLAT701. Bond distances in the CIF are cross-checked with the values calculated from the coordinates. Alerts are set at deviations of 3, 2 and 1 standard uncertainties. Small differences sometimes result from rounding, but larger differences often result from a mismatch between the id's of the symmetry codes for the space group as listed in one part of the CIF and the symmetry codes used in the specifications of the bonds in another part of the CIF. It is always wise to examine the list of bond distances and angles output by the CIF-generating program and prune out irrelevant values. Similar tests for standard uncertainties, angles, torsions and hydrogen bonds are carried out in **PLAT731–738**.

PLAT711–713. These test for problems with the atom labels for bonds, angles and torsions. When labels that are not in the coordinate list are found in bonds, angles and torsions, these alerts are issued. These are fairly common in CIFs from powder data.

PLAT751–758. These test for 'senseless' standard uncertainties on various geometrical quantitites. Such s.u.'s are senseless when the parameter has been the subject of a constraint or restraint. Application of constraints and/or restraints should always be indicated in tables of distances, angles, torsions and other parameters.

PLAT764. It is fairly common to take the list of geometrical parameters directly as written by the CIF-generating program. Often such lists contain more bonds *etc.* than are real or necessary. Manual trimming is generally necessary.

PLAT780. The atoms given in a CIF should form a connected set. Often a structure solution results in disconnected fragments. It is bad practice to accept this situation. Geometry listings become unwieldy if unconnected sets of atoms are used, and future users of the CIF will thank you if this is sorted out.

PLAT790. The centre of gravity of the molecule (or at least the main residue) should lie within the unit cell. Future users of the CIF will thank you if it does.

PLAT982–983. These test the resonant scattering terms f' and f'' against the values in *International Tables for Crystallography*. The use of characteristic radiation should not yield any alerts here, but it is fairly common for users of synchrotron radiation to neglect to include the appropriate terms for their wavelength. Although the errors in the resulting structure are generally small, they can be significant. It is always best practice to use the appropriate terms.

SHFSU01 (see **PLAT080**). Level-A, -B and -C alerts are issued when the value of `_refine_ls_shift/su_max` is greater than 0.20, in the range 0.10–0.20 and in the range 0.05–0.10, respectively. Final results need to come from a converged refinement, and any extraordinary measures that are needed to ensure such convergence need to be documented.

Permission from the International Centre for Diffraction Data to incorporate material from Kaduk (2007*a*,*b*, 2009) and Kaduk & Partenheimer (1997) is gratefully acknowledged. Work at MR-CAT was supported in part by funding from the Department of Energy under grant No. DEFG0200ER45811.

4.10. Use of CIF for powder diffraction data

B. H. Toby

4.10.1. Background

The Crystallographic Information Framework (originally named the Crystallographic Information File) was first adopted as a standard by the International Union of Crystallography in 1990 for the archive and exchange of structure factors and crystallographic results, as well as associated sample metadata (Hall *et al.*, 1991). Herein, the initially redundant term 'CIF file' will be used to describe a computer file containing information coded in this standard, while 'CIF' will refer to the standard itself. When CIF was initially developed, the text for a complete manuscript could also be placed in a CIF file, so that direct production of a journal article, including tables and figures, was possible from an ASCII computer file and this was soon used in production. Submission of the complete paper as a CIF file is an option for *Acta Crystallographica Section C*, and is required for *Section E*.

There are many critiques that could be aimed at CIF from a contemporary perspective, but it should be noted that it was developed at a time when the use of personal workstations or even email was not that widespread. Markup languages such as XML also arrived much later. CIF has evolved over the subsequent decades, benefiting from some of the ideas introduced in other standard formats, while largely maintaining compatibility with the initial format description.

Over a period that overlapped with the initial development of CIF, a subcommittee from the International Centre for Diffraction Data was developing yet another standard format for the exchange of raw powder diffraction data. While an initial format had been adopted, after the announcement of CIF it became clear that CIF was a better choice because of the superiority of the STAR (Self-defining Text Archive and Retrieval) syntax that CIF is based on, the well devised CIF dictionary (Hall, 1991), and the advantages of having powder diffraction and single-crystal crystallography use a common standard.

As will be described later, the CIF standard consists of a subset of STAR syntax, along with definitions for the labels associated with each set of values that will be specified in CIF files. These definitions, themselves formatted as a STAR file, are collected in a document referred to as a CIF dictionary. Thus, to accommodate powder diffraction in CIF, it was necessary to identify the additional types of values and data that would be needed and create definitions for them. Based on this work, a number of definitions were added to the core (general and single-crystal) CIF dictionary, since they would potentially be of multidisciplinary use, while others were placed in the newly created powder diffraction CIF dictionary, known as the pdCIF dictionary (Toby, 2005*a*). The initial comprehensive version of the pdCIF dictionary (version 1.0) was completed in 1997.

Subsequently, CIF has gone through several stages of development. The initial version was later structured through the addition of a set of rules called a data definition language (DDL), which provided an organizational context for the format and added some normalization rules to bring CIF closer to a relational database schema (DDL1.x). These rules were expanded to provide strict relational normalization with a second-generation DDL (DDL2.x). At the present time, powder diffraction CIF files may only be specified using DDL1.x, but macromolecular CIF files are specified using DDL2.x data names. A mixture of the two is needed for powder studies of macromolecular materials.

To make CIF even more versatile and add greater functionality, a next-generation DDL has been created (DDLm). Also, an augmented CIF standard (CIF2) was adopted in 2014. None of these revisions affect the validity of CIFs created using the initial CIF syntax and DDL1 dictionary. A backward-compatible DDLm compliant version of the pdCIF dictionary has been developed and approved, but further revisions are anticipated, which will allow powder diffraction to take advantage of the enhanced capabilities provided by DDLm.

4.10.2. A brief introduction to CIF

The reader is referred to *International Tables for Crystallography*, Vol. G, *Definition and Exchange of Crystallographic Data* (Hall & McMahon, 2005), for a comprehensive discussion of CIF and its associated dictionaries. However, a synopsis of CIF follows below for the purposes of discussion. Note that this is not intended to provide a complete description of the standard or its implementation, but it will help the novice powder diffractionist to understand how information is placed in a CIF file.

The most basic concept in CIF is that of a data name. CIF data names always begin with an underscore. The meaning and use of every defined CIF data name is spelled out in an entry in one of a series of separate files, called a CIF data dictionary. Each data name specifies something about the project stored in the CIF file, such as a lattice parameter or an author name. In the simplest CIF construct, files are populated with a value preceded by the data name to be associated with that value. A few examples are

```
_cell_volume   1811.00(5)
_cell_angle_gamma       120
_symmetry_cell_setting                  Hexagonal
_symmetry_space_group_name_H-M          "P 63/m m c"
```

A CIF data name and its associated value are together called a data item. Depending on how the data name is defined, the value can be a character string, a floating-point number or an integer. Values may include an uncertainty in parentheses. The use of quotation marks for strings is optional when the string contains no spaces. To specify a character string that spans multiple lines, one uses a different style of quoting:

```
_pd_proc_ls_background_function
;   GSAS Background function number 1 with 4 terms.
Shifted Chebyshev function of 1st kind
  1:  139.025    2:  -11.5408    3:  9.75652    4:  3.90497
;
```

The use of white space (blank spaces, tabs or new lines) to separate data names and values is required, but the use of more than one of these makes no difference, except within quoted strings. While it is expected that CIF data names will be defined in one of the existing CIF dictionaries, it is not an error to use an undefined data name. In fact, any CIF data name that begins with `_local_` is assumed to have a meaning only within the preparer's institution and should be ignored by others.

Copyright © 2019 International Union of Crystallography

CIF also allows a data name to be associated with a set of values. For this, a construct called a loop is used to specify a set of values, for example:

```
loop_
  _atom_site_label   _atom_site_fract_x
  _atom_site_fract_y   _atom_site_fract_z
Y1      0.125        0.0          0.25
O2     -0.02946(5)   0.05385(5)   0.15068(6)
```

A loop begins with the keyword `loop_` and is followed by one or multiple data names, most commonly more than one. In the example above, four data names are specified. Following the data names will be a number of data values that must be a multiple of the number of data names. Thus, each value is logically associated with each successive data name in a cyclic manner. The loop is terminated when another CIF data name or a CIF keyword such as `loop_` is encountered. Thus, in the example above, the values 'Y1' and 'O2' are associated with data name `_atom_site_label`. Further, the values specified in each group are also logically grouped so that the coordinates (0.125, 0.0, 0.25) are connected to the label 'Y1'. A loop can be envisioned as a data table with columns connected to each of the data names and as many rows as are specified. Note that formatting of loops is very flexible. The `loop_` keyword, the data names and the values must be separated by one or more white-space characters, but the placement of new lines is arbitrary. This means the table above could be specified equivalently with each value on a separate line, or with all eight values on a single line, or even as below:

```
loop_  _atom_site_label  _atom_site_fract_x
_atom_site_fract_y
_atom_site_fract_z
Y1
0.125        0.0          0.25
O2
   -0.02946(5)
    0.05385(5)
    0.15068(6)
```

Blank lines in a CIF file are ignored. Comments are also allowed. These have a hash mark (#) as the first non-blank character in the line. Comments are intended to assist a person reading through a CIF file, but not to convey meaning about the contents of the CIF file. The initial CIF standard specified that the maximum number of characters on a line could not exceed 80, but this was soon increased to 2048 characters.

There are two values with special meanings in CIF: a question mark (?) and an isolated period (.). A question mark indicates that a value has not been specified. The value ? commonly appears in templates for CIF to indicate a place where a value could be included. A value of . indicates that that value is undefined, inappropriate or, for a few specific cases, should be taken as the default. As an example, in a loop over author names, if ? is specified for an author's middle name, it would imply that the person preparing the CIF file did not know the information, while a value of . specifies that that author does not have a middle name.

Another requirement in CIF is the division of a file into logical units, called blocks. Before any data items are placed in a CIF file, a block must be started using a label that begins with the string `data_`, followed by an arbitrary set of non-blank characters, for example `data_block1`.

There must be a `data_` statement in the file before any data items are defined, but additional `data_` statements can appear later. The order in which CIF data items are specified in a data block is not significant, but the order in which groups of items are specified in a loop may be significant. Note that a data name can only appear once in a data block, since one could otherwise supply conflicting values for a given item.

As an example of block use, if one wishes to describe structures for two different chemical phases, one needs to specify multiple values for the lattice constants. If the data name `_cell_length_a` were to appear twice in a block, it would be ambiguous as to which phase would be associated with each value. Likewise, it would be unclear as to which atoms are associated with each phase. Thus, in order to describe two phases in a single file, each phase must appear in a separate data block to resolve this ambiguity. The CIF dictionary specifies that unit-cell lengths and angles (data names `_cell_length_` and `_cell_angle_`) may not be placed in a loop, so even in the case where cell parameters are determined for a large series of temperatures, each set of lattice parameters must be placed in a separate block. If there is a need to define a table of lattice parameters using a `loop_` construct, a new set of data names would need to be added to a CIF dictionary to allow this type of cell-parameter usage.

4.10.3. CIF usage for powder diffraction

The specific implementation of CIF to powder diffraction needs is discussed in detail in *International Tables for Crystallography*, Vol. G, *Definition and Exchange of Crystallographic Information*, where the CIF dictionary can be found in Chapter 4.2 and an explanation of the definitions and their use is found in Chapter 3.3. It should be noted that these definitions are expected to be used in combination with those found in the single-crystal CIF definitions in the core CIF dictionary (Vol. G, Chapter 4.2). The data names defined in the pdCIF dictionary begin with the four characters `_pd_`, while any other data name mentioned in this chapter can be assumed to be defined in the core dictionary. While CIF was initially devised as a mechanism to communicate the results from a crystallographic study, pdCIF was intended to also include and describe the raw and reduced powder data and the computed diffraction data, as will arise from a Rietveld refinement. For this reason, pdCIF includes a large number of data items to describe such metadata as the diffraction instrument configuration, the specimen preparation, and the data and analysis provenance.

CIF was initially envisioned to represent studies where each CIF block is completely self-defined, and where every block contains sample and instrumental information, structural results and the data (structure factors) used to obtain the results. However, one can envision single-crystal studies where a single structural model is obtained that cannot be incorporated into a single block, for example with a combination of X-ray and neutron single-crystal data sets. This need is rare. In powder diffraction, this paradigm of independence between data blocks is commonly violated, since a single sample can contain multiple phases, and likewise it can be good practice to combine different types of powder diffraction data sets in a single refinement. To introduce a mechanism to interrelate data blocks, pdCIF introduced a concept called a block pointer. The value for each block pointer is intended to be something that is highly unlikely to be duplicated and that can be assigned to every block, so that if data blocks are separated (which used to be a common practice), these references can still be resolved. The standard way of specifying a block pointer uses a date stamp, an instrument name and an author name, which is very likely to be a unique value.

The information that can be provided in a powder diffraction CIF file may be categorized by type, as is provided below. Note that there is no requirement that items from all categories be included in any one file.

(1) If a crystal structure model is included, then core CIF data items are used to specify the unit-cell constants, atomic coordinates *etc.*
(2) The IUCr allows the inclusion of a manuscript narrative in a CIF file with `_publ_` data items, although this usage is becoming less common.
(3) The powder diffraction instrument can be described using `_pd_instr_` data items.
(4) The instrument calibration process can be described using the `_pd_calib_` data items.
(5) The sample and specimen are described using core and `_pd_prep_`, `_pd_char_` and `_pd_spec_` data items.
(6) Measurement results (raw data) are included using the `_pd_meas_` data items.
(7) When the raw data are scaled or combined, or are reduced in some other fashion, there may be a set of `_pd_proc_` data items.
(8) When a pattern is simulated from a structural model, it will be included using the `_pd_calc_` data items.
(9) When a pattern is reduced to a set of diffraction peaks, for example to index the pattern, a table of peaks and intensities is determined, which can be included using the `_pd_peak_` data items. Note that a single peak can represent the superposition of multiple reflections that can arise from one or more chemical phases.
(10) After a diffraction pattern has been indexed, a table of reflections can be generated. The `_refln_` data items are used to specify reflection indices and intensities, along with `_pd_refln_` data items that define the phase giving rise to the reflection and/or interlink the peak and reflection tables.

Note that (6), (7) and (8) in the list above may be combined into a single loop when these data items all have the same number of values, but this is not always the case. Another useful point is that pdCIF can also have implied lists of values. As an example, when 2θ values are recorded with regular steps, it is preferable to spell out this relationship by specifying three single values, `_pd_meas_2theta_range_min`, `_pd_meas_2theta_range_max` and `pd_meas_2theta_range_inc`, rather than providing all the values with `_pd_meas_2theta_scan`.

4.10.4. Creation of pdCIF data files

Ideally, pdCIF files would be created and read by all commonly used powder diffraction software, but the community has been slow to adopt this standard and there are a considerable number of older computer programs still in common use that do not use it. Today, most common Rietveld programs read and write CIF files (both crystal structure and raw diffraction data). Most structure visualization programs will read and write crystal structures in CIF. The commonly used data-conversion programs *PowDLL* (Kourkoumelis, 2015) and *CMPR* (Toby, 2005*b*) currently read CIF files but do not write them. Even if a program reads and/or writes CIF files, there can still be pitfalls. Alternate choices of origin (origin 1 and 2 for some space groups) and non-standard space-group settings can still cause problems. A subtle problem which is sometimes encountered is that different programs list the symmetry operations in different orders. A consequence is that geometric quantities (bond distances, angles *etc.*) between symmetry-related atoms may differ among programs. The many conventions for reporting displacement coefficients can also cause problems, such as when one (B or U) is interpreted as the other (U or B). Overcoming such a situation can involve manual editing of the CIF file or the atom list in the Rietveld program. However, even in the absence of such software it can be fairly easy to create a rudimentary CIF file. As one example, it can be straightforward to convert an ASCII data file to a CIF file, assuming that an ASCII data file can be obtained that has the data in columns. When this is the case, one can add a short header to the file to obtain a valid CIF file. As an example, if one has a file that looks like this (2θ *versus* intensity),

```
     x        y_obs
  0.500      387.774
  0.501      413.941
  0.502      419.633
  0.503      418.683
  0.504      409.685
  ...
```

the file becomes a valid CIF file through the addition of two lines, as shown below: one with a `_data` keyword, to define a block, and the other with a `loop_` keyword, to add a loop header. (In fact, all this could be combined into a single line or spread out over more lines.)

```
data_CIF-example
loop_ _pd_meas_2theta_scan _pd_proc_intensity_total
       0.500      387.774
       0.501      413.941
       0.502      419.633
       0.503      418.683
       0.504      409.685
       ...
```

This editing can be done with any text editor that can edit and save an ASCII text file (such as *Wordpad* or *Textpad* on Windows, *Gedit* on Linux or *Textedit* on the Mac), but can also be done with the Cambridge Crystallographic Data Centre's (CCDC) *enCIFer* program (discussed in Section 4.10.6.1) (Allen *et al.*, 2004). There is, however, one limitation for the inclusion of diffraction data in this manner, which relates to uncertainties for intensity values. If the `_pd_meas_counts_total` data item is used, then the values are expected to have uncertainties following counting statistics (where the standard uncertainty is the square root of the intensity for larger intensity values). For `_pd_proc_intensity_total`, the standard uncertainties (s.u.'s) can be included with crystallographic notation, for example, 387.7 (9), or s.u. values can be entered with `_pd_proc_ls_weight`, but then as the inverse square of the s.u. values. At present, there is no way to specify directly in pdCIF a column of s.u. values.

Should the ASCII data file have extraneous columns, one can add a data name so that the column(s) will be ignored. A data name with the `_local_` prefix is perfect for this role.

```
data_CIF-example
loop_ _pd_meas_2theta_scan _pd_proc_intensity_total
      _local_unused1
#        x          y_obs    timestamp
       0.500      387.774    1001231
       0.501      413.941    1001247
       0.502      419.633    1001252
       0.503      418.683    1001267
       0.504      409.685    1001273
       ...
```

Note that it is also possible to add data to an existing CIF file by opening that file in a text editor and adding additional sections or by merging CIF files using *enCIFer*.

Creating a pdCIF file that describes, for example, the details of a Rietveld refinement is a more complex task because such a file should document the sample, the data collection and analysis methodology, the data, and the results. This requires a large number of CIF data items and considerable information that is not normally input to the analysis software. Template and example files, such as those found on the IUCr journals web site, http://journals.iucr.org/services/cif/powder.html, can be of value, but this will still be a rather time-consuming task to do manually. The *publCIF* utility, http://journals.iucr.org/services/cif/publcif/ (Westrip, 2010), can be very helpful.

Even if a Rietveld package creates a pdCIF file that includes all of the data and results, and provides a template with other data items for the user to include manually, this is still a less-than-optimal process. One reason is that a considerable amount of the information will be repeated for each fit, such as the descriptive information for a user's instrument. One would prefer not to insert such information manually for every study. Furthermore, it is common that, after one has completed a refinement and created a CIF file, a new idea for how the fit may be improved becomes clear. If the fit is improved, one would then like to merge the updated results with the previous CIF file rather than manually fill in the template again. The goal of a pdCIF export program for a Rietveld analysis program should be to document the results from the fit, as well as the original data and intermediates, such as the fitted pattern, since the graphical view of that can assist in determining the quality of the fit, as discussed further in Chapter 4.7 of this volume. Further, one should document the details of the data collection and sample processing, which are usually not input to the program. Also, since one may create several versions of the CIF file prior to the final publication of the study, one should be able to transfer this information easily, both between subsequent versions of the file and from one result to another where this information is shared. One program, *GSAS2CIF*, that was designed to facilitate this process has been discussed in the literature (Toby *et al.*, 2003). An even more streamlined approach has been implemented in the *GSAS-II* package, as will be presented below (Toby & Von Dreele, 2013).

4.10.5. Creating readers for pdCIF data files

One can find information from an individual pdCIF data file by opening the file with an ASCII text editor and browsing through it, though the *enCIFer* program provides more CIF-aware features that interpret the underlying CIF structure and links to the CIF dictionaries. However, in this era one would like information to simply flow between software packages, but this remains a work in progress for pdCIF, even though pdCIF is peerless as a powder diffraction data-exchange format.

Writing a program that will read a powder diffraction CIF file consists of two conceptually simple tasks.

First, one needs to parse the CIF file. This can be a trivial problem if someone else's code can be used to do this. The IUCr's website, http://www.iucr.org/resources/cif/software, lists a number of CIF software libraries that may be used for parsing CIF files. This author has had very good results with the well maintained *PyCifRW* package for Python programs (Hester, 2006). For C++ programming, the relatively recent *iotbx.cif* package may be of use (Gildea *et al.*, 2011). This package offers Python bindings as well, but programmers will probably find it easier to integrate *pyCifRW*, unless the large parent package to *iotbx*, *cctbx*, is already in use (Grosse-Kunstleve *et al.*, 2002).

Once the file is parsed, one needs to identify the data items that will needed. This is where pdCIF gets complex, since there is considerable flexibility in how data may be recorded to suit the many ways in which powder diffraction data are measured and processed. The most complex example of this occurs when extracting diffraction data from a CIF file. For that, one would need to look up the ordinate for the data (2θ, time of flight *etc.*), as well as at least one of several types of intensity data item. Below is an incomplete list of data items that may need to be checked.

4.10.5.1. *Ordinate*

The diffraction data are measured in terms of an independent variable that can be expressed in the original units or can be corrected and/or transformed to equivalent values. These are the CIF data names that can be used for recording this: `_pd_meas_2theta_scan`, `_pd_meas_time_of_flight`, `_pd_proc_2theta_corrected`, `_pd_proc_d_spacing`, `_pd_proc_recip_len_Q`; or the combinations of `_pd_meas_2theta_range_min`, `_pd_meas_2theta_range_max` and `_pd_meas_2theta_range_inc`; or likewise `_pd_proc_2theta_range_min`, `_pd_proc_2theta_range_max` and `_pd_proc_2theta_range_inc`.

One may combine several of these data names, although some do conflict (`_pd_meas_2theta_scan` and `_pd_meas_2theta_range_`, for example).

4.10.5.2. *Observed intensities*

The observed intensity values are recorded in one of several data names, which each have different meanings: `_pd_meas_counts_total`, `_pd_meas_intensity_total`, `_pd_proc_intensity_total` or `_pd_proc_intensity_net`. Note that standard uncertainties for the first (`_counts_`) data item are determined by Poisson statistics, but for the other data items σ can be indicated using crystallographic notation. Alternately, `_pd_proc_ls_weight` can be used to specify uncertainties (where the weight is $1/\sigma^2$).

4.10.5.3. *Background intensities*

There are several different values that can be specified for background measurements, such as `_pd_meas_intensity_background` and `_pd_meas_intensity_container`, which correspond to measurements with no scatterer and with an empty sample container, respectively. However, the most commonly used data item will be `_pd_proc_intensity_bkg_calc`, which represents the estimated background used in pattern fitting.

4.10.5.4. *Computed intensities*

The computed intensities can be recorded using `_pd_calc_intensity_net` or `_pd_calc_intensity_total`, which may have different scaling (as described in the pdCIF dictionary) and where the latter includes estimated background scattering.

Note that, when items appear together in a loop, this implies that the values are in correspondence. However, when items appear in separate loops this may not be true. As an example, if rebinning is used to change the point spacing, then `_pd_meas_2theta_scan` and `_pd_proc_2theta_corrected` are likely to have differing numbers of data points and should appear in different loops. Thus, these items would need to be grouped with (for example) `_pd_meas_intensity_total` and `_pd_proc_intensity_total`, respectively.

4.10.6. CIF software for powder diffraction

There are a large number of powder diffraction software packages that have some capability for reading and/or writing CIF files. No attempt will be made to provide a comprehensive review of all such implementations, but several programs are profiled here that provide novel capabilities and are available for all common computing platforms.

4.10.6.1. *enCIFer*

The *enCIFer* program (Allen *et al.*, 2004) was not the first general-purpose CIF editor and syntax checker to be published, but the CCDC has continued to maintain and improve this application as a service to the community, and it is the single most valuable application available for CIF creation, editing and browsing. The *enCIFer* application is oriented towards the CCDC's core audience of small-molecule crystallographers and includes simple molecular graphics. Nonetheless, the standard installation includes definitions for pdCIF data names. In addition to the editing of existing CIF files, it can be used to generate a CIF file from scratch or from a template, but can also be used to merge CIF files or to insert an ASCII data file into a CIF file where it can be provided with an appropriate `loop_` heading, as described in Section 4.10.4. It also provides a mechanism to validate the CIF file, establishing whether it is syntactically correct and can be used for submission to the IUCr's *checkCIF* utility for validation (see below) or to the CCDC for deposition to the Cambridge Structural Database. Unless a tool better suited to powder diffraction appears, anyone creating CIF files will find this a very useful utility to have.

4.10.6.2. *The IUCr publCIF application*

publCIF (Westrip, 2010) is an application designed for creating, editing and validating CIF files that are used for journal publication. It validates syntax and dictionary-defined data attributes through internal routines, and also provides an interface to the online *checkCIF* service of the IUCr. Access to the CIF dictionaries (both the definition of the item and valid data values) is particularly convenient, and the interface makes it easy to find entries causing an error, alert or warning. The graphical interface allows users to edit the CIF file, either in its raw ASCII form or as a formatted representation of a structure report. *publCIF* contains a number of convenient tools (such as spreadsheet representations of looped data), and provides access to options that facilitate the preparation of a structure report (databases of author details, experimental details, standard references *etc.*), along with tools for reference parsing, spell-checking, structure visualization and image management. *publCIF* was commissioned by the IUCr, and is available as free software for authors and as an in-house journal production tool, particularly for *Acta Crystallographica* Sections *C* and *E*.

4.10.6.3. *The IUCr checkCIF web application*

The IUCr runs a service called *checkCIF* where crystallographers can upload a CIF file for automated review at http://journals.iucr.org/services/cif/checking/checkfull.html. Use of this service is required as part of the editorial process for some journals. The *checkCIF* program validates the CIF file's syntax, as does *enCIFer*, but it also checks that the recommended fields are present. It also applies a number of consistency checks, including running the *PLATON* structural analysis program (Spek, 2003) and reporting indications of possible errors in the results, such as atoms located at improbably short distances from each other or the possible presence of higher-level symmetry. Currently, this service works best for the examination of discrete molecular rather than infinite structures and is best suited to organic and organometallic materials. Many of the alerts it reports are not appropriate for powder diffraction studies, but it still has value as it can catch a multitude of significant problems (see Chapter 4.9). The IUCr has determined that improvement of *checkCIF* for the review of powder diffraction crystallographic results would be beneficial, so it is hoped that the community will contribute to making this process even more valuable for the review of results.

Symmetry-mode analysis of the phase transitions in $SrLaZnRuO_6$ and $SrLaMgRuO_6$ ordered double perovskites

E. Iturbe-Zabalo, J. M. Igartua and M. Gateshki

Abstract: The crystal structures of double perovskites $SrLaMRuO_6$ (M = Zn and Mg) have been studied using X-ray and neutron diffraction data. Both compounds have monoclinic structure at room temperature with space group $P2_1/n$. A first-order structural phase transition $P2_1/n \rightarrow R\overline{3}$ has been observed in $SrLaZnRuO_6$ and $SrLaMgRuO_6$, at about 800 and 500 K, respectively, with the two phases coexisting in a temperature interval of 150 K. The temperature- and tolerance-factor-dependent phase diagram of the $SrLnMRuO_6$ (Ln = La, Nd and Pr; M = Zn, Co, Cu, Mg and Ni) family shows two different phase transition sequences depending on the A-site cation. The structures of the title compounds at room and high temperatures have been analyzed using the symmetry-mode decomposition approach.

Keywords: double perovskites; phase transitions; symmetry-mode analysis.

Figure 4.10.1
An example of an IUCr Journals web page where powder diffraction data have been submitted with the publication. Note the 'powder data' button that appears at the top left of the figure; this allows these data to be downloaded as a pdCIF file or plotted.

4.10.6.4. *The IUCr pdCIFplot application*

The IUCr has a web application named *plotCIF* based on an older program, *pdCIFplot* (Toby, 2003; Westrip & Toby, 2013). Scientists can obtain graphical views of observed and computed powder diffraction patterns by uploading pdCIF files at https://publcif.iucr.org/services/tools/pdcifplot.php. This same capability has been integrated into the IUCr journals and can also be used to view diffraction patterns graphically, where pdCIF files are submitted along with manuscripts to supply data and fits. When the CIF file contains coordinates without actual data, the application invokes *PLATON* to compute a powder pattern from the coordinates. These plots are displayed interactively in a web browser using the JavaScript *Flot* package (http://www.flotcharts.org/), where users can manipulate the plot using the mouse and menus. When a contemporary article is viewed in *Acta Crystallographica* or *Journal of Applied Crystallography* and when powder diffraction data have been submitted, a 'powder data' button appears on the web page, as shown in Fig. 4.10.1. From that button, the data can be displayed or downloaded, with the user having considerable control over how the data are

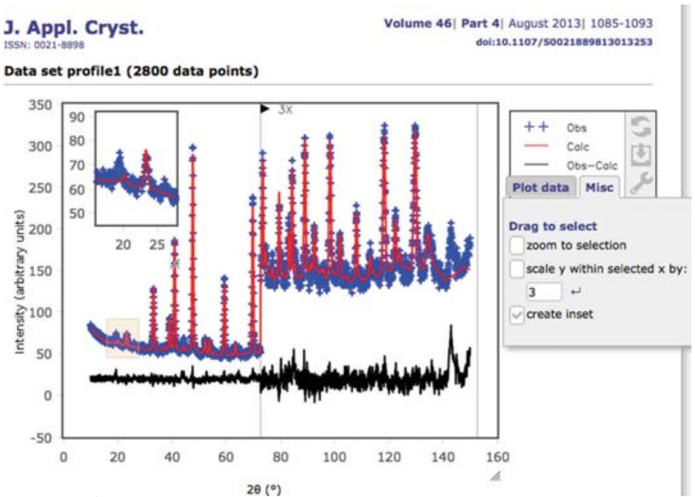

Figure 4.10.2

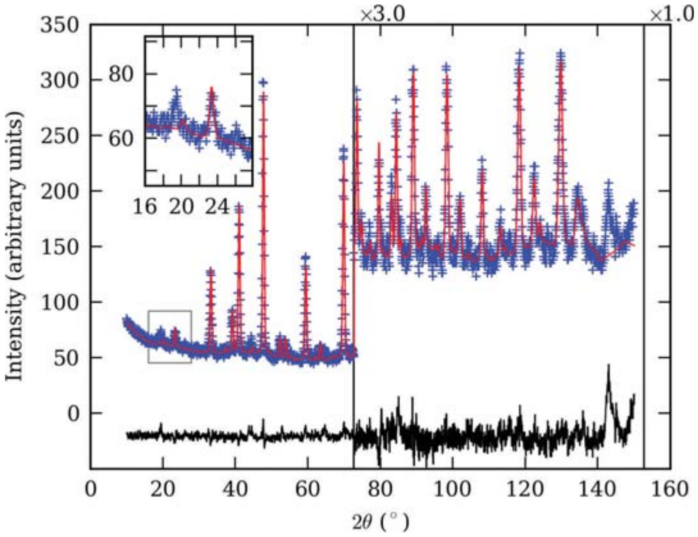

Figure 4.10.3
The publication-quality version of Fig. 4.10.2 from *pdCIFplot*. The generated figure is a bitmap file at 400 d.p.i.

displayed, as shown in Fig. 4.10.2. The generated graphic can also be exported as a high-resolution image, suitable for publication, as shown in Fig. 4.10.3. When coordinates are available in an article, the '3d view' button appears. This allows the structure to be plotted interactively in a web browser. A button within that web applet allows the generation and plotting or download of a simulated powder pattern.

4.10.6.5. *International Centre for Diffraction Data (ICDD) Genie application*

The *Genie* web submission application from the ICDD (http://www.icdd.com/websubmission/launch.html) shows how pdCIF can be integrated into the production process for the ICDD's Powder Diffraction File database. The *Genie* application is downloaded to the user's computer and runs in Java when the web launch link for the application is used. This provides an interactive program that can read and edit pdCIF files or build a pdCIF file from other input sources that provide raw data, a structural model and a peak or reflection table. The final pdCIF file created in *Genie* can then be submitted for editorial review by the ICDD for potential inclusion in the PDF database or for creation of a short publication in the journal *Powder Diffraction*. Alas, the final pdCIF file created in *Genie* cannot be saved locally by the user, thus limiting the utility of the application for other purposes.

4.10.6.6. *pdCIF creation in GSAS-II*

The *GSAS-II* crystallographic analysis program implements a very easy to use pdCIF file exporter that greatly simplifies the process of creating a CIF file (Toby & Von Dreele, 2013). After a refinement has been completed, the user may choose to export a CIF file of the project from a menu item (Export/Entire project as/Full CIF). This will include all data files and all phases that are interrelated. If a phase or data set is added to a project, but is not then utilized in a fit, that entry will be ignored. If the CIF file contains only one phase and one data set, a single-block CIF file will be created. Otherwise, a separate block will be used for each phase and each powder or single-crystal data set. Once the Full CIF menu item is invoked, the program will request, *via* a series of dialogue windows, those data items that are required for construction of the CIF block pointers, if this information has not already been input. This information includes the name of the author of the CIF file, atomic radii for searching distances and angles, and an instrument name for each data set, if that was not set by the instrument parameter file when the data were initially input. The values provided by the user are saved in the project file and are thus only input once.

Definition for _cell_measurement_temperature:

The temperature in kelvins at which the unit-cell parameters were measured (not the temperature of synthesis).

Figure 4.10.6
An example dialogue window from *GSAS-II* for editing the contents of a CIF template. Clicking on the help button (here labelled with '?') causes the definition for the selected data name to be shown at the bottom of the window.

Once this required information is input, a dialogue is presented, such as the example in Fig. 4.10.4. Note that each section of the CIF file has an associated template file. There is a default template for the overall section with publication information, and default templates for phases, powder diffraction data sets and single-crystal data sets. As this example shows, for each data set, if a default template is located that matches the name of the instrument (here ILL-D1A), that template is selected automatically. An alternative template file can be selected for use with the 'Select template file' button. For each phase, the 'Set distance/angle publication flag' button can be used to bring up an editing dialogue, as shown in Fig. 4.10.5, which can be used to set the publish/non-publish flag for bonding distances or angles. The 'Edit template' button opens a dialogue window, as shown in Fig. 4.10.6. This window allows information to be entered for each entry in the template, can show the dictionary definition and can save the information entered by the user, either in the *GSAS-II* project file or in a modified template file.

4.10.7. Conclusions

The pdCIF format for powder diffraction allows for the exchange of data, results and descriptive information in a facile manner. There is no other convenient mechanism for the exchange of this information. In contrast with single-crystal diffraction, where CIF is very widely used, at present this format has not been integrated into all commonly used powder diffraction software, but there are now many applications that do so for the benefit of all powder diffractionists.

The author is supported by the Advanced Photon Source, an Office of Science user facility operated for the US Department of Energy (DOE) Office of Science by Argonne National Laboratory, which is sponsored by the US DOE under contract No. DE-AC02–06CH11357. The author acknowledges Syd Hall and Brian McMahon for considerable input during the development process for the pdCIF dictionary.

5.1. Domain size and domain-size distributions

M. Leoni

5.1.1. Introduction

With the continuous advancement of studies in the field of nanostructured materials, the non-destructive and accurate determination of the size of nanometric objects has become a real issue. Powder diffraction is one of the tools for obtaining this information, provided that we know the meaning of the result and the limits of the available analysis techniques.

A century ago, Scherrer (1918) identified a relationship between the breadth of a diffraction profile and the size of the corresponding domains. The definition of size is quite important here. In this context, the size is that of the smallest crystalline entities in the specimen (*domains* or *crystallites*) providing a coherent diffraction signal, but diffracting independently (and incoherently) of one another. The case of two non-connected regions contributing coherently to the intensity is therefore excluded. Another often-used definition for these domains is that of *primary particles*. In a microscope, they would represent the smallest independent crystalline areas of the specimen. Therefore, a domain can be quite different, for example, from a *particle* or a *grain*, as these objects may easily contain more than one domain. The X-ray diffraction techniques proposed here are unable to provide an estimation of the grain size: when microscopy is not an option, small-angle scattering as well as a graininess analysis of the diffraction rings can be viable alternatives. The differences between domain and grain, however, become faint for a colloid and in general for a nanocrystalline powder or aggregate: these are the major fields of application of diffractometric techniques, as the sizes that can be accessed are limited to the sub-micrometre range. Grain size can be estimated, under certain conditions, from the observation of relative intensity variations.

The Scherrer formula is the origin of line-profile analysis (LPA), the branch of diffraction devoted to the extraction of microstructure information from a pattern. The literature on LPA is vast: several techniques have been proposed over the years to allow for a more complete microstructural analysis and to remove most of the limitations of the original formulation by Scherrer. Those techniques have been developed with the goal of separating the various contributions to line-profile broadening: the variance method (Wilson, 1962), the Williamson–Hall method (Williamson & Hall, 1953), the Warren–Averbach technique (Warren & Averbach, 1950, 1952) and whole-powder-pattern modelling (Scardi & Leoni, 2002; Scardi *et al.*, 2010; see also Chapter 3.6) are probably the most important milestones there. With the advent of personal computers, some of the methods have lost their popularity and advantages; this is the case for the variance method, which is now only used sporadically (see *e.g.* Pantoja-Cortés *et al.*, 2012).

Nevertheless, most of the modern literature still presents quantitative results based on the original formalism – results that in most cases are either in disagreement with the underlying physics or are wrong on an absolute scale.

Peak broadening is the key in the determination of a size from a diffraction pattern. If we assume that our specimen is free from defects, the only parameters affecting this broadening are the instrument, the size and shape of the domains, and their distributions. The instrument limits the maximum size that can be reliably measured: domains larger than a few hundred nanometres can be considered as 'particles of infinite size' (Jones, 1938, 1941). All contributions to the broadening are folded into the observed line profile. In particular, if g describes the instrumental peak (*i.e.* a delta function broadened by all instrumental aberrations) and f the peak resulting from the specimen effects alone, then the function describing the whole profile h can be calculated as (Jones, 1938; Alexander, 1954; Klug & Alexander, 1974, and references therein)

$$h(x) = \int_{-\infty}^{\infty} f(y) g(x-y)\, \mathrm{d}y = f \otimes g(x). \qquad (5.1.1)$$

Exhaustive discussion on this issue can be found in, for example, Klug & Alexander (1974), Snyder *et al.* (1999) and Mittemeijer & Scardi (2004). Instrumental effects should be taken into due account when extracting the size contribution, as they might considerably alter the shape of the profiles; for a nanocrystalline powder, however, they can be negligible with respect to the size-related broadening and thus only small errors are made if they are not included. Unless otherwise specified, all derivations in the following will be done considering the instrumental effects as negligible, or properly taken into account, or removed.

Two approaches are available for the analysis of the size and size distribution: pattern decomposition (or fitting) and pattern modelling. In the first case, the information is obtained from some fitting parameter (no direct connection exists between the model and the data); in the latter case, a microstructure model is employed to simulate the peak profile and the model parameters are directly refined against the experimental data. The most common methods for the analysis are discussed here and the formulae for the simulation of the size-broadened profile are provided.

5.1.2. The Scherrer formula and integral-breadth methods

The Scherrer formula relates the full width at half maximum (FWHM) of a diffraction peak to an average domain size value: this apparently simple nature of the problem is the key to the success of the Scherrer formula and justifies its wide abuse. The original equation (Scherrer, 1918), paired with a more modern formalism, reads

$$h = 2\sqrt{\frac{\ln 2}{\pi}} \frac{\lambda}{\Lambda} \frac{1}{\cos \vartheta/2}, \qquad \mathrm{FWHM} = \frac{K_w \lambda}{\langle D \rangle \cos \theta_{hkl}}, \qquad (5.1.2)$$

where h is the FWHM, λ is the wavelength, Λ (now identified as $\langle D \rangle$ where $\langle\rangle$ indicates averaging) is the edge length of the cube-shaped domains (*Kriställchens*, as per Scherrer), ϑ (now called $2\theta_{hkl}$) is the diffraction (Bragg) angle and K_w is the so-called (half-width) Scherrer constant ($K_w \simeq 0.94$ in this case).

Neither of the two most frequent references to the Scherrer equation (Scherrer, 1918, 1922) actually contain any derivation of the formula. Scherrer himself suggests that it was presented in his *Habilitation* thesis (Scherrer, 1962). Fortunately, Scherrer's idea

Copyright © 2019 International Union of Crystallography

and the whole formalism has been reprised and extended by several authors (*e.g.* von Laue, 1926; Bragg, 1930; Jones, 1938; Patterson, 1939*a*,*b*; Wilson, 1962; Klug & Alexander, 1974; Langford & Wilson, 1978; Langford & Louër, 1996) and a derivation of equation (5.1.2), albeit with a whole range of Scherrer constants, can be found. Differences are in some cases just related to the definition of the size parameter. Even if a characteristic edge length can be the most obvious choice, the cube root of the domain volume V is often employed. For a cube this makes no difference, as $V^{1/3} = D$, whereas for a sphere of diameter D, for example, the cube root of the volume is $V^{1/3} = (\pi/6)^{1/3}D \simeq 0.806D$. Particular care should therefore be taken when choosing K_w.

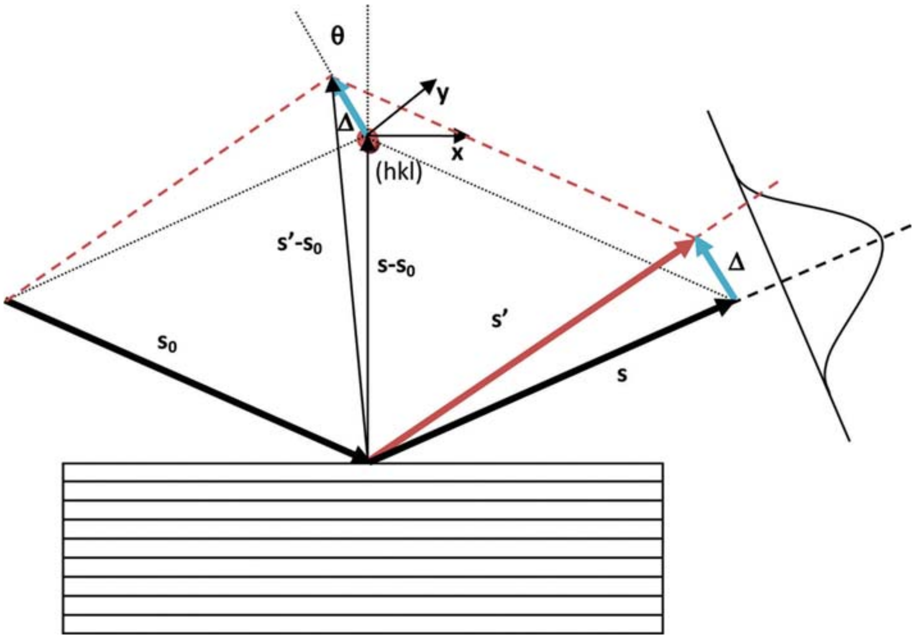

Figure 5.1.1
Geometry employed to derive the Scherrer equation.

The case of a small crystal of cubic shape and cubic lattice, on which the original Scherrer formula is based, will be shown here; the extension to different shapes and symmetries is straightforward and can be found in the cited literature. The powder-diffraction peak profile can be calculated by considering the object as a single crystal and integrating the corresponding intensity over all orientations in space. The diffracted intensity for a single crystal of cubic shape is (see *e.g.* von Laue, 1926; Jones, 1938; Warren, 1990)

$$I = I_e F^2 \frac{\sin^2\left[(\pi/\lambda)(\mathbf{s}-\mathbf{s}_0)\cdot N\mathbf{a}_1\right]}{\sin^2\left[(\pi/\lambda)(\mathbf{s}-\mathbf{s}_0)\cdot \mathbf{a}_1\right]} \frac{\sin^2\left[(\pi/\lambda)(\mathbf{s}-\mathbf{s}_0)\cdot N\mathbf{a}_2\right]}{\sin^2\left[(\pi/\lambda)(\mathbf{s}-\mathbf{s}_0)\cdot \mathbf{a}_2\right]} \times \frac{\sin^2\left[(\pi/\lambda)(\mathbf{s}-\mathbf{s}_0)\cdot N\mathbf{a}_3\right]}{\sin^2\left[(\pi/\lambda)(\mathbf{s}-\mathbf{s}_0)\cdot \mathbf{a}_3\right]}, \qquad (5.1.3)$$

where $\mathbf{s}_0$ and $\mathbf{s}$ are, respectively, the incident and diffracted beam, λ is the wavelength, N is the size of the cube in terms of numbers of cells along the three (real) directions $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$, F^2 is the square modulus of the structure factor and I_e is the scattering intensity for an atom in electron units. The size of the cube is $\langle D\rangle = Na$. Here we are interested in the behaviour of the diffraction pattern near a Bragg spot. We consider therefore that $|(\mathbf{s}-\mathbf{s}_0)/\lambda| = 2\sin\theta_{hkl}/\lambda = d^*_{hkl}$ and we calculate the intensity in a point $(\mathbf{s}-\mathbf{s}_0+\Delta\mathbf{s})$ obtained by varying slightly the incident and diffracted beams. As we are in the neighbourhood of a Bragg spot, equation (5.1.3) can be modified to (see *e.g.* Warren, 1990)

$$I_{hkl} = I_e F^2 \frac{\sin^2\left(\pi N\Delta\mathbf{s}\cdot\mathbf{a}_1/\lambda\right)}{\sin^2\left(\pi\Delta\mathbf{s}\cdot\mathbf{a}_1/\lambda\right)} \frac{\sin^2\left(\pi N\Delta\mathbf{s}\cdot\mathbf{a}_2/\lambda\right)}{\sin^2\left(\pi\Delta\mathbf{s}\cdot\mathbf{a}_2/\lambda\right)} \times \frac{\sin^2\left(\pi N\Delta\mathbf{s}\cdot\mathbf{a}_3/\lambda\right)}{\sin^2\left(\pi\Delta\mathbf{s}\cdot\mathbf{a}_3/\lambda\right)}. \qquad (5.1.4)$$

To reduce the difficulties in integrating (5.1.4) over all orientations, we can replace each trigonometric ratio (leading to a peak with oscillatory tails) with a bell-shaped function having, for example, the same maximum and the same area (Gauss and Lorentz profiles were explored by von Laue). In the Gaussian case we have

$$\frac{\sin^2 Nx}{\sin^2 x} \rightarrow N^2\exp\left(-N^2x^2/\pi\right). \qquad (5.1.5)$$

Substituting equation (5.1.5) in equation (5.1.4) and considering the orthonormality of the $\mathbf{a}_i$ basis, we obtain

$$I_{hkl} = I_e F^2 N^6 \exp\left[-K\Delta s^2\right], \quad K = \pi\left(\frac{Na}{\lambda}\right)^2. \qquad (5.1.6)$$

We can now integrate equation (5.1.6) in reciprocal space [in place of equation (5.1.4)] and obtain the powder-diffraction intensity. Instead of rotating the crystal in space, we can integrate by varying the $\mathbf{s}$ vectors. Fortunately, the intensity is just concentrated in a small region close to the Bragg spots (according to the Laue equations) and we can thus substitute the integration in space by the integration over a small volume around them. The integration on a sphere can also be substituted by the integration over the plane tangent to it and orthogonal to $\mathbf{s}-\mathbf{s}_0$ with local axes $\mathbf{x}$ and $\mathbf{y}$ (Fig. 5.1.1). As the variation with respect to the Bragg condition is small, our $\Delta\mathbf{s}$ becomes $\Delta\mathbf{s} = \mathbf{x}+\mathbf{y}+\boldsymbol{\Delta}$ (see Fig. 5.1.1) and thus

$$\Delta s^2 = (x-\Delta\sin\theta_{hkl})^2 + y^2 + (\Delta\cos\theta_{hkl})^2. \qquad (5.1.7)$$

We now have

$$\begin{aligned} I_{hkl}(\Delta) &= I_e F^2 N^6 \exp\left(-K\Delta^2\cos^2\theta_{hkl}\right) \\ &\quad\times \int\limits_{-\infty}^{\infty} \exp\left(-K(x-\Delta\sin\theta_{hkl})^2\right)\,\mathrm{d}x \int\limits_{-\infty}^{\infty} \exp(-Ky^2)\,\mathrm{d}y \\ &= I_e F^2 N^6 \frac{\pi}{K}\exp\left(-K\Delta^2\cos^2\theta_{hkl}\right) \qquad (5.1.8) \end{aligned}$$

and thus the FWHM of this profile can be obtained as

$$\begin{aligned} \frac{I_{hkl}(0)}{2} &= I_{hkl}\left(\mathrm{FWHM}_{hkl}/2\right) = I_{hkl}(\Delta) \\ &= I_{hkl}(0)\exp\Big(-K\left(\mathrm{FWHM}_{hkl}/2\right)^2\cos^2\theta_{hkl}\Big), \qquad (5.1.9) \end{aligned}$$

from which

$$\mathrm{FWHM}_{hkl} = \frac{2(\ln 2/K)^{1/2}}{\cos\theta_{hkl}} = \frac{2(\ln 2/\pi)^{1/2}\lambda}{Na\cos\theta_{hkl}} = \frac{2(\ln 2/\pi)^{1/2}\lambda}{\langle D\rangle\cos\theta_{hkl}} = \frac{K_w\lambda}{\langle D\rangle\cos\theta_{hkl}} \qquad (5.1.10)$$

as originally obtained by Scherrer. Equation (5.1.10) assumes a simpler form if we analyse the problem in reciprocal space. In fact, we can note that

$$d^* = \frac{2\sin(2\theta/2)}{\lambda} \rightarrow \frac{\partial d^*}{\partial 2\theta} = \frac{\cos\theta}{\lambda} \rightarrow \mathrm{FWHM}^*_{hkl} = \frac{K_w}{\langle D\rangle}, \qquad (5.1.11)$$

where * is used to indicate quantities in reciprocal space.

Scherrer's result is mathematically exact when the diffraction profile is Gaussian: this does not mean it is also physically plausible, as it would correspond to the case where a certain domain shape leads to an equation like (5.1.4) but built with Gaussians in place of the trigonometric ratios. Moreover, different shapes are considered in the formalism just through K_w: the domain shape affects the profile shape, but the Gaussian approximation is still employed. An extra term could be added to the original formulation to take the instrumental broadening into account (Scherrer, 1922; von Laue, 1926; Alexander, 1954; Stokes, 1955):

$$h = 2\left(\frac{\ln 2}{\pi}\right)^{1/2} \frac{\lambda}{\Lambda}\frac{1}{\cos\vartheta/2} + b. \qquad (5.1.12)$$

The additivity of breadths depends on the shape of the profiles. According to equation (5.1.1), we have to consider a convolution of profiles: for instance, the breadth of the convolution of two Lorentzian profiles is the sum of the breadths, whereas for the Gaussian it is the root of the sum of the squared breadths. In equation (5.1.12), a Gauss approximation was employed to obtain the Scherrer formula, and now the instrumental broadening is added straight away as in a Lorentz approximation: the two hypotheses are therefore contrasting. However, considering the level of approximation involved in the derivation of the Scherrer equation and the limited effect of the instrumental profile, an approximation like equation (5.1.12) is still acceptable.

For a practical estimation of the size, equation (5.1.2) is usually preferred: in most cases the Scherrer constant is arbitrarily chosen (0.94 and 0.89, representing the cases of a cube and a sphere, are usually adopted), but problems arise in the evaluation of the FWHM. In fact, peaks can be partly overlapping and a background can be present, limiting the ability to isolate a peak from the pattern. The choice of the peak is also arbitrary: most publications show a tendency to employ the most intense peak or an isolated peak above $\sim 30^\circ$ in 2θ (where instrumental aberrations leading to peak asymmetry start to be less important). Unless size is the only source of broadening, different values for the apparent average domain size are obtained from different profiles.

This is therefore a very crude approach to determining the size of the coherently scattering domains, and to line-profile analysis in general. To avoid some of the problems related to the estimation of the FWHM, the integral breadth (IB) introduced by von Laue (1926) and extensively employed by Stokes & Wilson (1942, 1944) can be used. The IB is defined as the ratio between the peak area and the peak maximum intensity, and is therefore the width of a rectangular peak having the same intensity and area as the measured one. In reciprocal space the integral breadth for the *hkl* reflection is

$$\beta^*_{hkl} = \frac{1}{I_{hkl}(0)}\int\limits_{-\infty}^{\infty} I_{hkl}(s)\,\mathrm{d}s, \qquad (5.1.13)$$

where $s = d^* - d^*_{hkl}$. The integral breadth is related to the FWHM. In fact, we can take a unit area Gaussian,

$$G(s) = \frac{2[\ln(2)/\pi]^{1/2}}{\mathrm{FWHM}}\exp\left[-4\ln(2)\frac{s^2}{\mathrm{FWHM}^2}\right], \qquad (5.1.14)$$

and calculate the corresponding integral breadth:

$$\beta^* = \frac{1}{2[\ln(2)/\pi]^{1/2}/\mathrm{FWHM}} = \frac{\mathrm{FWHM}}{2[\ln(2)/\pi]^{1/2}}. \qquad (5.1.15)$$

The constant in equation (5.1.15) is exactly the same as that appearing in the original formula of Scherrer. Equation (5.1.2) can thus be rewritten in terms of integral breadth as

$$\beta^*_{hkl} = \frac{1}{\Lambda}, \quad \beta_{hkl} = \frac{K_\beta}{\langle D\rangle}\frac{\lambda}{\cos\theta_{hkl}}, \quad \beta^*_{hkl} = \frac{K_\beta}{\langle D\rangle}, \qquad (5.1.16)$$

where the new constant K_β takes the shape of the domains into account. The inverse of the integral breadth is sometimes defined as the *apparent size*. With the goal of calculating the integral breadth for some common shapes (including the cube already considered by several authors), the article by Stokes & Wilson (1942) provides some new ideas for calculating the intensity profile and opens the way to a new type of analysis based on a Fourier approach.

5.1.3. Fourier methods

In the Scherrer formula, and in general in the methods based on the integral breadth, just part of the information contained in the pattern is employed in the analysis. The information on the microstructure is coded into the whole shape of the peak, so the breadth can only give some order-of-magnitude estimate of the size. Fourier methods go further, and provide a description of the whole intensity profile in reciprocal space; not surprisingly, the Fourier formalism is also at the basis of the modern methods for line-profile broadening analysis.

5.1.4. The peak profile and the common volume function ('ghost')

Stokes and Wilson proposed a simple method for calculating the size-broadened line profiles and the corresponding integral breadths. The derivation, initially proposed for cubic lattices (Stokes & Wilson, 1942), was then seamlessly extended to the general case (Stokes & Wilson, 1944); the diffracted intensity for a row of scatterers of length T laying parallel to the $\langle hkl\rangle$ direction in reciprocal space can be written as (Wilson, 1962, equation 5 on p. 39)

$$I_{hkl}(s)\,\mathrm{d}s \propto \frac{1}{U}\int\!\!\int \frac{\sin^2(\pi T s)}{(\pi s)^2}\,\mathrm{d}y\,\mathrm{d}z\,\mathrm{d}s = \frac{1}{U}\int\!\!\int T^2\mathrm{sinc}^2(\pi T s)\,\mathrm{d}y\,\mathrm{d}z\,\mathrm{d}s, \qquad (5.1.17)$$

where $s = d^* - d^*_{hkl}$ ($S - S_{hkl}$ in the original notation), U is the unit-cell volume and the direction x is along the line of scatterers. The proportionality sign is used in equation (5.1.17) as constants and known functions of s are omitted in the derivation. By noting that the area of the peak is given by V/U, where V is the volume of the domain, the apparent integral-breadth size can easily be calculated as

$$\begin{aligned}\langle D\rangle &= \frac{1}{\beta^*_{hkl}} = \frac{I_{hkl}(0)}{V/U} = \frac{1}{V}\int\int T^2\,\mathrm{d}y\,\mathrm{d}z = \frac{1}{V}\int\int\int T\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\\ &= \frac{1}{V}\int\limits_V T\,\mathrm{d}V. \end{aligned}\qquad (5.1.18)$$

According to Stokes & Wilson (1942), 'the reciprocal of the integral breadth [in reciprocal space] is the volume average of the thickness of the crystal measured perpendicular to the reflecting plane'. The integral in (5.1.18) can be conveniently rewritten as

$$(1/V)\int\int T^2\,\mathrm{d}y\,\mathrm{d}z = (1/V)\int\limits_{-\tau_{hkl}}^{\tau_{hkl}} V_{hkl}(L)\,\mathrm{d}L, \qquad (5.1.19)$$

where the function $V_{hkl}(L)$ is the self-convolution of the shape function of the domain (defined as unity inside the domain boundary and zero elsewhere), and it represents the volume common to the domain and its 'ghost' displaced by a quantity L along the *hkl* direction:

$$V_{hkl}(L) = \int\int (T - |L|)\,\mathrm{d}y\,\mathrm{d}z. \qquad (5.1.20)$$

From these definitions, it is clear that $V = V_{hkl}(0)$ and that $V_{hkl}(L) = V_{hkl}(-L)$. To simplify the notation, equation (5.1.20) is commonly assumed to be even (and employed for non-negative L), thus quite often L is found in place of $|L|$ in all expressions for the common volume function. The integration in (5.1.19) is limited to the distance τ_{hkl} where the common volume function (CVF) reaches zero. The geometrical interpretation of the CVF can be seen in Fig. 5.1.2.

Now, if we take the Fourier transform (FT) of the CVF, we obtain

$$\begin{aligned}&\int\limits_{-\tau}^{\tau} V_{hkl}(L)\exp(2\pi isL)\,\mathrm{d}L\\ &\quad= 2\int\limits_{0}^{\tau} V_{hkl}(L)\cos(2\pi sL)\,\mathrm{d}L + i\int\limits_{-\tau}^{\tau} V_{hkl}(L)\sin(2\pi sL)\,\mathrm{d}L\\ &\quad= 2\int\int\left(\int\limits_{0}^{\tau}(T-L)\cos(2\pi sL)\,\mathrm{d}L\right)\mathrm{d}y\,\mathrm{d}z + 0\\ &\quad= 2\int\int\left(T\int\limits_{0}^{\tau}\cos(2\pi sL)\,\mathrm{d}L - \int\limits_{0}^{\tau}L\cos(2\pi sL)\,\mathrm{d}L\right)\mathrm{d}y\,\mathrm{d}z\\ &\quad= \int\int\frac{\sin^2(\pi sT)}{(\pi s)^2}\,\mathrm{d}y\,\mathrm{d}z. \end{aligned}\qquad (5.1.21)$$

By comparing equations (5.1.17) and (5.1.21), we can conclude that the peak profile is related to the Fourier transform of the CVF:

$$\begin{aligned}I_{hkl}(s) &\propto \frac{1}{U}\int\limits_{-\tau}^{\tau} V_{hkl}(L)\exp(2\pi isL)\,\mathrm{d}L\\ &= \frac{2}{U}\int\limits_{0}^{\tau} V_{hkl}(L)\cos(2\pi sL)\,\mathrm{d}L\\ &\propto \frac{1}{U}\int\limits_{-1}^{1} V_{hkl}\left(\frac{L}{D}\right)\exp\left(2\pi is\frac{L}{D}\right)\mathrm{d}\frac{L}{D}\\ &= \frac{2}{U}\int\limits_{0}^{1} V_{hkl}\left(\frac{L}{D}\right)\cos\left(2\pi s\frac{L}{D}\right)\mathrm{d}\left(\frac{L}{D}\right). \end{aligned}\qquad (5.1.22)$$

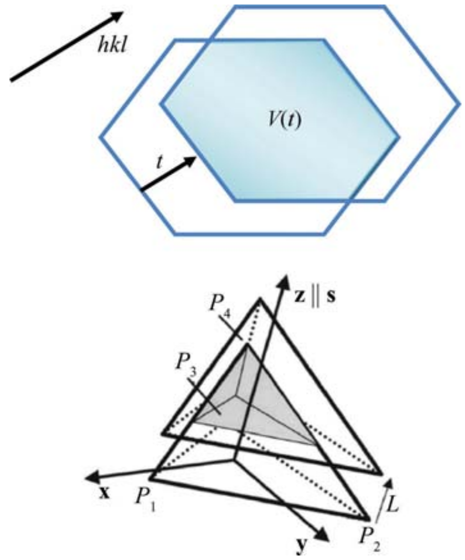

Figure 5.1.2
A domain and its ghost translated by a quantity L along *hkl*.

As can be seen, the limit of integration can be changed provided that the functions are defined consistently (see *e.g.* Adler & Houska, 1979). The normalized common volume function

$$A^S_{hkl}(L) = \frac{V_{hkl}(L)}{V_{hkl}(0)}, \qquad (5.1.23)$$

often referred to as the size Fourier term (or size Fourier coefficients), is traditionally used in place of the CVF in the description of line-profile broadening: the normalization is useful as it leads to unit-area peaks. Equation (5.1.22) can easily be rewritten in terms of $A^S_{hkl}(L)$. The size Fourier coefficients can also be employed to treat finite size effects in the total-scattering approach (Howell *et al.*, 2006).

The properties of the Fourier transform lead to an interesting result for the integral breadth (Bertaut, 1949*a*, 1950):

$$\beta^*_{hkl} = \frac{\int_{-\infty}^{\infty} I_{hkl}(s)\,\mathrm{d}s}{I_{hkl}(0)} = \frac{A^S_{hkl}(0)}{\int_{-\tau_{hkl}}^{\tau_{hkl}} A^S_{hkl}(L)\,\mathrm{d}L} = \left(\int\limits_{-\tau_{hkl}}^{\tau_{hkl}} A^S_{hkl}(L)\,\mathrm{d}L\right)^{-1}. \qquad (5.1.24)$$

This has important implications for practical size analysis using integral-breadth methods, as we can either work directly on the data (suitably represented in the correct space) or use the Fourier coefficients without actually calculating the profile. If we want to consider other broadening effects, working directly with the Fourier coefficients has undoubted advantages: in fact, the convolution theorem for the FT allows equation (5.1.1) to be written as

$$\begin{aligned}h(x) &= \mathrm{FT}^{-1}[\mathrm{FT}[h(x)]] = \mathrm{FT}^{-1}[\mathrm{FT}[f(x)]\cdot\mathrm{FT}[g(x)]]\\ &= f\otimes g(x),\end{aligned}\qquad (5.1.25)$$

where FT[x] and $\mathrm{FT}^{-1}[x]$ identify direct and inverse Fourier transformation. Convolution is thus transformed into a product in Fourier space and any additional broadening term k enters equation (5.1.22) as a multiplicative FT[k] element (*cf.* Paterson, 1952).

Equation (5.1.22) [together with equations (5.1.23) and (5.1.25)] can be used in two ways: we can simulate the profile *ab initio* and optimize the model parameters against the data, or we can extract the Fourier parameters directly from the data and try to work out the model parameters from them (see below). The first approach is the basis of the whole powder pattern modelling (Scardi & Leoni, 2002; Chapter 3.6), the second one is the basis of all Fourier methods of line-profile analysis, such as the Warren and Averbach method (Warren & Averbach, 1952; Paterson, 1952).

5.1.5. Common volume function for simple shapes

For simple shapes, the common volume function can be obtained in a simple closed form. For instance, the case of the sphere, obtained by Stokes & Wilson (1942), can be derived from the intersection of two circles (Fig. 5.1.3). In fact, the intersection of two spheres of diameter D is a lens (*i.e.* the sum of two equal spherical caps) with radius of the base r and height $(D - L)/2$ obtained by rotating the drawing of Fig. 5.1.3 around the segment connecting the centres of the circles. The volume of the lens is

$$V_{\rm lens}(L) = 2\pi \frac{h^2}{3}\left(3\frac{D}{2} - h\right) = \frac{\pi}{12}(D-L)^2(2D+L) = \frac{\pi D^3}{6} - \frac{\pi D^2 L}{4} + \frac{\pi L^3}{12} \tag{5.1.26}$$

and therefore the corresponding size Fourier coefficients read

$$A^s_{\rm sphere}(L) = \frac{V_{\rm lens}(L)}{V_{\rm lens}(0)} = \frac{\pi(D-L)^2(2D+L)/12}{\pi D^3/6} = 1 - \frac{3}{2}\frac{L}{D} + \frac{L^3}{2D^3}. \tag{5.1.27}$$

This function is analogous to the γ_0 function of Porod (1951), employed in the analysis of small-angle scattering data (see p. 12 of Guinier & Fournet, 1955). The size Fourier coefficients for the sphere reach zero at $L = \tau_{hkl} = D$ (τ_{hkl} is thus independent of hkl). We can immediately see [*cf.* equation (5.1.24)] that

$$\beta^* = \left(\int\limits_{-D}^{D} A^S_{\rm sphere}(L)\,{\rm d}L\right)^{-1} = \left[2\int\limits_{0}^{D}\left(1 - \frac{3}{2}\frac{L}{D} + \frac{L^3}{2D^3}\right){\rm d}L\right]^{-1} = \frac{4/3}{\langle D\rangle}. \tag{5.1.28}$$

Using the same approach we can also calculate the common volume of a hollow sphere that represents the case of a non-convex (not simply connected) object. Given a sphere of diameter D and a hole of diameter $d < D$, the common volume depends on the relative diameter and on the range of L. In particular, for $d < D/3$,

$$A^s_{\rm hollow}(L) = \begin{cases} 1 + \dfrac{3(d^2+D^2)L - 2L^3}{2(d^3 - D^3)} & 0 \le L \le d \\[2mm] \dfrac{4d^3 - (D-L)^2(2D+L)}{2(d^3 - D^3)} & d \le L \le (D-d)/2 \\[2mm] \dfrac{3(d^2-D^2)^2 - 16d^3L + 24d^2L^2 - 8L^4}{16(D^3 - d^3)L} & (D-d)/2 \le L \le (D+d)/2 \\[2mm] \dfrac{(D-L)^2(2D+L)}{2(D^3-d^3)} & (D+d)/2 \le L \le D, \end{cases} \tag{5.1.29}$$

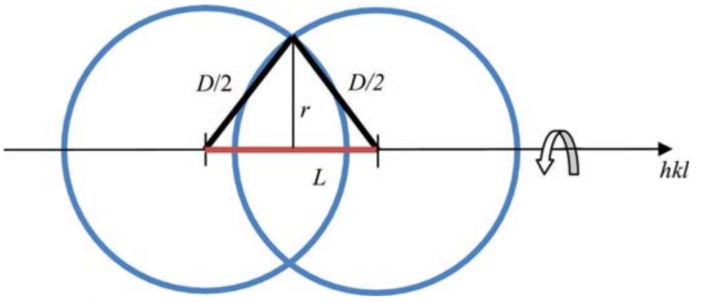

Figure 5.1.3
The intersection of two circles. The case of two spheres is obtained by rotating the system around the *hkl* axis.

whereas for $d \ge D/3$

$$A^s_{\rm hollow}(L) = \begin{cases} 1 + \dfrac{3(d^2+D^2)L - 2L^3}{2(d^3 - D^3)} & 0 \le L \le (D-d)/2 \\[2mm] \dfrac{3(D-d)(d+D)^2}{16(d^2+dD+D^2)L} & (D-d)/2 \le L \le d \\[2mm] \dfrac{3(d^2-D^2)^2 - 16d^3L + 24d^2L^2 - 8L^4}{16(D^3 - d^3)L} & d \le L \le (D+d)/2 \\[2mm] \dfrac{(D-L)^2(2D+L)}{2(D^3-d^3)} & (D+d)/2 \le L \le D. \end{cases} \tag{5.1.30}$$

The function is continuous, but defined over intervals: equation (5.1.29) reduces piecewise to the spherical case [equation (5.1.27)] when the inner diameter d is zero.

Things are more complex for any other (anisotropic) shape, as the CVF becomes a function of *hkl*. Taking the cube as an example, and working with a cubic lattice (Stokes & Wilson, 1942), the common volume for a displacement along $\langle h00\rangle$ is a prism with square base:

$$A^s_{\rm cube,100}(L) = 1 - (L/D) \tag{5.1.31}$$

with $\tau_{100} = D$, whereas for $\langle 111\rangle$ for example, we have

$$A^s_{\rm cube,111}(L) = \left(1 - \frac{L}{(3)^{1/2}D}\right)^3 \tag{5.1.32}$$

with $\tau_{111} = 3^{1/2}D$. The general equation for $h \ge k \ge l$ takes the form

$$A^s_{\rm cube,hkl}(L) = \left(1 - A\frac{L}{D}\right)\left(1 - B\frac{L}{D}\right)\left(1 - C\frac{L}{D}\right), \tag{5.1.33}$$

where $H = (h^2 + k^2 + l^2)^{1/2}$, $A = h/H$, $B = k/H$, $C = l/H$ and $\tau_{hkl} = D/A$. The formulae can be extended to the general lattice (lowest symmetry) by representing the *hkl* peak in the orthogonal frame defined by $\hat{\mathbf{e}}_1 \parallel \hat{\mathbf{a}}$, $\hat{\mathbf{e}}_3 \parallel \hat{\mathbf{c}}^*$ and $\hat{\mathbf{e}}_2 = \hat{\mathbf{e}}_3 \times \hat{\mathbf{e}}_1$ where $\hat{\mathbf{a}}$, $\hat{\mathbf{b}}$, $\hat{\mathbf{c}}$ and $\hat{\mathbf{a}}^*$, $\hat{\mathbf{b}}^*$, $\hat{\mathbf{c}}^*$ are, respectively, the direct- and reciprocal-lattice unit vectors (Giacovazzo *et al.*, 1991). From the metric tensor for the lattice,

$$\mathbf{G} = \begin{pmatrix} \mathbf{a}\cdot\mathbf{a} & \mathbf{a}\cdot\mathbf{b} & \mathbf{a}\cdot\mathbf{c} \\ \mathbf{b}\cdot\mathbf{a} & \mathbf{b}\cdot\mathbf{b} & \mathbf{b}\cdot\mathbf{c} \\ \mathbf{c}\cdot\mathbf{a} & \mathbf{c}\cdot\mathbf{b} & \mathbf{c}\cdot\mathbf{c} \end{pmatrix} = \begin{pmatrix} a^2 & ab\cos\gamma & ac\cos\beta \\ ab\cos\gamma & b^2 & bc\cos\alpha \\ ac\cos\beta & bc\cos\alpha & c^2 \end{pmatrix}, \tag{5.1.34}$$

we can compute the unit-cell volume:

Table 5.1.1

Coefficients for the calculation of the common volume function for a sphere, cube, tetrahedron and octahedron

Adapted from Scardi & Leoni (2001), assuming $H_0^c = 1$ and $\tau_{hkl} = DK_{hkl}$. See the text for the meaning of A, B, C. The errors present in Stokes & Wilson (1942) and Scardi & Leoni (2001) have been corrected.

			Tetrahedron		Octahedron

$$\begin{aligned} V_c^2 &= \det(\mathbf{G}) \\ &= a^2b^2c^2\left(1 + 2\cos\alpha\cos\beta\cos\gamma - \cos^2\alpha - \cos^2\beta - \cos^2\gamma\right) \end{aligned} \tag{5.1.35}$$

and, through Cholesky decomposition, $\mathbf{G} = \mathbf{M}^{-1} \cdot (\mathbf{M}^{-1})^T$, the orthogonalization matrix $\mathbf{M}$. This will give us the general values for the A, B and C coefficients appearing in (5.1.33):

$$\begin{aligned} \begin{pmatrix} A \\ B \\ C \end{pmatrix} &= \frac{1}{|\mathbf{H}_{hkl}|}\mathbf{M} \cdot \begin{pmatrix} h \\ k \\ l \end{pmatrix} \\ &= d_{hkl}\begin{pmatrix} 1/a & 0 & 0 \\ -\cos\gamma/(a\sin\gamma) & 1/(b\sin\gamma) & 0 \\ a^*\cos\beta^* & b^*\cos\alpha^* & c^* \end{pmatrix} \cdot \begin{pmatrix} h \\ k \\ l \end{pmatrix}, \end{aligned} \tag{5.1.36}$$

where the modulus of the scattering vector is

$$\begin{aligned} |\mathbf{H}_{hkl}|^2 &= \begin{pmatrix} h & k & l \end{pmatrix}\mathbf{G}^{-1}\begin{pmatrix} h \\ k \\ l \end{pmatrix} \\ &= (h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*) \cdot (h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*) = \frac{1}{d_{hkl}^2} \\ &= \left[(ha^*)^2 + (kb^*)^2 + (lc^*)^2 + 2hka^*b^*\cos\gamma^* + 2hla^*c^*\cos\beta^* \right. \\ &\quad \left. + 2klb^*c^*\cos\alpha^*\right] \\ &= \frac{a^2b^2c^2}{V_c^2}\left[\frac{h^2\sin^2\alpha}{a^2} + \frac{k^2\sin^2\beta}{b^2} + \frac{l^2\sin^2\gamma}{c^2} \right. \\ &\quad + 2\frac{hk}{ab}(\cos\alpha\cos\beta - \cos\gamma) + 2\frac{kl}{bc}(\cos\beta\cos\gamma - \cos\alpha) \\ &\quad \left. + 2\frac{lh}{ac}(\cos\alpha\cos\gamma - \cos\beta)\right]. \end{aligned} \tag{5.1.37}$$

The values computed from equation (5.1.36),

$$\begin{aligned} A &= hd_{hkl}/a \\ B &= -hd_{hkl}\cos\gamma/(a\sin\gamma) + kd_{hkl}/(b\sin\gamma) \\ &= -A\tan\gamma + kd_{hkl}/(b\sin\gamma) \\ C &= hd_{hkl}a^*\cos\beta^* + kd_{hkl}b^*\cos\alpha^* + ld_{hkl}c^* \\ &= hd_{hkl}\frac{bc(\cos\alpha\cos\gamma - \cos\beta)}{V_c\sin\gamma} + kd_{hkl}\frac{ac(\cos\beta\cos\gamma - \cos\alpha)}{V_c\sin\gamma} \\ &\quad + ld_{hkl}\frac{ab\sin\gamma}{V_c}, \end{aligned} \tag{5.1.38}$$

must be then sorted in such a way that $A \geq B \geq C$. This replaces the sorting of Miller indices ($h \geq k \geq l$) proposed for the cubic case and still allows us to write $\tau_{hkl} = D/A$. In the cubic case ($a = b = c$, $\alpha = \beta = \gamma = 90°$), we have

$$d_{hkl} = \frac{a}{(h^2 + k^2 + l^2)^{1/2}} \tag{5.1.39}$$

and (5.1.38) reduces to the previously known result.

An analogous reasoning was employed by Popa & Balzar (2008) to obtain the CVF of an ellipsoid and that of an elliptical cylinder.

The integral breadth of the profile of a cube-shaped crystallite can be easily calculated from equation (5.1.33) as

$$\begin{aligned} \beta^* &= \left(\int_0^{D/A} 2A^S_{\text{cube},hkl}(L)\,\mathrm{d}L\right)^{-1} \\ &= \left[2\int_0^{D/A}\left(1 - A\frac{L}{D}\right)\left(1 - B\frac{L}{D}\right)\left(1 - C\frac{L}{D}\right)\mathrm{d}L\right]^{-1} \\ &= \frac{6h^3}{DH(6h^2 - 2hk + kl - 2lh)}. \end{aligned} \tag{5.1.40}$$

The common volume functions for a wide set of convex objects can be found *e.g.* in Stokes & Wilson (1942) (sphere and simple polyhedra), Lele & Anantharaman (1966) (triangular, square, hexagonal prisms and cylinder), Wilson (1969) (cylinders, prisms, hemispheres), Langford & Louër (1982) (cylinders), Vargas *et al.* (1983) (hexagonal prisms), Grebille & Bérar (1985) (convex polyhedra), Scardi & Leoni, 2001 (sphere, simple and general polyhedra, distributions of spheres and polyhedra) and Leonardi *et al.* (2012) (general case, fast numerical calculation). Patterson (1939*b*) and Allegra & Wilson (1983) give some hints on how to work with linearly transformed objects as well.

As a general rule, complex convex polyhedra can be decomposed into a finite number of simpler convex polyhedra [*cf.* Grebille & Bérar (1985) and Scardi & Leoni (2001)], leading to the general result that the common volume function for any convex polyhedron is a cubic function of L:

$$\begin{aligned} A^S_{hkl}(L) &= 1 + H_1\frac{L}{D} + H_2\left(\frac{L}{D}\right)^2 + H_3\left(\frac{L}{D}\right)^3 = \sum_{n=0}^{3} H_n\left(\frac{L}{D}\right)^n, \\ A^S_{hkl}(L \geq \tau_{hkl}) &= 0, \end{aligned} \tag{5.1.41}$$

where τ_{hkl}, H_1, H_2 and H_3 are functions of hkl. The coefficient $H_0 = 1$. Equation (5.1.41) is written in terms of a variable L normalized by a characteristic length D; a polynomial in the sole L can also be employed. Table 5.1.1 presents a collection of data for polyhedral shapes that can be observed, for example, in nanosized powders of cubic systems. Equation (5.1.38) can be used to calculate the (sorted) values of A, B, and C entering Table 5.1.1.

As shown by Leonardi *et al.* (2012), the CVF of a non-convex polyhedron can be calculated in a straightforward way by suitably considering the CVF of the hole with the correct sign. The function is still a cubic in L, but it is defined piecewise: however, once the CVF is known, all general calculations proposed here can also be applied to this case.

For some non-polyhedral shapes (notably for cylinders), the common volume function is not a cubic in L. In fact, as shown *e.g.* by Lele & Anantharaman (1966) and reprised by Langford & Louër (1982), the size Fourier term for a cylinder of diameter D and height H displaced by a quantity L along a direction hkl making an angle φ with the cylinder axis is

$$A^{S}_{\text{cylinder},hkl}(L) = (2/\pi)(1 - T\alpha)\Big[\arccos(\alpha) - \alpha\big(1-\alpha^2\big)^{1/2}\Big], \tag{5.1.42}$$

where $\alpha = (L/D)\sin\varphi$, $\Phi = \tan^{-1}(D/H)$ and $T = \tan\Phi/\tan\varphi$. The value of τ_{hkl} depends on φ: for $0 \le \varphi \le \Phi$, $\tau_{hkl} = H/\cos\varphi$, whereas for $\Phi \le \varphi \le \pi/2$, $\tau_{hkl} = D/\sin\varphi$. The calculation of the CVF in these cases cannot be easily generalized. The object can, however, be represented as a polyhedron with a large number of faces and the general approach of Leonardi *et al.* (2012), for example, can be employed for the calculation. We can observe a convergence of this solution with the analytical one when increasing the number of faces. For very small domains, the polyhedral approximation can be considered as physically more plausible than the corresponding continuum case, as the atomic nature of the atomic aggregate starts to play a role.

5.1.6. Calculation of the intensity profile for simple shapes

According to equation (5.1.22), the knowledge of the common volume function suffices to calculate the corresponding diffraction profile in reciprocal space. For a single sphere, the intensity profile assumes a particularly simple mathematical form (Wilson, 1962):

$$\begin{aligned} I_{\text{Wilson}}(s) &\propto 2\int_0^D A^S_{\text{sphere}}(L)\cos(2\pi sL)\,\mathrm{d}L \\ &= 2\int_0^D \left(1 - \frac{3}{2}\frac{L}{D} + \frac{1}{2}\frac{L^3}{D^3}\right)\cos(2\pi sL)\,\mathrm{d}L \\ &= \frac{3}{4}D\left(\frac{1 + 2\psi^2 - \cos 2\psi - 2\psi\sin 2\psi}{2\psi^4}\right) \\ &= \frac{3}{4}D\left(\frac{1 - 2\,\mathrm{sinc}\,2\psi + \mathrm{sinc}^2\psi}{\psi^2}\right) \\ &= \frac{3}{4}D\left(\frac{\psi^2 - \psi\sin 2\psi + \sin^2\psi}{\psi^4}\right), \end{aligned} \tag{5.1.43}$$

where $\psi = \pi sD$. The integral breadth of this profile gives a size value of

$$\begin{aligned} \beta^* &= \frac{1}{I_{\text{Wilson}}(0)}\int_{-\infty}^{\infty} I_{\text{Wilson}}(s)\,\mathrm{d}s \\ &= \frac{2}{I_{\text{Wilson}}(0)}\int_0^{\infty} I(s)\,\mathrm{d}s = \frac{4/3}{\langle D\rangle} \\ &\to \langle D\rangle = \frac{4}{3}\frac{1}{\beta^*} \end{aligned} \tag{5.1.44}$$

in agreement with the result previously found [*cf.* equation (5.1.28)]. The Scherrer constant is $K_\beta = 4/3$ if we deal with the diameter, and becomes almost unity $[(4/3)(\pi/6)^{1/3} = 1.0747]$ if we consider the cube root of the volume.

An interesting extension of equation (5.1.43) was proposed by Allegra & Wilson (1983): a linear transformation of the real space (or, analogously, of the domain shape) is reflected in a linear transformation of the reciprocal space by a factor R. If $(\mathbf{a}_1^*, \mathbf{b}_1^*, \mathbf{c}_1^*)$ is the basis of the reciprocal space for the transformed (non-regular) domain, p_a, p_b and p_c are the sizes of such a domain along these basis directions, p is the unique size parameter of the corresponding regular-shaped crystallite and $(h_1k_1l_1)$ are the Miller indices of the peak in the transformed lattice, then R can be defined as (Allegra & Wilson, 1983)

$$\begin{aligned} R &= \big[(h_1a_1^*)^2 + (k_1b_1^*)^2 + (l_1c_1^*)^2 + 2(h_1a_1^*)(k_1b_1^*)\cos\gamma^* \\ &\quad + 2(h_1a_1^*)(l_1c_1^*)\cos\beta^* + 2(k_1b_1^*)(l_1c_1^*)\cos\alpha^*\big]^{1/2} \\ &\quad \times \left\{p\Big[\big(a_1a_1^*q_h/p_a\big)^2 + \big(b_1b_1^*q_k/p_b\big)^2 + \big(c_1c_1^*q_l/p_c\big)^2\Big]^{1/2}\right\}^{-1} \\ &= \left(pd_{h_1k_1l_1}\big[(\sin\alpha_1 q_h/p_a)^2 + (\sin\beta_1 q_k/p_b)^2 + (\sin\gamma_1 q_l/p_c)^2\big]^{1/2}\right)^{-1}, \end{aligned} \tag{5.1.45}$$

where

$$\begin{pmatrix} q_h \\ q_k \\ q_l \end{pmatrix} = \begin{pmatrix} a_1^*h_1 & b_1^*k_1 & c_1^*l_1 \end{pmatrix} \begin{pmatrix} 1 & \cos\gamma^* & \cos\beta^* \\ \cos\gamma^* & 1 & \cos\alpha^* \\ \cos\beta^* & \cos\alpha^* & 1 \end{pmatrix}. \tag{5.1.46}$$

For instance, the diffraction intensity for an ellipsoid with axes p_a, p_b and p_c along the coordinates axes (a linear transformation of the sphere of diameter p) can be computed from (5.1.43) by replacing $\psi = \pi sD$ with $\psi_R = \pi sRD$.

It is possible to further generalize the result of equation (5.1.43) by using equation (5.1.41). The finite order of the polynomial allows integrating equation (5.1.22) by parts leading to (Wilson, 1962)

$$\begin{aligned} I(s) &\propto \frac{1}{U}2\Bigg\{\left[V(L)\frac{\sin(2\pi sL)}{2\pi s}\right]_0^{\tau_{hkl}} + \left[V'(L)\frac{\cos(2\pi sL)}{(2\pi s)^2}\right]_0^{\tau_{hkl}} \\ &\quad - \left[V''(L)\frac{\sin(2\pi sL)}{(2\pi s)^3}\right]_0^{\tau_{hkl}} - \left[V'''(L)\frac{\cos(2\pi sL)}{(2\pi s)^4}\right]_0^{\tau_{hkl}} \\ &\quad + \int_0^{\tau} V^{IV}(L)\frac{\cos(2\pi sL)}{(2\pi s)^4}\,\mathrm{d}L\Bigg\} \\ &= \frac{1}{U}\big[a_1\psi^{-2} + a_2\psi^{-2}\cos(2\psi) + a_3\psi^{-3}\sin(2\psi) \\ &\quad + a_4\psi^{-4}(1 - \cos(2\psi))\big] \\ &= \frac{V(0)}{U}\big[b_1\psi^{-2} + b_2\psi^{-2}\cos(2\psi) + b_3\psi^{-3}\sin(2\psi) \\ &\quad + b_4\psi^{-4}(1 - \cos(2\psi))\big], \end{aligned} \tag{5.1.47}$$

where $\psi = \pi s\tau_{hkl}$, $a_1 = -\tau_{hkl}^2 V'(0)/2$, $a_2 = \tau_{hkl}^2 V'(\tau_{hkl})/2$, $a_3 = -\tau_{hkl}^3 V''(\tau_{hkl})/4$ and $a_4 = \tau_{hkl}^4 V'''(\tau_{hkl})/8$. The b_i coefficients can be calculated as $b_i = a_i/V(0)$ and allow the description of the intensity using the size Fourier coefficients. The cubic nature of the CVF guarantees that the last integral in (5.1.47) is identically null. For the spherical case, we can easily see that $\tau_{hkl} = D$, $a_1 = \pi D^4/8$, $a_2 = 0$, $a_3 = \pi D^4/8$ and $a_4 = \pi D^4/16$ or $b_1 = 3D/4$,

$b_2 = 0$, $b_3 = 3D/4$ and $b_4 = 3D/8$, and equation (5.1.43) is recovered. Hints are given later in the chapter on the interpretation of some of these coefficients.

The simplification of equation (5.1.47) cannot be applied to a shape showing some odd trend in the Fourier terms [*e.g.* the cylinder discussed in equation (5.1.42)]: the integration in this case has to be done analytically (or numerically) *via* equation (5.1.22).

5.1.7. Meaning of the size Fourier coefficients: mean size and column-length distribution

An interpretation of the size Fourier coefficients and some insight into the possibility of extracting domain-size distribution information comes directly from the works of Bertaut (1949*a*,*b*, 1950) and Warren & Averbach (1950).[1] The form of the scattered intensity equation is the same as that of a set of linear lattices orthogonal to the diffraction planes: each scattering domain can thus be thought of as an ensemble of columns of cells oriented along the scattering direction and diffracting independently from the others.[2] The common volume function 'samples' those columns, quantifying those having the same length. For a given shape we can therefore build a column-length distribution (CLD) $p(M)$, such that $p(M)\,\mathrm{d}M$ gives the fraction of columns with a length between M and $M + \mathrm{d}M$. For instance, $p(M) = 2M/D^2$ for a sphere of diameter D. Without changing the formalism presented so far, Bertaut introduces the additional function

$$t(L) = A^S_{hkl}(L) \Big/ \left(- \frac{\partial A^S_{hkl}(L)}{\partial L} \bigg|_{L=0} \right). \tag{5.1.48}$$

This function leads to some remarkable results. In fact, we can see that

$$t(0) = \langle D \rangle \;\Leftrightarrow\; \langle D \rangle = \left(- \frac{\partial A^S_{hkl}(L)}{\partial L} \bigg|_{L=0} \right)^{-1}, \tag{5.1.49}$$

i.e. the initial slope of the Fourier coefficients is the average domain size. The value is not the same as the one that comes from the integral breadth evaluation. As the Fourier coefficients are normalized, this also represents the intercept of the initial slope tangent with the abscissa (Fig. 5.1.4). We also have

$$\int_{-\infty}^{\infty} t(L)\,\mathrm{d}L = \langle D^2 \rangle, \tag{5.1.50}$$

$$-\frac{\partial t(L)}{\partial L} = \int_L^{\infty} p(M)\,\mathrm{d}M \Leftrightarrow \frac{\partial A^S_{hkl}(L)}{\partial L} = -\frac{1}{\langle D \rangle} \int_L^{\infty} p(M)\,\mathrm{d}M, \tag{5.1.51}$$

$$\frac{\partial^2 t(L)}{\partial L^2} = p(L) \Leftrightarrow \frac{\partial^2 A^S_{hkl}(L)}{\partial L^2} = \frac{p(L)}{\langle D \rangle} \tag{5.1.52}$$

and thus the second derivative of the size Fourier coefficients is proportional to the CLD. It is worth stressing that the CLD is not the size distribution of the system: nothing can be said about the domains unless a proper modelling is done for the columns assembly.

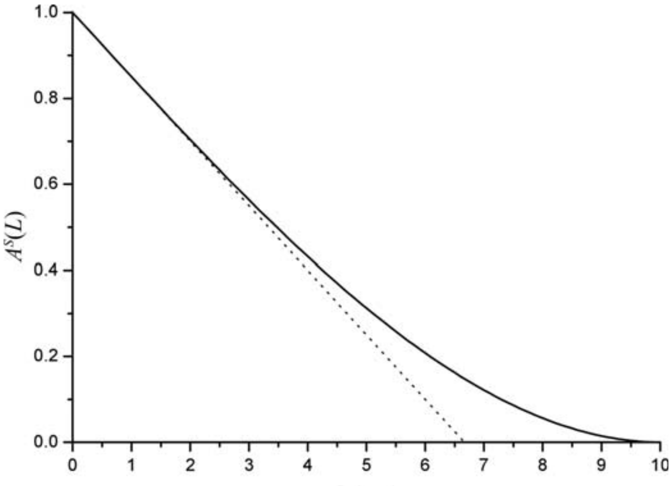

Figure 5.1.4
Size Fourier term for a sphere of 10 nm and tangent to the origin (initial slope).

For the sphere,

$$t(L) = \left(1 - \frac{3}{2}\frac{L}{D} + \frac{L^3}{2D^3} \right) \Big/ \left(\frac{3}{2D} \right) = \frac{(D-L)^2(2D+L)}{3D^2}, \tag{5.1.53}$$

$$\langle D \rangle = \left(- \frac{\partial A^S_{hkl}(L)}{\partial L} \bigg|_{L=0} \right)^{-1} = \left(\frac{3}{2D} \left(1 - \frac{L^2}{D^2} \right) \bigg|_{L=0} \right)^{-1} = \frac{2D}{3}, \tag{5.1.54}$$

$$p(L) = \langle D \rangle \frac{\partial^2 A^S_{hkl}(L)}{\partial L^2} = \frac{2D}{3} \times \frac{3L}{D^3} = \frac{2L}{D^2}. \tag{5.1.55}$$

A case where the CLD coincides with the size distribution (at least along one direction) is that of clays, as the domains are platelets with extended parallel faces (see *e.g.* Eberl *et al.*, 1996; Drits *et al.*, 1997).

The results of Bertaut place some restraints on the possible shape of a peak profile: it is in fact a misconception that peak profiles due to size contributions should be Voigtians. In fact, if we take the normalized Fourier transform of a Voigt function, $T_V(L)$ (Langford, 1978),

$$T_V(L) = \exp\left(-2\beta_C L - \pi^2 \beta_G^2 L^2\right), \tag{5.1.56}$$

where β_C and β_G are, respectively, the Cauchy and Gauss integral breadths, we obtain a column-length distribution $p_V(L)$,

$$p_V(L) = \left[4\left(\beta_C + \pi \beta_G^2 L\right)^2 - 2\pi\beta_G^2 \right] T_V(L). \tag{5.1.57}$$

Therefore, when $\beta_G \geq \beta_C (2\pi)^{1/2}$, $p_V(L)$ is negative for $0 \leq L \leq [\beta_G (2\pi)^{1/2} - 2\beta_C]/2\pi\beta_G^2$.

5.1.8. Extension of the Fourier approach to a size distribution

To what extent can the Scherrer formula be employed to the study of a real powder where a distribution of sizes is present? In 1955, Stokes wrote '*...It must be observed that this volume-average is all that we can find from measurements of breadths; we cannot find out anything about the distribution of sizes...*' (Stokes, 1955). In fact, the information on the distribution is contained in the whole profile and not in the breadth alone. Sixty years after the Scherrer equation, Langford & Wilson (1978) stated that '*. . . if there is a distribution of sizes, a modified Scherrer constant must be used*': however, the justification behind the use of a different Scherrer constant implies some *a priori* knowledge of the distribution.

---

[1] These authors state '*This important result has already been obtained by M. F. Bertaut by essentially the same method. The treatment given here is one developed by the authors before they were aware of Bertaut's work and it has been included here so as to present the particle size theory in the same notation used for distortion broadening.*' (Warren & Averbach, 1950).

[2] '*dans la méthode Debye–Scherrer un cristal est équivalent a un certain ensemble de réseaux linéaires et indépendants*' (Bertaut, 1950).

Several authors over the years have tried to propose a formalism to extract a size distribution from the diffraction data. The first milestone was the systematic work of Jones (1938), which among the several results shows that the size obtained from the integral breadth is the ratio of the fourth and third moments of the size distribution [Jones, 1938, equations (32)–(34)]. For a sufficiently large number of domains this results in

$$\langle D\rangle_{\rm IB}=\frac{\int_0^\infty p(D)D^4\,{\rm d}D}{\int_0^\infty p(D)D^3\,{\rm d}D},\quad \langle D\rangle_{\rm true}=\frac{\int_0^\infty p(D)D\,{\rm d}D}{\int_0^\infty p(D)\,{\rm d}D},\qquad(5.1.58)$$

where $\langle D\rangle_{\rm IB}$ and $\langle D\rangle_{\rm true}$ are, respectively, the size that we can measure *via* the integral breadth and the one that we would like to obtain. Jones obtained the arithmetic mean $\langle D\rangle_{\rm true}$ for a (non-physical) Gaussian distribution and for a Maxwellian one. The size obtained from the integral-breadth analysis is therefore a volume-weighted one. It can be also demonstrated that the size obtained from the Fourier analysis is an area-weighted one. The latter can be obtained as the ratio between the third and second moments of the distribution (Wilson, 1968):

$$\langle D\rangle_{\rm Fourier}=\frac{\int_0^\infty p(D)D^3\,{\rm d}D}{\int_0^\infty p(D)D^2\,{\rm d}D}.\qquad(5.1.59)$$

Therefore, if we know the two size values and we impose the type of distribution, we can obtain information on the first moment [see *e.g.* Krill & Birringer (1998) for the lognormal case].

A further discussion on the Fourier coefficients was presented by Smith (1976): with the intent of comparing the size measured from a transmission electron microscope (TEM) micrograph with that obtained from diffraction, he proposed the possibility of recovering the domain-size distribution directly from the column-length distribution, once the shape of the domain (and thus the common volume function) is known. Following Smith (1976), if the number of domains with sizes between A and A + dA is $G(A)$ dA and the number of columns with lengths between L and L + dL is given by $f(L, A)$dL, then the total number dN of columns with lengths between L and L + dL is

$${\rm d}N=p(L)\,{\rm d}L=\int\limits_{A_0(L)}^{\infty}f(L,A)G(A)\,{\rm d}A\,{\rm d}L,\qquad(5.1.60)$$

where $A_0(L)$ is the smallest A that can accommodate a column of length L. The column-length distribution $p(L)$, as seen previously [*cf.* equation (5.1.52)], is the second derivative of the Fourier coefficients. It is therefore possible, in principle, to obtain the size distribution $G(A)$ by suitably taking a derivative of the column-length distribution. Unfortunately the procedure, albeit correct from a mathematical point of view, can rarely be applied in practice for the estimation of the size distribution. It is in fact necessary to strip off the other sources of broadening and take a higher-order derivative of the (experimental) Fourier coefficients: noise can be a real issue with this (Le Bail & Louër, 1978).

A decade later, Rao & Houska (1986) started from the same point, but instead of extracting the size distribution from the CLD, they worked the other way round, deriving an approximate expression for $p(L)$ and using it to generate the size Fourier coefficients and build the profile. Vogel (1990) proposed a similar approach, based on the properties of the column-size distribution. To be a distribution, the CLD must in fact obey two simple rules:

$$\left.\frac{\partial^2A^S_{hkl}(L)}{\partial L^2}\right|_{L=0}=\left.\frac{p(L)}{\langle D\rangle}\right|_{L=0}=0,\qquad(5.1.61)$$

$$\lim_{L\to\infty}\frac{\partial^2A^S_{hkl}(L)}{\partial L^2}=\lim_{L\to\infty}\frac{p(L)}{\langle D\rangle}=0.\qquad(5.1.62)$$

A suitable class of functions possessing those two properties is of the type

$$A^S_{hkl}(L,D)=P(L/D)\exp(-L/D),\quad P(L/D)=\sum_{k=0}^{k_{\rm max}}a_kL^k\big/D^k.\qquad(5.1.63)$$

Vogel proposed two shapes for the function P above (identified as types I and II):

$$\text{I:}\quad a_0=1,\quad a_1=1/2,\qquad(5.1.64)$$

$$\text{II:}\quad a_0=1,\quad a_1=7/10,\quad a_2=1/5,\quad a_3=1/40.\qquad(5.1.65)$$

For spherical domains, the size distribution $H(D)$ compatible with the given CLD is proportional to

$$H(D)=\frac{\rm d}{{\rm d}L}\left.\left(\frac{1}{L}\frac{\partial^2A^S_{hkl}(L)}{\partial L^2}\right)\right|_{L=D}.\qquad(5.1.66)$$

The corresponding peak profile, obtained by Fourier transform, reads

$$I(x)=2D\sum_{k=0}^{k_{\rm max}}k!a_k{\rm Re}\big(u^{-k-1}\big),\quad u=1-2\pi ixD.\qquad(5.1.67)$$

If, according to (5.1.64), we set a_0 = 1 and $a_1=\frac{1}{2}$, we obtain a profile described as the sum of a Lorentzian and a squared Lorentzian:

$$I(x)=\big(1+4\pi^2x^2D^2\big)^{-1}+2\big(1+4\pi^2x^2D^2\big)^{-2}.\qquad(5.1.68)$$

The calculation of the profile for a polydisperse system is much simpler if we pass through the common volume function. The diffraction profile of an ensemble of scattering domains scattering incoherently with respect to one another is in fact the sum of the diffraction profiles from each of those domains. In turn, each domain contributes with a scattering power proportional to its volume (*i.e.* the number of scattering centres). For the *hkl* profile of a distribution of objects of shape *c*, we have

$$\begin{aligned}I_{c,hkl}(s)&\propto\frac{\int_0^\infty I_{c,hkl}(s,D)g(D)V_c(D)\,{\rm d}D}{\int_0^\infty g(D)V_c(D)\,{\rm d}D}\\&=\frac{\int_0^\infty I_{c,hkl}(s,D)w(D)\,{\rm d}D}{\int_0^\infty w(D)\,{\rm d}D},\end{aligned}\qquad(5.1.69)$$

where $g(D)$ is the size distribution function and where $I_{c,hkl}(s, D)$ and $V_c(D)$ are, respectively, the profile and the volume of the domain of shape c and size D. The weighting (or visibility) function $w(D) = g(D)V_c(D)$ is introduced: the larger the volume, the larger the contribution of the corresponding domain(s). If we now insert in equation (5.1.69) the explicit formula for the intensity profile of a single domain of shape c and size D, we obtain

$$
\begin{aligned}
I_{c,hkl}(s) &\propto \frac{\int_0^\infty \left(\int_{L=0}^{D/K_{hkl}} A^S_{c,hkl}(L,D)\exp(2\pi iLs)\,\mathrm{d}L\right) w(D)\,\mathrm{d}D}{\int_0^\infty w(D)\,\mathrm{d}D}\\
&\propto \frac{\int_{L=0}^\infty \left(\int_{D=LK_{hkl}}^\infty A^S_{c,hkl}(L,D)w(D)\,\mathrm{d}D\right)\exp(2\pi iLs)\,\mathrm{d}L}{\int_0^\infty w(D)\,\mathrm{d}D}\\
&\propto \int_{L=0}^\infty \left(\frac{\int_{D=LK_{hkl}}^\infty A^S_{c,hkl}(L,D)w(D)\,\mathrm{d}D}{\int_0^\infty w(D)\,\mathrm{d}D}\right)\exp(2\pi iLs)\,\mathrm{d}L
\end{aligned}
\tag{5.1.70}
$$

with $K_{hkl} = \tau_{hkl}/D$ (see Table 5.1.1). By introducing the Fourier coefficients $A^S_{hkl}(L)$ for the system of domains,

$$
A^S_{hkl}(L) = \frac{\int_{D=LK_{hkl}}^\infty A^S_{c,hkl}(L,D)w(D)\,\mathrm{d}D}{\int_0^\infty w(D)\,\mathrm{d}D},
\tag{5.1.71}
$$

we obtain an expression for the intensity analogous to that of a single domain [*cf.* equation (5.1.22)]:

$$
I(s) \propto \int\limits_{L=0}^{\infty} A^S_{hkl}(L)\exp(2\pi iLs)\,\mathrm{d}L.
\tag{5.1.72}
$$

5.1.9. Analytical distributions

In the general case, it is not possible to obtain the profile of a polydispersed system in closed form, as the existence of an analytical primitive for equation (5.1.72) cannot be guaranteed. It is, however, possible to find solutions both for the Fourier coefficients and for the profiles in some particular cases (Scardi & Leoni, 2001; Scardi *et al.*, 2006). For instance, the Fourier coefficients for a lognormal distribution of D defined as

$$
g_l(D) = \frac{1}{D\sigma_l(2\pi)^{1/2}}\exp\left[-\frac{(\ln D-\mu_l)^2}{2\sigma_l^2}\right]
\tag{5.1.73}
$$

with moments

$$
M_{l,n} = \exp\left(n\mu_l + \frac{n^2}{2}\sigma_l^2\right)
\tag{5.1.74}
$$

can easily be obtained as (Scardi & Leoni, 2001)

$$
\begin{aligned}
&A^S_{l,hkl}(L)\\
&\quad= \int_{D=LK_{hkl}}^\infty \sum\nolimits_{n=0}^3 \left(H^c_n\frac{L^n}{D^n}\right)D^3\frac{1}{D\sigma_l(2\pi)^{1/2}}\\
&\qquad\times \exp\left(-(\log D-\mu_l)^2/\left(2\sigma_l^2\right)\right)\mathrm{d}D\\
&\qquad\times\left[\int_0^\infty D^3\frac{1}{D\sigma_l(2\pi)^{1/2}}\exp\left(-(\log D-\mu_l)^2/\left(2\sigma_l^2\right)\right)\mathrm{d}D\right]^{-1}\\
&\quad= \sum_{n=0}^3 H^c_n\,\mathrm{erfc}\left[\frac{\ln(LK_{hkl})-\mu_l-(3-n)\sigma_l^2}{\sigma_l(2)^{1/2}}\right]\frac{M_{l,3-n}}{2M_{l,3}}L^n,
\end{aligned}
\tag{5.1.75}
$$

whereas the corresponding profile

$$
\begin{aligned}
I_{l,hkl}(s) \propto \int\limits_{L=0}^{\infty}\sum_{n=0}^{3} H^c_n\,\mathrm{erfc}\left[\frac{\ln(LK_{hkl})-\mu_l-(3-n)\sigma_l^2}{\sigma_l(2)^{1/2}}\right]\\
\times\frac{M_{l,3-n}}{2M_{l,3}}L^n\cos(2\pi Ls)\,\mathrm{d}L
\end{aligned}
\tag{5.1.76}
$$

can just be calculated *via* (fast) Fourier transform. Popa & Balzar (2002) and Ida *et al.* (2003) have proposed approximate expressions for the case of spherical domains. Popa & Balzar employed Gauss–Hermite quadrature, leading to a quite large error in the intensity for wide distributions. Ida *et al.* used a smart change of variables and employed Gauss–Legendre quadrature, obtaining a profile that closely resembles the true one.

An alternative to the lognormal is the gamma distribution, defined as

$$
\begin{aligned}
g_p(D) &= \frac{\sigma_p}{\mu_p\Gamma(\sigma_p)}\left(\frac{\sigma_pD}{\mu_p}\right)^{\sigma-1}\exp\left(-\frac{\sigma_pD}{\mu_p}\right),\\
\Gamma(x) &= \int\limits_0^\infty y^{x-1}\exp(-y)\,\mathrm{d}y,
\end{aligned}
\tag{5.1.77}
$$

with moments

$$
M_{p,n} = \left(\frac{\mu_p}{\sigma_p}\right)^n\frac{\Gamma(n+\sigma_p)}{\Gamma(\sigma_p)}.
\tag{5.1.78}
$$

The Fourier coefficients can easily be calculated as (Scardi & Leoni, 2001)

$$
A^S_{p,hkl}(L) = \sum_{n=0}^3 H^c_n\left(\frac{\sigma_p}{\mu_p}\right)^n\frac{\Gamma\left[\sigma_p+(3-n),K_{hkl}L\sigma_p/\mu_p\right]}{\Gamma(\sigma_p+3)}L^n.
\tag{5.1.79}
$$

An approximation of the corresponding line profile was proposed by Popa & Balzar (2002), who employed Gauss–Laguerre quadrature for the calculation. An analytical, albeit wrong, expression was obtained by Pielaszek (2004): its derivation lacks a proper volume weighting. The correct result can be found in Scardi *et al.* (2006) for any polyhedron having a common volume function described by equation (5.1.41). The intensity in this case reads

$$
\begin{aligned}
I_p(s;\mu_p,\sigma_p) = \frac{k(s)\mu_p\Phi^{-(3+\sigma)/2}}{4\psi^3K^3_{hkl}}&\left\{\frac{K_{hkl}\sigma_p(\Phi)^{1/2}}{(2+\sigma_p)}\right.\\
&\times\left[2(3H_3+K_{hkl}(2H_2+H_1K_{hkl}))\psi\cos\left((2+\sigma_p)\Theta\right)\right.\\
&\left.+\frac{K^2_{hkl}}{\psi}\Phi\left(\frac{3H_3\sigma_p}{1+\sigma_p}\left(\Phi^{\sigma/2}-\cos(\sigma_p\Theta)\right)-2H_1\psi^2\Phi^{\sigma/2}\right)\right]\\
&-2\left[\frac{K^2_{hkl}\sigma_p^2\Phi(3H_3+H_2K_{hkl})}{(2+\sigma_p)(1+\sigma_p)}\sin\left((1+\sigma_p)\Theta\right)\right.\\
&\left.\left.-2\psi^2(H_3+K_{hkl}(H_2+K(H_1+H_0K_{hkl})))\sin\left((3+\sigma_p)\Theta\right)\right]\right\},
\end{aligned}
\tag{5.1.80}
$$

where as usual $\psi = \pi s\tau_{hkl}$ and also $\Omega = 2\psi/(K\sigma)$, $\Theta = \tan^{-1}\Omega$ and $\Phi = 1+\Omega^2$. For the case of a lognormal distribution of spheres, equation (5.1.80) reduces to

$$
\begin{aligned}
I_{p,\mathrm{sphere}}(s;\mu,\sigma) = k(s)\frac{3\mu\sigma}{8\psi^4}&\left\{\frac{2\psi^2}{2+\sigma}+\frac{\sigma}{2+3\sigma+\sigma^2}\right.\\
&\times\left[1-\left(1+\left(\frac{2\psi}{\sigma}\right)^2\right)^{-\sigma/2}\cos\left(\sigma\,\mathrm{atan}\left(\frac{2\psi}{\sigma}\right)\right)\right.\\
&\left.\left.-2\psi\left(1+\left(\frac{2\psi}{\sigma}\right)^2\right)^{-(\sigma+1)/2}\sin\left((1+\sigma)\,\mathrm{atan}\left(\frac{2\psi}{\sigma}\right)\right)\right]\right\}.
\end{aligned}
\tag{5.1.81}
$$

5.1.10. Histogram (arbitrary) distributions

An analytical distribution is not always able to describe the observed profiles. In fact, the presence of a multimodal distribution or a complex arrangement cannot be excluded. The Fourier formalism proposed in equation (5.1.70) is still valid in this case. As shown by Leoni & Scardi (2004), the analytical distribution can be replaced by a histogram and the integration thus replaced with a sum over all histogram bins:

$$A^S_{hkl}(L) = \frac{\sum_{k=k_{hkl}}^{n} A^S_{c,hkl}(L, D_k) g(D_k) W_k D_k^3}{\sum_{k=k_{hkl}}^{n} g(D_k) W_k D_k^3},$$
$$\exists k_{hkl} : 1 \le k_{hkl} \le n, D_{\max(1, k_{hkl}-1)} \le L K_{hkl} \le D_{k_{hkl}}, \tag{5.1.82}$$

where n is the number of bins, D_k is the average size corresponding to the kth histogram bin, $g(D_k)$ is the number of domains of average size D_k and W_k is the width of the kth bin (*e.g.* equal to the difference of the D values of consecutive bins in a linear sampling). For a given L the sum runs from the first bin corresponding to a size not smaller than $L\tau_{hkl}$. Very high quality data and a reasonably small number of bins should be employed to avoid the extraction of information from the noise and from the background. Failure to do so often results in the appearance of an unphysical fraction of small domains that represents the contributions of a smooth background and of thermal diffuse scattering. In this case, we can either start the distribution at a larger size or, as suggested by Matěj *et al.* (2011), use Tikhonov regularization and/or a logarithmically sampled histogram to stabilize the algorithm.

An alternative was proposed by David *et al.* (2010), working directly in 2θ space and using the result of Wilson for a single sphere [equation (5.1.43)]: the global profile is simply the weighted sum of the profiles corresponding to each size component.

5.1.11. Example

The determination of the size of the domains in a ceria specimen is described here. The specimen was thoroughly characterized both by diffraction and transmission electron microscopy (Leoni *et al.*, 2004) and the corresponding powder-diffraction pattern is shown in Fig. 5.1.5. The data were collected on a Bragg–Brentano diffractometer showing quite a narrow and symmetrical instrumental profile using Cu $K\alpha$ radiation and a secondary graphite monochromator. The domains are spherical (*cf.* Leoni *et al.*, 2004) and the lattice is face-centred cubic, so most of the calculations can be done analytically. For the practical application of some of the formulae, the software *PM2K* (Leoni *et al.*, 2006) was used.

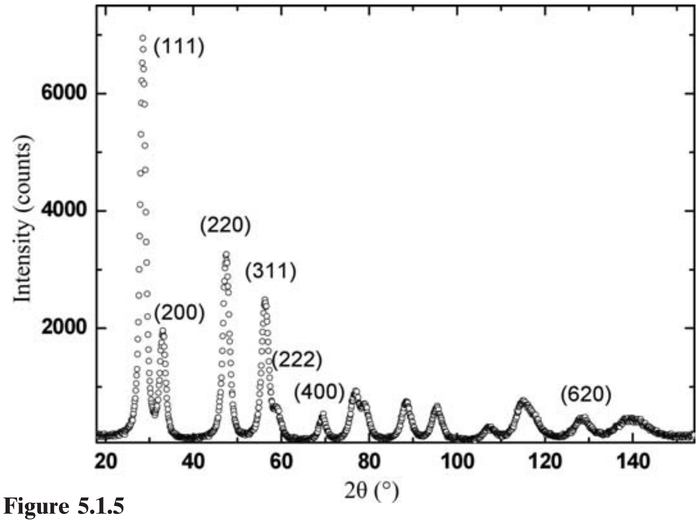

Figure 5.1.5
Nanocrystalline ceria pattern; the indices for some reflections are indicated.

The analysis will be done for the 111 and 200 reflections of ceria using several of the approaches proposed in this chapter. The analysis will be thus limited to the 2θ range 20–40°.

To apply the original Scherrer formula, we can estimate by eye (or using a ruler) the width of the 111 and 200 reflections, as in Fig. 5.1.6(*a*): this results in FWHM_{111} = 1.53° and FWHM_{200} = 1.68°. We cannot resolve the two emission components, we do not have any information on the instrumental effects and the estimation for the smaller peak is definitely more difficult. Scherrer analysis gives

$$\begin{aligned}\left.\frac{\langle D\rangle}{K_w}\right|_{111} &= \frac{\lambda}{\mathrm{FWHM}_{111}\cos\theta_{111}}\\ &= \frac{1.5406\times10^{-1}}{\dfrac{(29.28-27.75)^{\circ}\,\pi}{180^{\circ}}\cos\left(\dfrac{(29.28+27.75)/2^{\circ}}{2}\right)}\ \mathrm{nm}\\ &= 5.95\ \mathrm{nm},\\ \left.\frac{\langle D\rangle}{K_w}\right|_{200} &= \frac{\lambda}{\mathrm{FWHM}_{200}\cos\theta_{200}}\\ &= \frac{1.5406\times10^{-1}}{\dfrac{(33.89-32.21)^{\circ}\,\pi}{180^{\circ}}\cos\left(\dfrac{(33.89+32.21)/2^{\circ}}{2}\right)}\ \mathrm{nm}\\ &= 5.48\ \mathrm{nm}.\end{aligned} \tag{5.1.83}$$

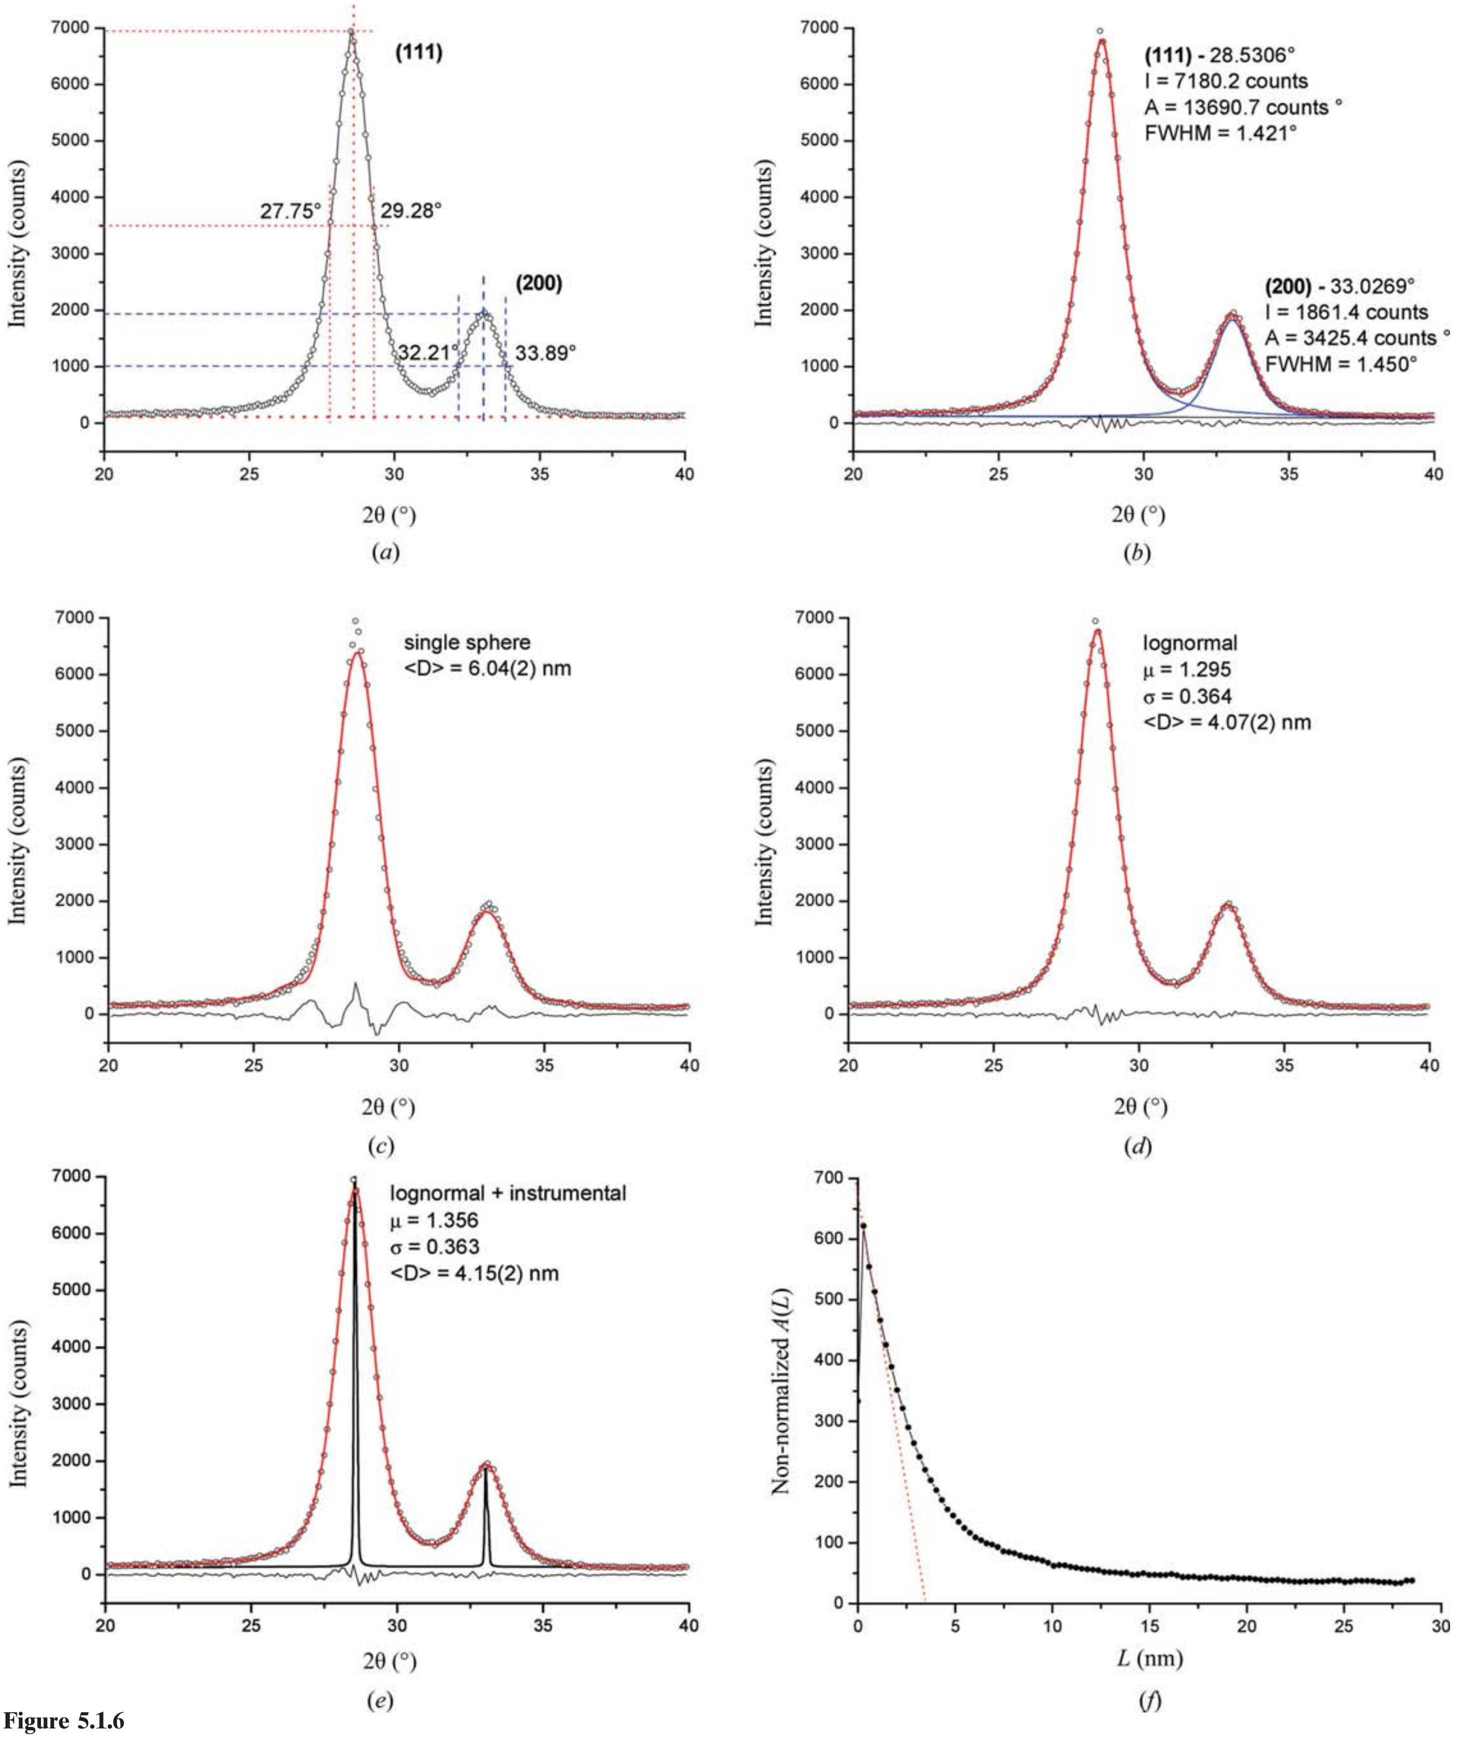
The choice of the wavelength (an average value of 1.5406 Å was employed in this case) is definitely not critical. The two values are slightly different. We can also calculate the integral breadth of the profile, for example by fitting each peak with a couple of Voigt functions (to take the emission profile into account) and considering a linear Chebyshev polynomial background. The FWHM estimated in this way is smaller than the one estimated before (therefore the instrument plays some role, even if the effects cannot be easily seen). The integral-breadth analysis gives in this case (*cf.* Fig. 5.1.6*b*)

$$\left.\frac{\langle D\rangle}{K_\beta}\right|_{111} = \frac{1}{\beta_{111}} = \frac{1.5406\times10^{-1}}{\dfrac{13690.7}{7180.2}\dfrac{\pi}{180}\cos\left(\dfrac{28.5306^{\circ}}{2}\right)}\ \mathrm{nm} = 4.77\ \mathrm{nm}, \tag{5.1.84}$$

$$\left.\frac{\langle D\rangle}{K_\beta}\right|_{200} = \frac{1}{\beta_{200}} = \frac{1.5406\times10^{-1}}{\dfrac{3425.4}{1861.4}\dfrac{\pi}{180}\cos\left(\dfrac{33.0269^{\circ}}{2}\right)}\ \mathrm{nm} = 5.00\ \mathrm{nm}. \tag{5.1.85}$$

We see some differences between the values calculated with the two methods. However, we should remember the different definition of the Scherrer constant in the two cases.

We can also apply the Fourier formalism, using the known common volume function for the sphere. We show at the beginning the best fit of the model to the experimental data. For consistency, neither the instrumental contribution nor other sources of broadening were considered. Fig. 5.1.6(*c*) shows the modelling using the peak profile for a single sphere. It is clear that the oscillations present in the profile [*cf.* equation (5.1.43)] are



(*a*) (*b*) (*c*) (*d*) (*e*) (*f*)

Figure 5.1.6

Analysis of the 111 and 200 reflections of ceria: (*a*) calculation using the FWHM, (*b*) fit using Voigt functions: the single profiles are shown, (*c*) modelling as a single sphere, (*d*) modelling as a lognormal distribution of spheres, (*e*) comparison of the instrumental profile with the measured profile and modelling using a lognormal distribution of spheres, taking the instrumental contribution into account, and (*f*) cosine Fourier transform of the left side of the 111 peak. The difference between the data and the model is plotted at the bottom of (*b*)–(*e*).

not observed in the experimental pattern and do not allow for a perfect match. The size is highly overestimated. If we consider a lognormal distribution of size [Fig. 5.1.6(*d*) and equation (5.1.76)], we obtain a match quite similar to that of Fig. 5.1.6(*b*), but with a stronger physical meaning (the whole profile shape is compatible with the microstructure).

The instrument plays little role in this case. Fig. 5.1.6(*e*) shows the instrumental profile obtained by collecting the data for the

NIST SRM 660a (LaB_6) line-profile standard, fitting all reflections with pseudo-Voigt functions, parameterizing the profile parameters according to the Caglioti *et al.* (1958) equation and calculating the corresponding peak in the position of the ceria peaks and with a maximum intensity equal to that obtained from Fig. 5.1.6(*b*). The effect of this contribution on the value of the size can be seen at the second decimal place (see the ceria peaks modelling in Fig. 5.1.6*e*). The size value tends to become closer to the average one obtained by TEM (*cf.* Leoni *et al.*, 2004), but cannot reach it, as the other sources of broadening (notably strain) are not considered.

Fig. 5.1.6(*f*) shows what happens if we try to extract the Fourier coefficients from the data: to avoid any biasing introduced by the choice of the profile function, size Fourier coefficients were extracted from the (111) peak of ceria directly. The left tail of the (111) peak, remapped in $s = d^* - d^*_{hkl}$ space, was selected (this limits the problems with the emission-profile doublet). The position of the experimental point corresponding to the peak top ($2\theta = 28.5^\circ$) was chosen as d^*_{hkl}. The point at zero clearly does not follow the trend. This is one of the manifestations of the so-called ‘hook effect’: the causes are several and are all related to the choice of the centre of the peak and of the other (non-size) broadening sources. In our case, we selected the centre in a measured position and not where it was supposed to be. Moreover, the peak is still affected by the emission profile and the neighbouring 222 reflection. If we simply skip the first point, we can indeed calculate an initial slope tangent whose intercept provides an average size of 3.50 nm [which should correspond to an average diameter of 5.25 nm for a delta distribution if we take equation (5.1.54) into account].

5.2. Stress and strain

N. C. Popa

5.2.1. The importance of determining stress and the diffraction method

The determination of the elastic stress and strain state in polycrystalline samples is one of the oldest applications of the powder diffraction technique. Stress, which can be either residual or loading, can be beneficial or, in contrast, can provoke premature failures of manufacturing materials and machine parts. Consequently, determination of the stress and strain state is of major importance in engineering and technological applications and also in geology, mining and earth science.

There are several methods for investigating stress: mechanical, acoustic, optical and the diffraction of X-rays and neutrons, with the latter being the most appropriate for crystalline matter. The diffraction method is based on the variation in interplanar distance (*d*-spacing) caused by the strain induced by stress. There are two possible *d*-spacing variation effects that can be observed and measured by diffraction: peak shift and peak broadening. Peak shift is observed if the average strain on the irradiated sample volume (the macroscopic strain) differs from zero, while peak broadening is connected to the strain dispersion. There is a rich literature on these subjects. The comprehensive monographs by Noyan & Cohen (1987) and Hauk (1997) are strongly recommended for macrostrain peak shift, and the books by Wilson (1962) and by Warren (1969) for strain broadening.

5.2.2. Strain and stress in single crystals, elastic constants and transformations

The strain and stress are symmetrical tensors of rank 2. If $\mathbf{u}(\mathbf{r})$ is a small displacement of the point at position vector $\mathbf{r}$ in a single crystal, then the strain tensor is defined as

$$\varepsilon_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \quad (i, j = 1, 2, 3), \qquad (5.2.1)$$

where u_i and x_i are the components of $\mathbf{u}$ and $\mathbf{r}$ in an orthogonal coordinate system ($\mathbf{x}_i$, $i = 1, 2, 3$). The element σ_{ij} of the stress tensor is defined as the i component of the force acting on the unit area normal to the vector $\mathbf{x}_j$. For $i \neq j$ we have $\sigma_{ij} - \sigma_{ij} = 0$, otherwise the body rotates around the vector $\mathbf{x}_h = \mathbf{x}_i \times \mathbf{x}_j$. Thus, while the strain tensor is symmetrical by definition, the symmetry of the stress tensor is imposed by the mechanical equilibrium.

The magnitudes of the strain-tensor and stress-tensor elements are different in different reference systems. Let us consider another reference system ($\mathbf{y}_i$, $i = 1, 2, 3$) and denote by $\mathbf{a}(g)$ the Euler matrix transforming this system into ($\mathbf{x}_i$, $i = 1, 2, 3$),

$$\mathbf{x}_i = \sum_{j=1}^{3} a_{ij}(g)\mathbf{y}_j, \qquad (5.2.2)$$

$$\mathbf{a}(g) = \begin{pmatrix} \cos\varphi_1\cos\varphi_2 - \sin\varphi_1\sin\varphi_2\cos\Phi_0 & \sin\varphi_1\cos\varphi_2 + \cos\varphi_1\sin\varphi_2\cos\Phi_0 & \sin\varphi_2\sin\Phi_0 \\ -\cos\varphi_1\sin\varphi_2 - \sin\varphi_1\cos\varphi_2\cos\Phi_0 & -\sin\varphi_1\sin\varphi_2 + \cos\varphi_1\cos\varphi_2\cos\Phi_0 & \cos\varphi_2\sin\Phi_0 \\ \sin\varphi_1\sin\Phi_0 & -\cos\varphi_1\sin\Phi_0 & \cos\Phi_0 \end{pmatrix}. \qquad (5.2.3)$$

Here, the triplet $g = \varphi_1, \Phi_0, \varphi_2$ denotes the standard Euler angles, namely $\varphi_1 \in (0, 2\pi)$ is a rotation of the reference system ($\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3$) around $\mathbf{y}_3$, resulting in ($\mathbf{y}_1', \mathbf{y}_2', \mathbf{y}_3$), $\Phi_0 \in (0, \pi)$ is the rotation of this system around $\mathbf{y}_1'$, resulting in ($\mathbf{y}_1', \mathbf{y}_2'', \mathbf{x}_3$), and, finally, $\varphi_2 \in (0, 2\pi)$ is the rotation of the last system around $\mathbf{x}_3$, resulting in ($\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$). Let us denote the strain and stress tensors in the system ($\mathbf{y}_i$, $i = 1, 2, 3$) by the Latin characters e_{ij} and s_{ij}, respectively. The transformations of the strain- and the stress-tensor elements in the coordinate-system transformation (5.2.2) are easily derived starting from the tensor definitions. For the strain tensor these are the following, with similar expressions being valid for stress:

$$\varepsilon_{ij} = \sum_{k=1}^{3}\sum_{m=1}^{3} a_{ik}a_{jm}e_{km}, \qquad (5.2.4a)$$

$$e_{km} = \sum_{i=1}^{3}\sum_{j=1}^{3} a_{ik}a_{jm}\varepsilon_{ij}. \qquad (5.2.4b)$$

The quantity observable in a diffraction experiment is the *d*-spacing variation along the reciprocal-lattice vector $\mathbf{H}(h, k, l)$ of unit vector $\mathbf{h}$,

$$[d(hkl) - d_0(hkl)]/d_0(hkl) = \Delta d/d_0 = -\Delta H/H_0 = \varepsilon_{hh} \equiv e_{hh}. \qquad (5.2.5)$$

To calculate this quantity from the strain-tensor elements ε_{ij} in ($\mathbf{x}_i$), we must define the reference system ($\mathbf{k}$, $\mathbf{l}$, $\mathbf{h}$) with the axis $\mathbf{k}$ in the plane ($\mathbf{x}_3$, $\mathbf{h}$) and normal to $\mathbf{h}$ and $\mathbf{l} = \mathbf{h} \times \mathbf{k}$. Describing the unit vector $\mathbf{h}$ by the polar and azimuthal angles (Φ, β), the connection between the ($\mathbf{k}$, $\mathbf{l}$, $\mathbf{h}$) and ($\mathbf{x}_i$) systems is

$$\begin{pmatrix} \mathbf{k} \\ \mathbf{l} \\ \mathbf{h} \end{pmatrix} = \mathbf{m}(\Phi, \beta)\begin{pmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \mathbf{x}_3 \end{pmatrix}, \qquad (5.2.6)$$

$$\mathbf{m}(\Phi, \beta) = \begin{pmatrix} \cos\Phi\cos\beta & \cos\Phi\sin\beta & -\sin\Phi \\ -\sin\beta & \cos\beta & 0 \\ \sin\Phi\cos\beta & \sin\Phi\sin\beta & \cos\Phi \end{pmatrix}. \qquad (5.2.7)$$

A comparison of (5.2.6) with (5.2.2) allows the use of a transformation similar to (5.2.4*a*) to calculate ε_{hh},

$$\varepsilon_{hh} = \sum_{k=1}^{3}\sum_{m=1}^{3} m_{3k}(\Phi, \beta)m_{3m}(\Phi, \beta)\varepsilon_{km} = \sum_{k=1}^{3}\sum_{m=1}^{3} a_k a_m \varepsilon_{km}. \qquad (5.2.8)$$

Here, $(a_1, a_2, a_3) = (\cos\beta\sin\Phi, \sin\beta\sin\Phi, \cos\Phi)$ are the direction cosines of $\mathbf{h}$ in ($\mathbf{x}_i$). If the polar and azimuthal angles of $\mathbf{h}$ in ($\mathbf{y}_i$)

Copyright © 2019 International Union of Crystallography

are (Ψ, γ), then the direction cosines are $(b_1, b_2, b_3) = (\cos\gamma \sin\Psi, \sin\gamma \sin\Psi, \cos\Psi)$ and in place of (5.2.8) we have

$$e_{hh} = \sum_{k=1}^{3} \sum_{m=1}^{3} m_{3k}(\Psi, \gamma) m_{3m}(\Psi, \gamma) e_{km} = \sum_{k=1}^{3} \sum_{m=1}^{3} b_k b_m e_{km}. \quad (5.2.9)$$

Hereafter, we denote ε_{hh} and e_{hh} simply by $\varepsilon_{\mathbf{h}}$ and $e_{\mathbf{h}}$, respectively. We have $e_{\mathbf{h}} \equiv \varepsilon_{\mathbf{h}}$ as they define the same quantity.

In the limits of an elastically deformed body the stress and strain tensors are connected by the Hooke equations. To derive these equations, one starts from the elastic free energy per unit volume. The differential of this quantity is $\mathrm{d}F = \sum_{i=1}^{3} \sum_{j=1}^{3} \sigma_{ij}\, \mathrm{d}\varepsilon_{ij}$, and the Hooke equations are then

$$\sigma_{ij} = \frac{\partial F}{\partial \varepsilon_{ij}} \quad (i, j = 1, 2, 3). \quad (5.2.10)$$

As the magnitudes of the strain-tensor elements are small, the elastic free energy can be expanded in powers of these quantities, limiting the expansion to the second-order terms. As the terms of order zero and of order one are zero because F and σ_{ij} are zero when $\varepsilon_{ij} = 0$, we can write

$$F = \frac{1}{2} \sum_{i=1}^{3} \sum_{j=1}^{3} \sum_{k=1}^{3} \sum_{l=1}^{3} C_{ijkl} \varepsilon_{ij} \varepsilon_{kl}. \quad (5.2.11)$$

Here, C_{ijkl} are the stiffness elastic constants forming a fourth-rank tensor of 81 elements. As the strain tensor is symmetrical, the product $\varepsilon_{ij}\varepsilon_{kl}$ does not change if the indices i, j and k, l, as well as the pairs ij, kl, are permuted. The tensor C_{ijkl} can be chosen to have the same properties; as a consequence 21 independent constants remain for triclinic crystals, and their number decreases on increasing the Laue symmetry. By applying (5.2.10) to (5.2.11), one obtains

$$\sigma_{ij} = \sum_{k=1}^{3} \sum_{l=1}^{3} C_{ijkl} \varepsilon_{kl} \quad (i, j = 1, 2, 3). \quad (5.2.12)$$

There are nine equations in (5.2.12), but only six are independent because for every $i \neq j$ there are two equal strain and stress elements, respectively, and thus two identical equations. Inverting (5.2.12), we have

$$\varepsilon_{ij} = \sum_{k=1}^{3} \sum_{l=1}^{3} S_{ijkl} \sigma_{kl} \quad (i, j = 1, 2, 3), \quad (5.2.13)$$

where S_{ijkl} is a fourth-rank tensor of compliance elastic constants with exactly the same symmetry properties as the tensor of stiffness constants C_{ijkl}.

We can take advantage of the symmetry of the strain, stress and elastic constants tensors to introduce reduced indices defined as follows:

$$\begin{aligned} &11 \rightarrow 1, \quad 22 \rightarrow 2, \quad 33 \rightarrow 3, \quad 23 = 32 \rightarrow 4, \\ &\qquad 13 = 31 \rightarrow 5, \quad 12 = 21 \rightarrow 6. \end{aligned} \quad (5.2.14)$$

By using the reduced indices the strain and stress tensors are represented as vectors of dimension 6 and the elastic-constants tensors as symmetrical matrices of dimensions 6 × 6.

We then pass to the reduced-indices representation according to the convention described by Wooster (1973),[1]

$$\begin{aligned} &\varepsilon_{ij} = \varepsilon_{ji} \rightarrow \varepsilon_m \quad (m = 1, \ldots, 6), \\ &C_{ijkl} = C_{jikl} = C_{ijlk} = C_{klij} \rightarrow C_{mn} \quad (m, n = 1, \ldots, 6), \end{aligned} \quad (5.2.15)$$

and similarly for the stress tensor and compliance constants.

Accounting for (5.2.14) and (5.2.15), the transformations (5.2.4) for strain and for stress become

$$\varepsilon_i = \sum_{j=1}^{6} Q_{ij} e_j, \quad (5.2.16a)$$

$$e_i = \sum_{j=1}^{6} P_{ij} \varepsilon_j, \quad (5.2.16b)$$

$$\sigma_i = \sum_{j=1}^{6} Q_{ij} s_j, \quad (5.2.16c)$$

$$s_i = \sum_{j=1}^{6} P_{ij} \sigma_j. \quad (5.2.16d)$$

The matrices $\mathbf{Q}$ and $\mathbf{P} = \mathbf{Q}^{-1}$ of dimensions 6 × 6 in (5.2.16) can be expressed by another four matrices of dimensions 3 × 3 that are calculated from the elements of the Euler matrix (5.2.3),

$$\mathbf{Q} = \begin{pmatrix} \mathbf{L} & 2\mathbf{M} \\ \mathbf{N} & \mathbf{O} \end{pmatrix}, \quad (5.2.17a)$$

$$\mathbf{P} = \begin{pmatrix} \mathbf{L}^t & 2\mathbf{N}^t \\ \mathbf{M}^t & \mathbf{O}^t \end{pmatrix}, \quad (5.2.17b)$$

$$\left.\begin{aligned} &L_{kl} = a_{kl}^2, \quad M_{lk} = a_{li} a_{lj}, \quad N_{kl} = a_{il} a_{jl} \\ &O_{ij} = a_{kk} a_{ji} + a_{ki} a_{jk}, \; O_{kk} = a_{ii} a_{jj} + a_{ij} a_{ji} \end{aligned}\right\}, \; \left\{\begin{aligned} &i, j, k, l = 1, 2, 3 \\ &i \neq j \neq k \end{aligned}\right. . \quad (5.2.17c)$$

The following notation will be used:

$$(\rho_1, \ldots, \rho_6) = (1, 1, 1, 2, 2, 2), \quad (5.2.18)$$

$$(E_1, \ldots, E_6) = (a_1^2, a_2^2, a_3^2, a_2 a_3, a_1 a_3, a_1 a_2), \quad (5.2.19)$$

$$(F_1, \ldots, F_6) = (b_1^2, b_2^2, b_3^2, b_2 b_3, b_1 b_3, b_1 b_2). \quad (5.2.20)$$

Using this notation, the strain along the reciprocal-lattice vector (5.2.8) and (5.2.9) becomes

$$\varepsilon_{\mathbf{h}} = \sum_{j=1}^{6} E_j \rho_j \varepsilon_j, \quad (5.2.21a)$$

$$e_{\mathbf{h}} = \sum_{j=1}^{6} F_j \rho_j e_j. \quad (5.2.21b)$$

The free-energy expression (5.2.11) and the direct Hooke equations (5.2.10) and (5.2.12) become

$$F = \frac{1}{2} \sum_{m=1}^{6} C_{mm} \rho_m^2 \varepsilon_m^2 + \sum_{m=1}^{5} \sum_{n=m+1}^{6} C_{mn} \rho_m \rho_n \varepsilon_m \varepsilon_n, \quad (5.2.22)$$

$$\sigma_m = \frac{\partial F}{\partial \varepsilon_m} \quad (m = 1, 2, 3), \quad (5.2.23a)$$

$$2\sigma_m = \frac{\partial F}{\partial \varepsilon_m} \quad (m = 4, 5, 6), \quad (5.2.23b)$$

$$\left\{\begin{aligned} \sigma_m &= C_{m1}\varepsilon_1 + C_{m2}\varepsilon_2 + C_{m3}\varepsilon_3 \\ &\quad + 2C_{m4}\varepsilon_4 + 2C_{m5}\varepsilon_5 + 2C_{m6}\varepsilon_6 \quad (m = 1, 2, 3), \\ 2\sigma_m &= 2C_{m1}\varepsilon_1 + 2C_{m2}\varepsilon_2 + 2C_{m3}\varepsilon_3 \\ &\quad + 4C_{m4}\varepsilon_4 + 4C_{m5}\varepsilon_5 + 4C_{m6}\varepsilon_6 \quad (m = 4, 5, 6). \end{aligned}\right. \quad (5.2.24)$$

[The factor of 2 in the left-hand side of (5.2.23*b*) is due to the fact that for $i \neq j$ there are two contributions to the differential of the free energy, $\mathrm{d}F = \sigma_{ij}\mathrm{d}\varepsilon_{ij} + \sigma_{ji}\mathrm{d}\varepsilon_{ji} = 2\sigma_{ij}\mathrm{d}\varepsilon_{ij}$, and thus $\partial F/\partial\varepsilon_{ij} = 2\sigma_{ij}$.] The inverse Hooke equations obtained by solving (5.2.24) have exactly the same form except that the vectors ε_m and σ_m change places and the matrix **S** replaces **C**. From (5.2.24) it can be observed that the inversion relations between the matrices **C** and **S** are $\mathbf{S} = (\mathbf{C}')^{-1}$ and $\mathbf{C} = (\mathbf{S}')^{-1}$, where $\mathbf{C}'$ and $\mathbf{S}'$ are obtained by partitioning **C** and **S** into four 3 × 3 blocks multiplied as follows: the upper left block by 1, the upper right and bottom left by 2 and the bottom right block by 4. Once the relation between **C** and **S** has been established, the factor of 2 in (5.2.24*b*) can be dropped and the Hooke equations written unitarily as follows:

---

[1] Some of the literature uses a different convention, which is described in Nye (1957). The Wooster convention is preferred as it keeps the values of the tensor elements, and for symmetries higher than triclinic gives identical structures for the matrices **C** and **S**.

$$\sigma_i = \sum_{j=1}^{6} C_{ij}\rho_j\varepsilon_j \quad (i = 1, \ldots, 6), \qquad (5.2.25a)$$

$$\varepsilon_i = \sum_{j=1}^{6} S_{ij}\rho_j\sigma_j \quad (i = 1, \ldots, 6). \qquad (5.2.25b)$$

The matrices **C** for all Laue classes are given in Table 5.2.1. The matrices **S** have exactly the same structure. For a given Laue group the matrix **C** is found from the invariance conditions of the free energy (5.2.22) to the operations of this group.[2] This results in a system of 21 homogenous equations determining a number of linear constraints between the matrix elements and, consequently, a number of independent elastic constants specific to the Laue group. The simplest structure of **C** with many elements equal to zero is obtained if the crystal reference system ($\mathbf{x}_i$) is taken with $\mathbf{x}_3$ along the *n*-fold axis and $\mathbf{x}_1$ along the twofold axis normal to the *n*-fold axis for groups where this axis exists or in an arbitrary direction[3] for groups where this axis does not exist. On passing to the system $\mathbf{y}_i$, the Hooke equations and the single-crystal elastic constants change as follows:

$$s_i(g) = \sum_{j=1}^{6} C_{ij}(g)\rho_j e_j(g), \qquad (5.2.26a)$$

$$e_i(g) = \sum_{j=1}^{6} S_{ij}(g)\rho_j s_j(g), \qquad (5.2.26b)$$

$$C_{il}(g) = \rho_l^{-1}\sum_{j=1}^{6}\sum_{k=1}^{6} C_{jk}\rho_k P_{ij}(g)Q_{kl}(g), \qquad (5.2.27a)$$

$$S_{il}(g) = \rho_l^{-1}\sum_{j=1}^{6}\sum_{k=1}^{6} S_{jk}\rho_k P_{ij}(g)Q_{kl}(g). \qquad (5.2.27b)$$

Table 5.2.1
The matrix **C** for all Laue groups represented by specific constraints

An identical table can be written for the matrix **S**.

5.2.3. Strain and stress in polycrystalline samples

5.2.3.1. *Types of strains and stresses, and the strain/stress orientation distribution function*

A textured polycrystalline sample is formed from a large number of small single-crystal blocks with different orientations following a certain distribution called the *orientation distribution function* (ODF). The elastic strain and stress state of an individual crystallite is determined by the Hooke equations together with the boundary conditions. In a polycrystalline sample the boundary conditions are the result of the interaction of the crystallite with its neighbours, and this interaction depends on the crystallite shape and orientation. To describe both the texture and the strain/stress state of a polycrystalline sample two reference systems should be defined: one linked to the crystallite and the second to the sample. The crystallite reference system is ($\mathbf{x}_i$, $i = 1, 2, 3$) defined for every Laue group, as described in the previous section. The sample system ($\mathbf{y}_i$, $i = 1, 2, 3$) can be defined by using some prominent surfaces and directions resulting from the manufacturing process or given by the geometrical characteristics of the sample. In the most general case the strain and stress in a crystallite are not homogenous and are described by functions depending on the crystallite orientation *g* and on the position vector in the crystallite. Let us denote by $\mathbf{R}_k$ the position vector with respect to the sample system of the crystallite *k* with an orientation in the range (g, $g + \mathrm{d}g$). If **r** is the position vector of a point in this crystallite in the crystal reference system, then the elastic strain at this point in this system is $\varepsilon_i(\mathbf{R}_k + \mathbf{r}, g)$. Denoting the crystallite volume by V_k, the averaged strain in this crystallite is

$$\varepsilon_i(\mathbf{R}_k, g) = V_k^{-1}\int \varepsilon_i(\mathbf{R}_k + \mathbf{r}, g)\,\mathrm{d}\mathbf{r}. \qquad (5.2.28)$$

If N_g is the number of crystallites of orientation *g*, then the second average can be defined as

$$\varepsilon_i(g) = N_g^{-1}\sum_{k=1}^{N_g}\varepsilon_i(\mathbf{R}_k, g). \qquad (5.2.29)$$

Further, the third average can be defined by integrating (5.2.29) over the crystallites' orientations. Denoting the orientation distribution function (ODF) by $f(g)$, this average is

$$\overline{\varepsilon}_i = \iiint \mathrm{d}g\, f(g)\,\varepsilon_i(g). \qquad (5.2.30)$$

The functions $\varepsilon(g)$ are the *type-I* strains and the following differences define the *type-III*, *type-II* and *intergranular* strains:

$$\text{Type III: } \Delta\varepsilon_i(\mathbf{R}_k + \mathbf{r}, g) = \varepsilon_i(\mathbf{R}_k + \mathbf{r}, g) - \varepsilon_i(\mathbf{R}_k, g); \qquad (5.2.31)$$

$$\text{Type II: } \Delta\varepsilon_i(\mathbf{R}_k, g) = \varepsilon_i(\mathbf{R}_k, g) - \varepsilon_i(g); \qquad (5.2.32)$$

$$\text{Intergranular: } \Delta\varepsilon_i(g) = \varepsilon_i(g) - \overline{\varepsilon}_i. \qquad (5.2.33)$$

---

[2] Invariance to inversion is assured by the quadratic form.

[3] $\mathbf{x}_i = \mathbf{a}/a$ is appropriate in all cases if the twofold axis, when it exists, is taken along the unit-cell vector **a**.

The type-I strain, as well as its average, and the intergranular strain are macroscopic quantities. For simplicity, both the type-II and type-III strains are called *microscopic* strains, although the type-II strain is mesoscopic. Obviously, the following averages are zero:

$$V_k^{-1} \int \Delta\varepsilon_i(\mathbf{R}_k + \mathbf{r}, g)\,\mathrm{d}\mathbf{r} = 0, \tag{5.2.34a}$$

$$N_g^{-1} \sum_{k=1}^{N_g} \Delta\varepsilon_i(\mathbf{R}_k, g) = 0, \tag{5.2.34b}$$

$$\iiint \mathrm{d}g\, f(g)\,\Delta\varepsilon_i(g) = 0. \tag{5.2.34c}$$

The strain at the point **r** in the crystallite *k* of orientation *g* can be written as a sum of type-I, type-II and type-III strains,

$$\varepsilon_i(\mathbf{R}_k+\mathbf{r}, g) = \varepsilon_i(g) + \Delta\varepsilon_i(\mathbf{R}_k, g) + \Delta\varepsilon_i(\mathbf{R}_k+\mathbf{r}, g) \quad (i = 1, \ldots, 6). \tag{5.2.35}$$

Expressions similar to (5.2.28)–(5.2.35) can be written for any elastic strain or stress component in any reference system. In these expressions ε_i is, in fact, a placeholder for ε_i, e_i, σ_i or s_i.

Similarly to the texture, we can call $\varepsilon_i(g)$ the *strain/stress orientation distribution functions* (SODF). In contrast to the ODF, the average of the SODF over all variables is not unity but the *averaged macroscopic strain/stress* $\overline{\varepsilon}_i$. In general, both the averaged value and the intergranular strain/stress are necessary for a complete description of the macroscopic strain/stress state in a material. The intergranular strains/stresses have various origins such as elastic and plastic deformations, phase transformations, thermal treatments, mismatch of *d*-spacings in composite materials and differences in the coefficients of thermal expansion (Behnken, 2000). It is advantageous to group all of these elastic intergranular strains/stresses of different origins into only two terms, $\Delta\varepsilon_i^{\rm elastic}$ and $\Delta\varepsilon_i^{\rm plastic}$; the SODF can then be written as

$$\varepsilon_i(g) = \overline{\varepsilon}_i + \Delta\varepsilon_i^{\rm elastic}(g) + \Delta\varepsilon_i^{\rm plastic}(g). \tag{5.2.36}$$

The first two terms in the right-hand side of (5.2.36) represent the elastically induced part of the SODF, with the last term being the plastically induced part.

5.2.3.2. *The mean and variance of the observable strain, the peak shift and broadening*

According to (5.2.21*a*), the strain along **h** and its square in terms of the strain-tensor elements in the crystal reference system are the following:

$$\varepsilon_{\mathbf{h}}(\mathbf{R}_k + \mathbf{r}, g) = \sum_{i=1}^{6} E_i \rho_i \varepsilon_i(\mathbf{R}_k + \mathbf{r}, g), \tag{5.2.37}$$

$$\varepsilon_{\mathbf{h}}^2(\mathbf{R}_k + \mathbf{r}, g) = \sum_{i=1}^{6}\sum_{j=1}^{6} E_i E_j \rho_i \rho_j \varepsilon_i(\mathbf{R}_k + \mathbf{r}, g)\varepsilon_j(\mathbf{R}_k + \mathbf{r}, g). \tag{5.2.38}$$

The peak shift and the integral breadth caused by strain are obtained from (5.2.37) and (5.2.38), respectively, after substituting (5.2.35) and performing three averages. The first two averages are over **r** and over *k*, respectively, for a given orientation *g*. Taking account of (5.2.34*a*) and (5.2.34*b*), the following macroscopic quantities depending only on the crystallite orientation are obtained:

$$\varepsilon_{\mathbf{h}}(g) = \sum_{i=1}^{6} E_i \rho_i \varepsilon_i(g), \tag{5.2.39}$$

$$\varepsilon_{\mathbf{h}}^2(g) = \sum_{i=1}^{6}\sum_{j=1}^{6} E_i E_j \rho_i \rho_j \big[\varepsilon_i(g)\varepsilon_j(g) + \Delta_{ij}(g)\big], \tag{5.2.40}$$

$$\begin{aligned}\Delta_{ij}(g) = {}& \frac{1}{N_g}\sum_{k=1}^{N_g} \Delta\varepsilon_i(\mathbf{R}_k, g)\Delta\varepsilon_j(\mathbf{R}_k, g)\\ &+ \frac{1}{N_g}\sum_{k=1}^{N_g}\frac{1}{V_k}\int \mathrm{d}\mathbf{r}\,\Delta\varepsilon_i(\mathbf{R}_k + \mathbf{r}, g)\Delta\varepsilon_j(\mathbf{R}_k + \mathbf{r}, g).\end{aligned} \tag{5.2.41}$$

The third average is performed only over those crystallite orientations g^+ for which **h** is parallel to **y**, the unit vector of the scattering vector. This means that only crystallites with orientations fulfilling the Bragg reflection condition are considered. Under this constraint, the Euler matrix (5.2.3) can be written as

$$\mathbf{a}(g^+) = \mathbf{a}(\varphi_1^+, \Phi_0^+, \varphi_2^+) = \mathbf{m}^t(\Phi, \beta)\mathbf{n}(\omega)\mathbf{m}(\Psi, \gamma), \tag{5.2.42}$$

where **m** is given by (5.2.7), (Φ, β) and (Ψ, γ) are the polar and azimuthal angles of **h** in $(\mathbf{x}_i)$ and of **y** in $(\mathbf{y}_i)$, respectively, and where $\mathbf{n}(\omega)$ is a simple rotation matrix of angle $\omega \in (0, 2\pi)$. Now, by taking into account that the sample could be textured and denoting the (texture) pole distribution function by $p_{\mathbf{h}}(\mathbf{y}) = (1/2\pi)\int_{\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega f(g^+)$, the average over g^+ of the observable strain ($n = 1$) and of its square ($n = 2$) are

$$\big\langle\varepsilon_{\mathbf{h}}^n(\mathbf{y})\big\rangle = (1/2\pi)\int_{\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\, f(g^+)\varepsilon_{\mathbf{h}}^n(g^+)/p_{\mathbf{h}}(\mathbf{y}). \tag{5.2.43}$$

This equation contains the texture pole distribution $p_{\mathbf{h}}(\mathbf{y})$ as a normalizing factor, which is not accessible to the diffraction measurements. This can be replaced by the *reduced pole distribution* $P_{\mathbf{h}}(\mathbf{y}) = (1/2)[p_{\mathbf{h}}(\mathbf{y}) + p_{-\mathbf{h}}(\mathbf{y})]$ because the peak positions for $-\mathbf{h}$ and **h** are not distinguishable. Therefore, in place of (5.2.43) we have

$$\begin{aligned}\big\langle\varepsilon_{\mathbf{h}}^n(\mathbf{y})\big\rangle P_{\mathbf{h}}(\mathbf{y}) &= \frac{1}{2}\left[\frac{1}{2\pi}\int_{\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\varepsilon_{\mathbf{h}}^n(g^+)f(g^+) + \frac{1}{2\pi}\int_{-\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\varepsilon_{\mathbf{h}}^n(g^-)f(g^-)\right]\\ &= \frac{1}{2\pi}\int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\varepsilon_{\mathbf{h}}^n(g^\pm)f(g^\pm).\end{aligned} \tag{5.2.43$'$}$$

Here, the significance of the ± symbol is the average of the two terms; the Euler matrix for $-\mathbf{h}\|\mathbf{y}$ is calculated using (5.2.42) with (Φ, β) replaced by $(\pi - \Phi, \beta + \pi)$. Now, substituting (5.2.39) and (5.2.40) into (5.2.43′), one obtains the following expressions for the *mean* [equation (5.2.44)] and for the *variance* [equations (5.2.45)] of the *observable* strain:

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle P_{\mathbf{h}}(\mathbf{y}) = \sum_{i=1}^{6} E_i\rho_i \frac{1}{2\pi}\int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\varepsilon_i(g^\pm)f(g^\pm), \tag{5.2.44}$$

$$V_{\mathbf{h}}(\mathbf{y}) = \big\langle\varepsilon_{\mathbf{h}}^2(\mathbf{y})\big\rangle - \langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle^2 = V_{\mathbf{h}}^M(\mathbf{y}) + V_{\mathbf{h}}^m(\mathbf{y}), \tag{5.2.45a}$$

$$\begin{aligned}V_{\mathbf{h}}^M(\mathbf{y}) = {}& \sum_{i=1}^{6}\sum_{j=1}^{6} E_i E_j \rho_i \rho_j\\ &\times \left[\begin{aligned}&P_{\mathbf{h}}^{-1}(\mathbf{y})(2\pi)^{-1}\int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\Delta\varepsilon_i(g^\pm)\Delta\varepsilon_j(g^\pm)f(g^\pm)\\ &- P_{\mathbf{h}}^{-2}(\mathbf{y})(2\pi)^{-2}\int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\Delta\varepsilon_i(g^\pm)f(g^\pm)\int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\Delta\varepsilon_j(g^\pm)f(g^\pm)\end{aligned}\right],\end{aligned} \tag{5.2.45b}$$

$$V_{\mathbf{h}}^m(\mathbf{y}) = \sum_{i=1}^{6}\sum_{j=1}^{6} E_i E_j \rho_i \rho_j \left[P_{\mathbf{h}}^{-1}(\mathbf{y})(2\pi)^{-1}\int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\,\Delta_{ij}(g^\pm)f(g^\pm)\right]. \tag{5.2.45c}$$

The mean determines the peak shift; the variance determines the peak breadth caused by strain. The variance has two components: the microstrain variance $V_{\mathbf{h}}^{m}(\mathbf{y})$ and the macrostrain variance $V_{\mathbf{h}}^{M}(\mathbf{y})$. The contributions to the peak shift of the second and of the third terms in (5.2.35) are zero because the averages of these terms over $\mathbf{r}$ and k, respectively, are zero. The peak shift is exclusively caused by type-I strain. Type-II and -III strains only contribute to the peak broadening. The broadening effect of microstrains is explained by correlations differing from zero appearing in (5.2.41); it can be observed that only correlations of strains of the same level are involved. Finally, macrostrain broadening is produced only by intergranular strain and, as will be seen later, can be considered to be a small correction of the microstrain broadening.

There is an alternative derivation of the peak shift and broadening, starting from (5.2.21b), giving the strain along $\mathbf{h}$ in terms of the strain-tensor elements in the sample reference system. The resulting mean and variance of the observable strain retain exactly the same structure as equations (5.2.44) and (5.2.45) with ε in the right-hand side[4] replaced by e and E_i replaced by F_i:

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle P_{\mathbf{h}}(\mathbf{y}) = \sum_{i=1}^{6} F_i \rho_i \frac{1}{2\pi} \int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\, e_i(g^{\pm}) f(g^{\pm}), \qquad (5.2.44')$$

$$V_{\mathbf{h}}(\mathbf{y}) = \langle\varepsilon_{\mathbf{h}}^{2}(\mathbf{y})\rangle - \langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle^{2} = V_{\mathbf{h}}^{M}(\mathbf{y}) + V_{\mathbf{h}}^{m}(\mathbf{y}) \qquad (5.2.45'a)$$

$$\begin{aligned} V_{\mathbf{h}}^{M}(\mathbf{y}) &= \sum_{i=1}^{6}\sum_{j=1}^{6} F_i F_j \rho_i \rho_j \\ &\times \left[\begin{aligned} &P_{\mathbf{h}}^{-1}(\mathbf{y})(2\pi)^{-1} \int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\, \Delta e_i(g^{\pm}) \Delta e_j(g^{\pm}) f(g^{\pm}) \\ &- P_{\mathbf{h}}^{-2}(\mathbf{y})(2\pi)^{-2} \int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\, \Delta e_i(g^{\pm}) f(g^{\pm}) \int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\, \Delta e_j(g^{\pm}) f(g^{\pm}) \end{aligned} \right] \end{aligned} \qquad (5.2.45'b)$$

$$V_{\mathbf{h}}^{m}(\mathbf{y}) = \sum_{i=1}^{6}\sum_{j=1}^{6} F_i F_j \rho_i \rho_j \left[P_{\mathbf{h}}^{-1}(\mathbf{y})(2\pi)^{-1} \int_{\pm\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega\, \Delta_{ij}(g^{\pm}) f(g^{\pm}) \right]. \qquad (5.2.45'c)$$

For a given problem, the appropriate choice of one or the other alternative can save a significant amount of calculation.

The peak shift (5.2.44) can be also called the *strain pole distribution function*. The strain pole distribution is to the SODF what the pole distribution is to the texture, with an important difference: in the place of one distribution, six independent SODFs in a determined linear combination [equations (5.2.21)] are projected onto the space (Ψ, γ).

5.2.4. Determining the strain/stress by diffraction

5.2.4.1. *Determining the macrostrain/stress*

Although diffraction is able, in principle, to determine both the averaged strain/stress tensors $\overline{e}_i/\overline{s}_i$ as well as the intergranular strain/stress $\Delta e_i(g)/\Delta s_i(g)$, the principal aim for many decades was to determine only the averaged tensors. The determination was based on the supposition that the elastic strain and stress tensors $e_i(g)$, $s_i(g)$ in a crystallite are connected to the average tensors $\overline{s}_i$, $\overline{e}_i$ as follows (see, for example, Behnken, 2000):

$$e_i(g) = \sum_{j=1}^{6} S_{ij}^{\#}(g) \rho_j \overline{s}_j, \qquad (5.2.46a)$$

$$s_i(g) = \sum_{j=1}^{6} C_{ij}^{\#}(g) \rho_j \overline{e}_j. \qquad (5.2.46b)$$

Here, $S_{ij}^{\#}(g)$ and $C_{ij}^{\#}(g)$ are fourth-rank tensors describing the elastic behaviour of the crystallites in the polycrystalline materials, not necessarily the single-crystal compliance and stiffness tensors as in (5.2.26). Equations of type (5.2.46) are obtained if the plastically induced term in (5.2.36) is zero, and the elastically induced term of the strain/stress differs from zero only if the averaged stresses/strains differ from zero. If the equations (5.2.46) are valid, then the mean strain measured by diffraction can be expressed as

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle = \sum_{j=1}^{6} R_j(\Psi, \gamma; \Phi, \beta) \overline{s}_j. \qquad (5.2.47)$$

The coefficients R_j are called *diffraction stress factors* and can be calculated analytically or numerically using (5.2.44) or (5.2.44′). Classical models such as those of Voigt (1928), Reuss (1929) and Kroner (1958) fit perfectly into this category. The average stresses can be obtained by fitting (5.2.47) to the measured data for a number of peaks and directions in the sample. For isotropic (non-textured) samples (5.2.47) becomes linear in $\sin^2\Psi$ and $\sin 2\Psi$, and is the basic equation of the traditional '$\sin^2\Psi$' method (Hauk, 1952; Christenson & Rowland, 1953). Most experimental data can be processed using this method, even if the sample has a weak texture.

For textured samples the relation between the peak shifts and $\sin^2\Psi$ becomes nonlinear. Analytical expressions can sometimes be found by approximating the texture pole distribution by δ functions in some prominent sample directions (Dölle, 1979). In general, this is a rough approximation, with numerical calculation of the diffraction stress factors being preferable. Many applications to thin films can be found in the review paper by Welzel *et al.* (2005).

Determination of the stress in a textured sample requires a prior, accurate determination of the texture. To eliminate this time-consuming step and to increase the accuracy of stress determination, Ferrari & Lutterotti (1994) proposed the inclusion of stress analysis in the Rietveld method, with the stress parameters being refined together with the texture spherical-harmonics coefficients and the structural parameters. Balzar *et al.* (1998) also used the Rietveld method with a Voigt-type formula implemented in *GSAS* by Larson & Von Dreele (2004) to determine the average strain tensor from multiple time-of-flight neutron diffraction patterns on Al/SiC composites.

The dependence of the measured strain on $\sin^2\Psi$ sometimes becomes strongly nonlinear, especially in metals after plastic deformation, and cannot be explained by the texture or by the stress-gradient effect. In general, equations (5.2.46) are too restrictive because they do not take the plastically induced part of the strain and stress into account. They must be replaced by the exact equations (5.2.26); in other words, the averaged strain and stress tensors and the whole intergranular strains and stresses must be considered. There are two possibilities for accounting for the whole intergranular stress. The first is to calculate the plastically induced part of the stress starting from models of the plastic flow of crystallites within a polycrystalline sample (Van Acker *et al.*, 1996). The second possibility is to construct the SODF $\varepsilon_i(g)$ by inverting the strain pole distributions $\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle$ measured for several peaks and in a large number of sample directions. No model is necessary to assume the elastic or plastic interactions of crystallites. In contrast, determination of the SODF for elastically loaded or plastically deformed samples gives essential information on the mechanisms of crystallite interactions.

---

[4] Remembering that $e_{\mathbf{h}} \equiv \varepsilon_{\mathbf{h}}$, in the left-hand side of (5.2.44′) and (5.2.45′) we have $\langle e_{\mathbf{h}}(\mathbf{y})\rangle^{n} \equiv \langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle^{n}$.

To determine the SODF, Wang *et al.* (1999, 2001, 2003) and Behnken (2000) proposed an approach based on the representation of these functions by generalized spherical harmonics. These approaches presume prior determination of the ODF (texture) and of the peak positions considered as free parameters in pattern decomposition. Only isolated or weakly overlapping peaks can be used for accurate position determination, and a large part of the information contained in the diffraction pattern is then lost. To eliminate these drawbacks, Popa & Balzar (2001, 2014) proposed a variant of strain representation by generalized spherical harmonics that is appropriate for implementation in the Rietveld method.

In the following, three subjects concerning macrostrain/stress determination are developed: classical approximations for the macrostrain/stress in isotropic polycrystals and for isotropic polycrystals under hydrostatic pressure, and a spherical-harmonics analysis in the variant that can be implemented in Rietveld programs.

5.2.4.2. *Determining the microstrain*

The microstrain is part of the microstructure: it is the departure caused by the imperfections of a real polycrystal compared with an ideal polycrystal. The microstructure affects the profile of the diffraction peaks, and its study is then performed by *line profile analysis* (LPA) techniques. A historical overview of LPA techniques can be found in Langford (2004).

LPA is as old as powder diffraction itself, having its origin in the Scherrer equation (Scherrer, 1918). In terms of the physical quantities used today, the Scherrer equations for the constant wavelength and the time-of-flight diffraction methods are

$$\beta_H^D = \lambda/[D_V(\mathbf{h})\cos\theta_H] \text{ and}$$
$$\beta_H^D = \lambda_H^2/[2D_V(\mathbf{h})\sin\theta],$$

respectively. Here, θ_H and λ_H are the Bragg angle and wavelength, respectively, $D_V(\mathbf{h})$ is the *volume-averaged column length* along the reciprocal-lattice vector and β_H^D is the corresponding integral breadth of the diffraction line. During the two decades after the publication of the paper by Scherrer, diffraction phenomena that were not interpretable using his formula were observed, but only after 1940 were these understood and treated theoretically. Stokes & Wilson (1944) realized that peak broadening caused by strain may coexist with broadening due to the crystallite size, and that in reciprocal space the former increases linearly with the reflection order, while the latter is independent of this order. Consequently, considering a Gaussian for the distribution of the observable strain, the dependence of the strain breadth β_H^S on the strain variance [equation (5.2.45)] is

$$\beta_H^S = 2\tan\theta_H[2\pi V_{\mathbf{h}}(\mathbf{y})]^{1/2}, \qquad (5.2.48a)$$
$$\beta_H^S = \lambda_H[2\pi V_{\mathbf{h}}(\mathbf{y})]^{1/2}. \qquad (5.2.48b)$$

The sample peak profile is a convolution of the size and strain profiles, and the central problem of LPA is to separate the two contributions. Separation is possible owing to the different dependence of the breadth on the scanning variable. There are two kinds of methods for separation: *integral breadth methods*, which require models for the peak profiles, and *Fourier methods*, which do not require such models.

Based on the dependence of the size and strain breadths on the reflection order (Stokes & Wilson, 1944), Hall (1949) proposed an integral breadth method of separation known today as a *Williamson–Hall plot*. It consists of plotting $\beta_H^* = \beta_H\cos\theta_H/\lambda$ *versus* $d_H^* = m/d_h$, where m is the reflection order, d_h is the interplanar distance of the lattice planes (hkl) and β_H is the integral breadth of the experimental line profile corrected for the instrumental resolution. Presuming that $\beta_H = \beta_H^D + \beta_H^S$, which means that both the size and strain profiles are Lorentzian, we have $\beta_H^* = 1/D_V(\mathbf{h}) + (2\pi V_{\mathbf{h}})^{1/2} d_H^*$, and the crystallite size and strain variance are then obtained from the intercept and the slope of this line. Similar linear plots can be drawn for the Gauss sample profile and for the Voigt sample profile (Lorentz for size, Gauss for strain) if the coordinates (d_H^{*2}, β_H^{*2}) are used in place of (d_H^*, β_H^*).

Also based on Stokes & Wilson (1944), Averbach & Warren (1949) first proposed a Fourier method for separating the strain and size. According to these authors, the logarithms of the cosines of the Fourier coefficients of the sample line profile, which are the product of the size and strain Fourier coefficients, can be written as

$$\ln[A_n(m)] = \ln\left[A_n^D A_n^S(m)\right] = \ln(A_n^D) - 2\pi^2 n^2 m^2 V_{\mathbf{h}},$$

where n is the harmonic index and m is the order of reflection. More than two orders are rarely available. In a plot of $\ln(A_n)$ *versus* m^2 for different values of n, the slope and intercept give the strain variance and parameters connected with the crystallite size, respectively, namely the *area- and volume-averaged column lengths* and the *faulting probabilities*, if this is the case. Details can be found in Warren (1969).

Over the years, the Warren–Averbach method has been modified and improved, becoming a standard method in LPA; for details, see Langford (2004). Unfortunately, like the Williamson–Hall plot, this method has a serious limitation: it requires isolated diffraction peaks without overlaps, a condition that is rarely fulfilled.

Peak overlap is not an impediment to the integral breadth method called *whole powder pattern fitting* (WPPF) or *pattern decomposition*. WPPF aims to fit the whole diffraction pattern by using analytical functions for the peak profiles with at least one obligatory constraint: the breadth of a given peak is not a free, refinable parameter, but is calculated with a parameterized function depending on the scanning variable. For the strain breadth this function is (5.2.48*a*) or (5.2.48*b*), and one expects to have a parameterized expression describing the dependence of the strain variance on the directions in the crystal and sample. Such expressions for all Laue groups were recently derived by Popa & Lungu (2013) using the spherical-harmonics approach described below in Section 5.2.8. They have as classical limits the expressions of strain variance that are dependent only on crystal direction derived by Popa (1998) and independently by Stephens (1999), which are now implemented in all popular Rietveld programs.

5.2.5. Macrostrain/stress in isotropic samples: classical approximations

As stated in the previous section, if the aim of the diffraction experiment is determination of the averaged strain and stress tensors, the classical models of Voigt, Reuss and Kroner are good enough to process most experimental data. Moreover, the determination becomes a very simple routine if the sample is isotropic. The term ‘isotropic’ for a polycrystalline sample denotes the absence of a preferred orientation, which means that $f(g) = 1$. With regard to the elastic properties, such a sample is isotropic only on average; the behaviour of crystallites, with rare exceptions, is anisotropic. For this reason, it is appropriate to call this sample *quasi-isotropic*. As a consequence of isotropy, two averaged elastic constants specific to the model can be derived from the single-crystal elastic constants.

5.2.5.1. *The Voigt model*

According to Voigt (1928), the intergranular strain in the sample reference system is zero and the macroscopic strain tensor in the crystallite is thus identical to the averaged strain,

$$e_i(\varphi_1, \Phi_0, \varphi_2) = \overline{e}_i. \tag{5.2.49}$$

To find the averaged stress tensor in the same system, we substitute (5.2.49) into (5.2.26*a*) and integrate over Euler space. The integral acts only on the single-crystal stiffness tensor elements (5.2.27*a*) and can be calculated analytically. The averaged stress is

$$\overline{s}_i = \sum_{j=1}^{6} \overline{C}_{ij}^V \rho_j \overline{e}_j. \tag{5.2.50}$$

In (5.2.50) $\overline{C}_{ij}^V$ are the Voigt-averaged elastic stiffness constants for the isotropic polycrystal. They are calculated from the single-crystal stiffness constants as follows:

$$\overline{C}_{11}^V = \frac{(C_{11} + C_{22} + C_{33})}{5} + \frac{2(C_{12} + C_{13} + C_{23} + 2C_{44} + 2C_{55} + 2C_{66})}{15}, \tag{5.2.51a}$$

$$\overline{C}_{12}^V = \frac{(C_{11} + C_{22} + C_{33} - 2C_{44} - 2C_{55} - 2C_{66})}{15} + \frac{4(C_{12} + C_{13} + C_{23})}{15}. \tag{5.2.51b}$$

To find the peak shift for the Voigt model, equation (5.2.49) must be substituted into (5.2.44′). The integral in (5.2.44′) is trivial and one obtains

$$\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle = \sum_{j=1}^{6} F_j \rho_j \overline{e}_j. \tag{5.2.52}$$

Equation (5.2.52) can be arranged to be similar to (5.2.47). By inverting (5.2.50) and substituting the resulting $\overline{e}_j$ in (5.2.52), this equation becomes

$$\begin{aligned}\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle = {} & [F_1 \overline{S}_{11}^V + (F_2 + F_3)\overline{S}_{12}^V]\overline{s}_1 + [F_2 \overline{S}_{11}^V + (F_1 + F_3)\overline{S}_{12}^V]\overline{s}_2 \\ & + [F_3 \overline{S}_{11}^V + (F_1 + F_2)\overline{S}_{12}^V]\overline{s}_3 \\ & + 2(\overline{S}_{11}^V - \overline{S}_{12}^V)(F_4\overline{s}_4 + F_5\overline{s}_5 + F_6\overline{s}_6).\end{aligned} \tag{5.2.53}$$

In (5.2.53) $\overline{S}_{ij}^V$ is the compliance tensor obtained by inverting the stiffness tensor $\overline{C}_{ij}^V$,

$$\begin{aligned}\overline{S}_{11}^V &= (\overline{C}_{11}^V + \overline{C}_{12}^V)/[\overline{C}_{11}^V(\overline{C}_{11}^V + \overline{C}_{12}^V) - 2(\overline{C}_{12}^V)^2], \\ \overline{S}_{12}^V &= -\overline{C}_{12}^V/[\overline{C}_{11}^V(\overline{C}_{11}^V + \overline{C}_{12}^V) - 2(\overline{C}_{12}^V)^2].\end{aligned} \tag{5.2.54}$$

We can see from (5.2.52) or (5.2.53) that in the frame of the Voigt model of crystallite interactions the relative peak shift does not depend on the Miller indices, a fact that is frequently contradicted by experiment. The Reuss model gives such a dependence.

5.2.5.2. *The Reuss model*

In the hypothesis of Reuss (1929), the intergranular stress in the sample system is zero and thus

$$s_i(\varphi_1, \Phi_0, \varphi_2) = \overline{s}_i. \tag{5.2.55}$$

To find the averaged strain, equation (5.2.55) is substituted into (5.2.26*b*), which is integrated in Euler space, and one obtains

$$\overline{e}_i = \sum_{j=1}^{6} \overline{S}_{ij}^R \rho_j \overline{s}_j. \tag{5.2.56}$$

Here, $\overline{S}_{ij}^R$ are the Reuss-averaged compliance constants for the isotropic polycrystals. They are calculated from the single-crystal compliances with formulae similar to (5.2.51),

$$\overline{S}_{11}^R = \frac{(S_{11} + S_{22} + S_{33})}{5} + \frac{2(S_{12} + S_{13} + S_{23} + 2S_{44} + 2S_{55} + 2S_{66})}{15}, \tag{5.2.57a}$$

$$\overline{S}_{12}^R = \frac{(S_{11} + S_{22} + S_{33} - 2S_{44} - 2S_{55} - 2S_{66})}{15} + 4\frac{(S_{12} + S_{13} + S_{23})}{15}. \tag{5.2.57b}$$

Note that $\overline{S}_{ij}^R$ and $\overline{S}_{ij}^V$ are different. Also note that the stiffness constants $\overline{C}_{ij}^R$ obtained by inverting $\overline{S}_{ij}^R$ are different from $\overline{C}_{ij}^V$ defined previously.

To calculate the peak shift, there are two possibilities that should give identical results. According to Behnken & Hauk (1986), equations (5.2.55) and (5.2.27*b*) are substituted into (5.2.26*b*), (5.2.26*b*) is substituted into (5.2.21*b*), and the peak shift is then calculated with (5.2.44′), which becomes

$$\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle = \sum_{i=1}^{6} F_i \rho_i \sum_{l=1}^{6} \overline{s}_l \sum_{j=1}^{6} \sum_{k=1}^{6} S_{jk} \rho_k \langle P_{ij} Q_{kl} \rangle.$$

Alternatively, according to Popa (2000), equation (5.2.55) is substituted into (5.2.16*c*), (5.2.16*c*) into (5.2.25*b*), and (5.2.25*b*) into (5.2.21*a*), and the peak shift is then calculated with (5.2.44), which becomes

$$\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle = \sum_{i=1}^{6} E_i \rho_i \sum_{l=1}^{6} \overline{s}_l \sum_{j=1}^{6} S_{ij} \rho_j \langle Q_{jl} \rangle. \tag{5.2.58}$$

Obviously the last possibility, which is adopted here, is much cheaper computationally as there are only 36 average $\langle Q_{ij} \rangle$ to calculate in place of 1296 $\langle P_{ij} Q_{kl} \rangle$. Taking account of (5.2.17), (5.2.42) and (5.2.7), the integrals

$$\langle Q_{ij} \rangle = \frac{1}{2\pi} \int_0^{2\pi} \mathrm{d}\omega \, Q_{ij}(\varphi_1^{\pm}, \Phi_0^{\pm}, \varphi_2^{\pm}) \tag{5.2.59}$$

can be calculated analytically and one obtains

$$\langle Q_{ij} \rangle = \begin{cases} (3F_j - 1)E_i/2 + \delta_i(1 - F_j)/2 & \text{for } j = 1, 2, 3 \\ 3F_j E_i - \delta_i F_j & \text{for } j = 4, 5, 6 \end{cases} \tag{5.2.60}$$

$$(\delta_1, \ldots, \delta_6) = (1, 1, 1, 0, 0, 0).$$

Inserting (5.2.60) into (5.2.58) and rearranging the terms, the peak shift becomes

$$\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle = (\overline{t}_s - \overline{s}_{\mathbf{y}})r_2/2 + (3\overline{s}_{\mathbf{y}} - \overline{t}_s)r_4/2, \tag{5.2.61}$$

Table 5.2.2
Quadratic and quartic forms for symmetries higher than triclinic

(*a*) Quadratic forms r_2.

Symmetry (Laue groups)	Quadratic form

$2/m$ (unique axis c)	$S_{11}a_1^4 + S_{22}a_2^4 + S_{33}a_3^4 + 2(S_{23}+2S_{44})a_2^2a_3^2$ $+ 2(S_{13}+2S_{55})a_1^2a_3^2 + 2(S_{12}+2S_{66})a_1^2a_2^2$ $+ 4(S_{36}+2S_{45})a_1a_2a_3^2 + 4S_{16}a_1^3a_2 + 4S_{26}a_1a_2^3$
mmm	$S_{11}a_1^4 + S_{22}a_2^4 + S_{33}a_3^4 + 2(S_{23}+2S_{44})a_2^2a_3^2$ $+ 2(S_{13}+2S_{55})a_1^2a_3^2 + 2(S_{12}+2S_{66})a_1^2a_2^2$
$4/mmm$	$S_{11}(a_1^4+a_2^4) + S_{33}a_3^4 + 2(S_{13}+2S_{44})(a_1^2+a_2^2)a_3^2$ $+ 2(S_{12}+2S_{66})a_1^2a_2^2$
$4/m$	As for $4/mmm$, plus $4S_{16}(a_1^2-a_2^2)a_1a_2$
$\bar{3}m$	$S_{11}(a_1^2+a_2^2)^2 + S_{33}a_3^4 + 2(S_{13}+2S_{44})(a_1^2+a_2^2)a_3^2$ $+ 4S_{14}(3a_1^2-a_2^2)a_2a_3$
$\bar{3}$	As for $\bar{3}m$, plus $4S_{15}(a_1^2-3a_2^2)a_1a_3$
Hexagonal Laue groups	$S_{11}(a_1^2+a_2^2)^2 + S_{33}a_3^4 + 2(S_{13}+2S_{44})(a_1^2+a_2^2)a_3^2$
Cubic Laue groups	$S_{11}(a_1^4+a_2^4+a_3^4)$ $+ 2(S_{12}+2S_{44})(a_2^2a_3^2+a_1^2a_3^2+a_1^2a_2^2)$

where $\bar{t}_s$ is the trace of the averaged stress tensor and $\bar{s}_{\mathbf{y}}$ is the mean stress along **y**,

$$\bar{t}_s = \bar{s}_1 + \bar{s}_2 + \bar{s}_3, \qquad (5.2.62a)$$

$$\bar{s}_{\mathbf{y}} = F_1\bar{s}_1 + F_2\bar{s}_2 + F_3\bar{s}_3 + 2F_4\bar{s}_4 + 2F_5\bar{s}_5 + 2F_6\bar{s}_6. \qquad (5.2.62b)$$

The dependence of the peak shifts on the Miller indices is given by the factors r_2 and r_4, which are the quadratic and quartic forms, respectively, of the direction cosines a_i. For triclinic symmetry these factors are the following:

$$\begin{aligned} r_2 = {} & (S_{11}+S_{12}+S_{13})a_1^2 + (S_{12}+S_{22}+S_{23})a_2^2 \\ & + (S_{13}+S_{23}+S_{33})a_3^2 + 2(S_{14}+S_{24}+S_{34})a_2a_3 \\ & + 2(S_{15}+S_{25}+S_{35})a_1a_3 + 2(S_{16}+S_{26}+S_{36})a_1a_2, \end{aligned} \qquad (5.2.63)$$

$$\begin{aligned} r_4 = {} & S_{11}a_1^4 + S_{22}a_2^4 + S_{33}a_3^4 + 2(S_{23}+2S_{44})a_2^2a_3^2 \\ & + 2(S_{13}+2S_{55})a_1^2a_3^2 + 2(S_{12}+2S_{66})a_1^2a_2^2 \\ & + 4(S_{14}+2S_{56})a_1^2a_2a_3 + 4(S_{25}+2S_{46})a_1a_2^2a_3 \\ & + 4(S_{36}+2S_{45})a_1a_2a_3^2 + 4S_{24}a_2^3a_3 \\ & + 4S_{34}a_2a_3^3 + 4S_{15}a_1^3a_3 + 4S_{35}a_1a_3^3 \\ & + 4S_{16}a_1^3a_2 + 4S_{26}a_1a_2^3. \end{aligned} \qquad (5.2.64)$$

For higher symmetries, r_2 and r_4 can be derived from (5.2.63) and (5.2.64), taking Table 5.2.1 into account. They are given in Tables 5.2.2(*a*) and (*b*). The expressions in these tables are identical to those derived by Behnken & Hauk (1986) except for two Laue classes.

5.2.5.3. *The Hill average*

The Voigt and the Reuss models are two extreme cases of crystallite interactions that roughly describe the strain/stress state of isotropic polycrystalline samples. Hill (1952) observed that the real elastic constants are generally close enough to the arithmetic average of the constants calculated within the two models. Consequently, a very good description of the peak shift is obtained in practice by using the arithmetic average of the Voigt and Reuss peak shifts (5.2.53) and (5.2.61). Even better is to use a weighted average with the weight w ($0 < w < 1$) as a refinable parameter in a least-squares analysis (Popa, 2000):

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle = w\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle^V + (1-w)\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle^R. \qquad (5.2.65)$$

5.2.5.4. *The Kroner model*

A model for crystallite interaction that is better than the Voigt or the Reuss model was proposed by Kroner (1958). According to Kroner, every crystallite is an inclusion in a continuous and homogenous matrix that has the elastic properties of the polycrystal. For the isotropic polycrystal, the strain on inclusion is

$$e_i(g) = \sum_{j=1}^{6}\left[\overline{S}_{ij}^R + t_{ij}(g)\right]\rho_j\bar{s}_j. \qquad (5.2.66)$$

In this expression, similar to (5.2.46*a*), the first term is the strain of the isotropic matrix given by (5.2.56). The second term is the strain induced in the crystallite by the matrix and is given by the theory of ellipsoidal inclusion of Eshelby (1957). The tensor $t_{ij}(g)$ accounts for the differences between the compliances of the inclusion and the matrix and has the property $\bar{t}_{ij} = 0$. To calculate the peak shift, (5.2.66) is substituted into (5.2.44′). Analytical calculations can only be performed for a spherical crystalline inclusion that has cubic symmetry. For the peak shift an expression similar to (5.2.53) is obtained but with different compliances. According to Bollenrath *et al.* (1967), the Voigt compliance constants in (5.2.53) must be replaced as follows:

$$\overline{S}_{11}^V \rightarrow \overline{S}_{11}^R + T_{11} - 2T_0\Gamma, \qquad (5.2.67a)$$

$$\overline{S}_{12}^V \rightarrow \overline{S}_{12}^R + T_{12} + T_0\Gamma, \qquad (5.2.67b)$$

$$T_0 = T_{11} - T_{12} - 2T_{44}, \qquad (5.2.67c)$$

$$\Gamma = a_2^2a_3^2 + a_1^2a_3^2 + a_1^2a_2^2. \qquad (5.2.67d)$$

The matrix compliances $\overline{S}_{11}^R$ and $\overline{S}_{12}^R$ are given by (5.2.57) for the case of cubic symmetry. The induced compliances T_{11}, T_{21} and T_{44} are also calculated from cubic single-crystal compliances by bulky algebraic expressions that have been reproduced in many papers: Bollenrath *et al.* (1967), Dölle (1979), Gnäupel-Herold *et al.* (1998) and Welzel *et al.* (2005).

5.2.5.5. *The ‘sin² Ψ’ method*

The peak-shift equations (5.2.53) and (5.2.61) can be arranged in the following form, which is convenient for experimental data processing:

$$\begin{aligned} \langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle = {} & S_1(\bar{s}_1+\bar{s}_2+\bar{s}_3) + \tfrac{1}{2}S_2\bar{s}_3 \\ & + \tfrac{1}{2}S_2(\bar{s}_1\cos^2\gamma + \bar{s}_2\sin^2\gamma - \bar{s}_3 + \bar{s}_6\sin 2\gamma)\sin^2\Psi \\ & + \tfrac{1}{2}S_2(\bar{s}_4\sin\gamma + \bar{s}_5\cos\gamma)\sin 2\Psi. \end{aligned} \qquad (5.2.68)$$

The factors S_1 and S_2 are called *diffraction elastic constants*. For the models examined above they are the following:

$$\begin{aligned} &S_1 = \overline{S}^V_{12}, \quad S_2 = 2(\overline{S}^V_{11} - \overline{S}^V_{12}); && \text{Voigt} \\ &S_1 = (r_2 - r_4)/2, \quad S_2 = 3r_4 - r_2; && \text{Reuss} \\ &S_1 = \overline{S}^R_{12} + T_{12} + T_0\Gamma, && \\ &S_2 = 2(\overline{S}^R_{11} - \overline{S}^R_{12} + T_{11} - T_{12} - 3T_0\Gamma). && \text{Kroner (cubic)} \end{aligned} \tag{5.2.69}$$

Except for the Voigt model, the diffraction elastic constants are dependent on the Miller indices.

If we consider the peak shifts for γ and $\gamma + \pi$ at the same value of Ψ, equation (5.2.68) is split into two linear equations, one in $\sin^2\Psi$ and the other in $\sin 2\Psi$:

$$\begin{aligned} \langle\varepsilon_{\mathbf{h}}\rangle^+ &= \langle\varepsilon_{\mathbf{h}}(\Psi,\gamma)\rangle + \langle\varepsilon_{\mathbf{h}}(\Psi,\gamma+\pi)\rangle \\ &= 2S_1(\overline{s}_1 + \overline{s}_2 + \overline{s}_3) + S_2\overline{s}_3 \\ &\quad + S_2(\overline{s}_1\cos^2\gamma + \overline{s}_2\sin^2\gamma - \overline{s}_3 + \overline{s}_6\sin 2\gamma)\sin^2\Psi, \end{aligned} \tag{5.2.70a}$$

$$\begin{aligned} \langle\varepsilon_{\mathbf{h}}\rangle^- &= \langle\varepsilon_{\mathbf{h}}(\Psi,\gamma)\rangle - \langle\varepsilon_{\mathbf{h}}(\Psi,\gamma+\pi)\rangle \\ &= S_2(\overline{s}_4\sin\gamma + \overline{s}_5\cos\gamma)\sin 2\Psi. \end{aligned} \tag{5.2.70b}$$

Consequently, if the peak shifts for one or more peaks are measured as a function of Ψ in the range $(0, \pi/2)$ at γ and $\gamma + \pi$ for three fixed values of γ (for example 0, $\pi/4$ and $\pi/2$), the stress-tensor elements $\overline{s}_i$ can be determined from the intercepts and slopes of these lines. It is presumed that the single-crystal elastic constants are known and the diffraction elastic constants in equations (5.2.70) can be calculated following one of the models presented previously. This is the conventional '$\sin^2\Psi$' method. Alternatively, equation (5.2.68) can be used in a least-squares analysis or implemented in the Rietveld codes. If diffraction patterns measured at a number of points (Ψ, γ) are available, then the stress-tensor elements $\overline{s}_i$ can be refined together with the structural and other parameters.

5.2.5.6. *Determining the single-crystal elastic constants*

The dependence of the diffraction elastic constants on the Miller indices can be exploited to find the single-crystal elastic constants from powder diffraction data. Indeed, let us presume that an axial, known stress $\overline{s}_3$ is applied to a polycrystalline sample. All other components of the stress tensor are zero and equation (5.2.68) then becomes

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle = (S_1 + \tfrac{1}{2}S_2\cos^2\Psi)\overline{s}_3. \tag{5.2.71}$$

By measuring the peak shift for $\Psi = 0$ and $\Psi = \pi/2$, both S_1 and S_2 can be determined. If the measurement is repeated for many peaks, the single-crystal elastic constants can be calculated by minimizing the value of χ^2 calculated using the differences between the measured diffraction elastic constants and those calculated with one of the models presented above (except for the Voigt model). For a given Laue group, the number of measured diffraction peaks must be greater than the number of independent single-crystal elastic constants. A comparison of the single-crystal elastic constants determined in this way for aluminium, copper and steel (Gnäupel-Herold *et al.*, 1998) with those measured on single crystals using ultrasonic pulses proved the reliability of the diffraction method.

5.2.6. The hydrostatic state in isotropic polycrystals

A hypothesis that has only recently been examined in the literature (Popa, 2008) is that the intergranular strain in the crystallite reference system is zero and then

$$\varepsilon_i(\varphi_1, \Phi_0, \varphi_2) = \overline{\varepsilon}_i. \tag{5.2.72}$$

To obtain the strain tensor in the sample reference system, (5.2.72) is substituted into (5.2.16*b*); to obtain the stress tensor, (5.2.72) is substituted into (5.2.25*a*), and (5.2.25*a*) into (5.2.16*d*). We then have

$$e_i(g) = \sum_{j=1}^{6} P_{ij}(g)\overline{\varepsilon}_j, \tag{5.2.73a}$$

$$s_i(g) = \sum_{l=1}^{6} \rho_l\overline{\varepsilon}_l \sum_{j=1}^{6} P_{ij}(g)C_{jl}. \tag{5.2.73b}$$

To calculate the macroscopic strains and stresses, equations (5.2.73) are averaged in Euler space. Presuming an isotropic polycrystal, the average acts only on the matrix $\mathbf{P}$ and one obtains

$$\overline{P}_{ij} = \begin{cases} 1/3 & \text{if } i,j = 1,2,3 \\ 0 & \text{if } i \text{ or } j > 3. \end{cases} \tag{5.2.74}$$

The macroscopic strains and stresses are then the following:

$$\overline{e}_1 = \overline{e}_2 = \overline{e}_3 = \overline{e} = (\overline{\varepsilon}_1 + \overline{\varepsilon}_2 + \overline{\varepsilon}_3)/3, \ \ \overline{e}_4 = \overline{e}_5 = \overline{e}_6 = 0, \tag{5.2.75a}$$

$$\overline{s}_1 = \overline{s}_2 = \overline{s}_3 = \overline{s} = \frac{1}{3}\sum_{l=1}^{6} \rho_l\overline{\varepsilon}_l(C_{1l} + C_{2l} + C_{3l}), \ \ \overline{s}_4 = \overline{s}_5 = \overline{s}_6 = 0. \tag{5.2.75b}$$

The structure of equations (5.2.75) is specific for the strain/stress state in a sample under a hydrostatic pressure.

To calculate the peak shift, we insert (5.2.72) into (5.2.44) and obtain

$$\langle\varepsilon_{\mathbf{h}}\rangle = \overline{\varepsilon}_1 a_1^2 + \overline{\varepsilon}_2 a_2^2 + \overline{\varepsilon}_3 a_3^2 + 2\overline{\varepsilon}_4 a_2 a_3 + 2\overline{\varepsilon}_5 a_1 a_3 + 2\overline{\varepsilon}_6 a_1 a_2. \tag{5.2.76}$$

As expected, the peak shift is independent of the direction in the sample. Crystal symmetries that are higher than triclinic impose constraints on the strains $\overline{\varepsilon}_i$ that can be found by setting the invariance conditions of the peak shift (5.2.76) to these symmetry operations. Hence, for monoclinic $2/m$, $a_1 \to -a_1$ and $a_2 \to -a_2$ by a twofold axis along $\mathbf{c}$, and one then finds $\overline{\varepsilon}_4 = \overline{\varepsilon}_5 = 0$. The peak shifts for all Laue classes higher than triclinic are given in the l = 2 row of Table 5.2.6. These formulae can be easily implemented in the Rietveld codes with $\overline{\varepsilon}_i$ refinable parameters. In fact they have already been implemented in *GSAS* (profile #5), but the derivation presented in the *GSAS* manual (Larson & Von Dreele, 2004) is different, with the concrete connection between the refined parameters and the macroscopic hydrostatic strain and stress not being revealed.

The hydrostatic state can be also modelled presuming zero intergranular stress in the crystal reference system:

$$\sigma_i(\varphi_1, \Phi_0, \varphi_2) = \overline{\sigma}_i. \tag{5.2.77}$$

Substituting (5.2.77) into (5.2.16*d*) and also into (5.2.25*b*), which is further substituted into (5.2.16*b*), one finds

$$s_i(g) = \sum_{j=1}^{6} P_{ij}(g)\overline{\sigma}_j, \tag{5.2.78a}$$

$$e_i(g) = \sum_{l=1}^{6} \rho_l\overline{\sigma}_l \sum_{j=1}^{6} P_{ij}(g)S_{jl}, \tag{5.2.78b}$$

and averaging in Euler space one obtains

$$\overline{s}_1 = \overline{s}_2 = \overline{s}_3 = \overline{s} = (\overline{\sigma}_1 + \overline{\sigma}_2 + \overline{\sigma}_3)/3, \ \overline{s}_4 = \overline{s}_5 = \overline{s}_6 = 0, \quad (5.2.79a)$$

$$\overline{e}_1 = \overline{e}_2 = \overline{e}_3 = \overline{e} = \frac{1}{3}\sum_{l=1}^{6} \rho_l \overline{\sigma}_l (S_{1l} + S_{2l} + S_{3l}), \ \overline{e}_4 = \overline{e}_5 = \overline{e}_6 = 0. \quad (5.2.79b)$$

The peak shift is given by the same equation (5.2.76) but with $\overline{\varepsilon}_i$ calculated from $\overline{\sigma}_i$,

$$\overline{\varepsilon}_i = \sum_{j=1}^{6} S_{ij} \rho_j \overline{\sigma}_j. \quad (5.2.80)$$

The hypotheses (5.2.72) and (5.2.77) fully describe the hydrostatic strain/stress state in isotropic samples. Indeed, from the refined parameters $\overline{\varepsilon}_i$ or $\overline{\sigma}_i$ the averaged strain and stress $\overline{e}_i$ and $\overline{s}_i$ can be calculated, and also the intergranular strains and stresses $\Delta e_i(g)$ and $\Delta s_i(g)$, both of which differ from zero. Relations of the type (5.2.46) cannot be obtained from equations (5.2.72) and (5.2.77), but only those of the type (5.2.26). For this reason, a linear homogenous equation of the Hooke type between the averaged stress and strain cannot be established.

5.2.7. Calculating the macroscopic strain/stress using spherical harmonics

As discussed in Section 5.2.4, in many cases the classical models of crystallite interactions cannot explain the strongly nonlinear dependence of the diffraction-peak shift on $\sin^2\Psi$, even if the texture is accounted for. A possible solution to this problem is to renounce any physical model and to find the strain/stress orientation distribution functions (SODFs) by inverting the measured strain pole distributions $\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle$.

Similar to the ODF (texture), the SODF can be subjected to a Fourier analysis by using generalized spherical harmonics. However, there are two important differences. The first is that in place of one distribution (the ODF), six SODFs are analysed simultaneously. The components of the strain or the stress tensor in the sample or in the crystal reference system can be used for analysis. The second difference involves the invariance to the crystal and sample symmetry operations. The ODF is invariant to both crystal and sample symmetry operations. In contrast, the six SODFs in the sample reference system are invariant to the crystal symmetry operations, but they transform similarly to equations (5.2.16) if the sample reference system is replaced by an equivalent system. Inversely, the SODFs in the crystal reference system transform like (5.2.16) if an equivalent system replaces this system and remain invariant to any rotation of the sample reference system. Consequently, for the spherical-harmonics coefficients of the SODF one expects selection rules that differ from those for the ODF.

In the literature, three different approaches based on the spherical-harmonics representation of the SODF have been reported: those of Wang *et al.* (1999, 2001, 2003), Behnken (2000) and Popa & Balzar (2001, 2014). Wang and co-workers represented the stress tensor in the sample reference system $s_i(g)$ by spherical harmonics. Consequently, the harmonic coefficients with $l = 0$ are the averaged stresses $\overline{s}_i$, but to calculate the averaged strains $\overline{e}_i$ coefficients with $l = 0, 2, 4$ are necessary. Behnken proposed the expansion of both $e_i(g)$ and $s_i(g)$ independently in spherical harmonics. In this case $\overline{e}_i$ and $\overline{s}_i$ are the coefficients with $l = 0$ of the two series, but the volume of calculations by least squares to find the harmonic coefficients is greater. Both Wang and Behnken used (5.2.44′) to calculate the strain pole distribution $\langle \varepsilon_{\mathbf{h}}(\mathbf{y}) \rangle$. When the calculation starts from the harmonic series of $s_i(g)$, the single-crystal compliances in the sample reference system appear in (5.2.44′) as supplementary factors to the SODF and ODF. Behnken performs the integrals (5.2.44′) numerically. Wang and co-workers used the spherical-harmonics representation of the ODF and the Clebsch–Gordon coefficients to express the product of the SODF, ODF and the single-crystal compliances in a series that is further integrated like the ODF for texture. Both Wang and Behnken only considered the case of cubic crystal symmetry and orthorhombic sample symmetry, and constructed the corresponding symmetrized spherical harmonics according to the invariance and non-invariance properties in Euler space. The third approach, reported by Popa & Balzar (2001, 2014), is similar to those of Wang and Behnken, but with an important distinction that makes the problem of the strain and stress determination equivalent to the texture problem, for which a solution had been implemented in the Rietveld method. This approach, which is described below, extends to any sample and crystal symmetry and is appropriate for implementation in the Rietveld method. It was implemented by Lutterotti in his Rietveld program *MAUD* (Lutterotti, 2010) and integrated into a system of ‘combined analysis’ by Chanteigner, as described in his book of the same title (Chateigner, 2010).

5.2.7.1. *Strain expansion in generalized spherical harmonics: the Popa and Balzar approach*

In the approach of Popa & Balzar (2001, 2014), the representation by spherical harmonics is performed on the product of the SODF and the ODF; that is, the SODF weighted by texture (WSODF). In this product, a strain-tensor component in the crystallite reference system is used for SODF. We then have

$$\varepsilon_i(\varphi_1, \Phi_0, \varphi_2) f(\varphi_1, \Phi_0, \varphi_2) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \sum_{n=-l}^{l} c_{il}^{mn} \exp(im\varphi_2) P_l^{mn}(\Phi_0) \exp(in\varphi_1), \quad (5.2.81)$$

where the Legendre functions $P_l^{mn}(\Phi_0)$ are defined by equation (14.2) from Bunge (1982); denoting $x = \cos\varphi_0$ these are

$$P_l^{mn}(x) = \frac{(-1)^{l-m} i^{n-m}}{2^l (l-m)!} \left[\frac{(l-m)!(l+n)!}{(l+m)!(l-n)!}\right]^{1/2} (1-x)^{-(n-m)/2} \times (1+x)^{-(n+m)/2} \frac{d^{l-n}}{dx^{l-n}} [(1-x)^{l-m}(1+x)^{l+m}].$$

The functions P_l^{mn} are real for $m + n$ = even and imaginary for $m + n$ = odd, and have the following properties:

$$P_l^{mn\,*}(\Phi) = (-1)^{m+n} P_l^{mn}(\Phi), \quad (5.2.82a)$$

$$P_l^{nm}(\Phi) = P_l^{mn}(\Phi) = P_l^{-m,-n}(\Phi), \quad (5.2.82b)$$

$$P_l^{mn}(\pi - \Phi) = (-1)^{l+m+n} P_l^{-mn}(\Phi), \quad (5.2.82c)$$

$$\int_0^{\pi} P_l^{mn}(\Phi) P_{l'}^{mn\,*}(\Phi) \sin\Phi \, \mathrm{d}\Phi = \frac{2}{2l+1} \delta_{ll'}. \quad (5.2.82d)$$

The last equation says that the functions P_l^{mn} of different harmonics indices l are orthogonal. By using equation (5.2.82a) and taking into account that WSODFs are real functions, one obtains the following condition for the complex coefficients c_l^{mn}:

$$c_{il}^{-m,-n} = (-1)^{m+n} c_{il}^{mn\,*}. \quad (5.2.83)$$

The integral in Euler space of (5.2.81) gives $c_{i0}^{00} = \overline{\varepsilon}_i$, and thus the term $l = 0$ (the ground state) represents the hydrostatic strain/stress state of the isotropic polycrystal discussed in Section 5.2.6. The rest of the terms represent the deviation of the real strain/stress from the hydrostatic state of an isotropic polycrystal (the perturbation of the ground state). To calculate the peak shift, equation (5.2.44) with the integrand replaced by (5.2.81) is used. Further, the integral over the crystallites in Bragg reflection in (5.2.44) is performed using the following equation derived from equation (14.160) in Bunge (1982):

$$\begin{aligned}&\frac{1}{2\pi}\int_{\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega \, \exp(im\varphi_2^+)P_l^{mn}(\Phi_0^+)\exp(in\varphi_1^+)\\ &\qquad = \frac{2}{2l+1}\exp(-im\beta)P_l^m(\Phi)\exp(in\gamma)P_l^n(\Psi). \qquad (5.2.84)\end{aligned}$$

In this equation P_l^m is the adjunct Legendre function (equation 14.39 in Bunge, 1982); denoting $x = \cos\Phi$ or $x = \cos\Psi$, this function is

$$\begin{aligned}P_l^m(x) = {}& \frac{(-1)^{l-m}}{2^l l!}\left(\frac{2l+1}{2}\right)^{1/2}\left[\frac{(l+m)!}{(l-m)!}\right]^{1/2}\\ &\times (1-x^2)^{-m/2}\frac{d^{l-m}}{dx^{l-m}}(1-x^2)^l.\end{aligned}$$

There is an obvious relation between the functions P_l^{m0} and P_l^m:

$$P_l^{m0}(\Phi) = P_l^{0m}(\Phi) = i^{-m}[2/(2l+1)]^{1/2}P_l^m(\Phi). \qquad (5.2.85)$$

By substituting (5.2.85) into equations (5.2.82) one obtains the following properties for P_l^m:

$$P_l^m(\Phi) = (-1)^m P_l^{-m}(\Phi), \qquad (5.2.86a)$$

$$P_l^m(\pi - \Phi) = (-1)^{l+m}P_l^m(\Phi), \qquad (5.2.86b)$$

$$\int_0^\pi P_l^m(\Phi)P_{l'}^m(\Phi)\sin\Phi \, \mathrm{d}\Phi = \delta_{ll'}. \qquad (5.2.86c)$$

Accounting for the properties of (5.2.84), (5.2.86*a*) and (5.2.86*b*), the resulting terms in the expression for the peak shift after integration over ω are rearranged to have only positive indices, and one obtains

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle P_{\mathbf{h}}(\mathbf{y}) = \sum_{l=0}^{\infty}[2/(2l+1)]I_l^M(\mathbf{h},\mathbf{y}), \quad l = \text{even}, \qquad (5.2.87)$$

$$I_l^M(\mathbf{h},\mathbf{y}) = \sum_{i=1}^{6} E_i\rho_i t_{il}(\mathbf{h},\mathbf{y}), \qquad (5.2.88)$$

$$t_{il}(\mathbf{h},\mathbf{y}) = A_{il}^0(\mathbf{y})P_l^0(\Phi) + \sum_{m=1}^{l}\left[A_{il}^m(\mathbf{y})\cos m\beta + B_{il}^m(\mathbf{y})\sin m\beta\right]P_l^m(\Phi), \qquad (5.2.89)$$

$$\begin{aligned}A_{il}^m(\mathbf{y}) = {}& \alpha_{il}^{m0}P_l^0(\Psi) + \sum_{n=1}^{l}\left(\alpha_{il}^{mn}\cos n\gamma + \beta_{il}^{mn}\sin n\gamma\right)P_l^n(\Psi)\\ &(m = 0, \ldots, l). \qquad (5.2.90a)\end{aligned}$$

$$\begin{aligned}B_{il}^m(\mathbf{y}) = {}& \gamma_{il}^{m0}P_l^0(\Psi) + \sum_{n=1}^{l}\left(\gamma_{il}^{mn}\cos n\gamma + \delta_{il}^{mn}\sin n\gamma\right)P_l^n(\Psi)\\ &(m = 1, \ldots, l). \qquad (5.2.90b)\end{aligned}$$

The first observation about equation (5.2.87) is that, as for the texture ODF, it is impossible to determine the odd-l Fourier coefficients of the WSODF from measured pole figures. This is a consequence of the action of Friedel's law.

The coefficients α_{il}^{mn}, β_{il}^{mn}, γ_{il}^{mn} and δ_{il}^{mn} in (5.2.90*a*) and (5.2.90*b*) are obtained from the coefficients c_{il}^{mn} according to the corrected[5] Table 1 from Popa & Balzar (2001, 2014). Equations (5.2.88) to (5.2.90) are valid for triclinic sample and crystal symmetries, and for a given value of l the total number of coefficients is $6(2l+1)^2$. If the crystal and sample symmetries are higher than triclinic, the number of coefficients is reduced, with some coefficients being zero and others being correlated.

5.2.7.2. *The selection rules for all Laue classes*

To find the selection rules for all Laue classes, the invariance conditions to rotations are applied to the peak shift weighted by texture $\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle P_{\mathbf{h}}(\mathbf{y})$. As the terms with different l in (5.2.87) are independent, the invariance conditions must be applied to every I_l^M.

We begin with the selection rules imposed by the crystal symmetry. An r-fold axis along $\mathbf{x}_3$ transforms Φ, β, a_1, a_2 as follows: $\Phi \to \Phi$, $\beta \to \beta + 2\pi/r$, $a_1 \to a_1\cos(2\pi/r) - a_2\sin(2\pi/r)$ and $a_2 \to a_1\sin(2\pi/r) + a_2\cos(2\pi/r)$. By applying the invariance conditions to (5.2.88) one obtains a system of six linear equations:

$$t_{il}(\Phi, \beta + 2\pi/r, \mathbf{y}) = \sum_{k=1}^{6} f_{ik}(r)t_{kl}(\Phi, \beta, \mathbf{y}). \qquad (5.2.91)$$

These equations are just the transformations (5.2.16) for a particular value of r. Furthermore, if (5.2.89) is substituted into (5.2.91) one obtains a system of homogenous equations in A_{il}^m and B_{il}^m that has a nontrivial solution only for certain values of m. If, besides the r-fold axis in $\mathbf{x}_3$, there is a twofold axis along $\mathbf{x}_1$, then A_{il}^m and B_{il}^m must fulfil supplementary conditions resulting from the invariance of I_l^M to the transformations $\Phi \to \pi - \Phi$, $\beta \to -\beta$ and $(a_2, a_3) \to (-a_2, -a_3)$. The selection rules imposed by the crystal symmetry for the non-cubic Laue groups are given in Tables 4–7 and 9–12 in Popa & Balzar (2001, 2014). Note that coefficients belonging to different strain-tensor components are correlated, but only two coefficients are involved in all correlations. The threefold axis added on the long diagonal of the *mmm* and 4/*mmm* prisms to obtain the cubic groups $m\overline{3}$ and $m\overline{3}m$ introduces supplementary correlations between the coefficients A_{il}^m and B_{il}^m of the orthorhombic and tetragonal groups, respectively. These correlations involve more than two coefficients and are found by evaluating I_l^M in terms of the direction cosines a_i and setting the condition of invariance to the transformation $(a_1, a_2, a_3) \to (a_2, a_3, a_1)$. The supplementary correlations added to *mmm* and 4/*mmm* by the cubic threefold axis are given in Tables 13 and 14 in Popa & Balzar (2001, 2014).

One would expect the selection rules imposed by the sample symmetry to be identical to those for the texture of the same sample symmetry. Indeed, the invariance conditions that act directly on (5.2.90*a*) and (5.2.90*b*) are identical to the spherical-harmonics coefficients of the texture pole distribution [see, for example, Popa (2008)]. Hence, the selection rules in index n for the coefficients α_{il}^{mn}, β_{il}^{mn}, γ_{il}^{mn} and δ_{il}^{mn} are those from Table 2 in Popa & Balzar (2001, 2014).

5.2.7.3. *Generalized spherical harmonics of real type, and the WSODF index*

The coefficients α_{il}^{mn}, …, δ_{il}^{mn} fulfilling the selection rules are determined by fitting (5.2.87) truncated at $l = l_0$ to the experimental diffraction-peak shifts caused by strain. The fit can be performed directly using a regular least-squares program

---

[5] According to the corrigendum, a factor of 2 must be added to the right-hand sides of the equations.

Table 5.2.3
Assignment of functions $T_l^\nu(\Phi, \beta; \Psi, \gamma)$ to the coefficients g_{il}^ν

g_{il}^ν	$\leftarrow$	$T_l^\nu(\Phi, \beta; \Psi, \gamma)$
α_{il}^{mn}	$\leftarrow$	$\cos m\beta P_l^m(\Phi) \cos n\gamma P_l^n(\Psi)$
β_{il}^{mn}	$\leftarrow$	$\cos m\beta P_l^m(\Phi) \sin n\gamma P_l^n(\Psi)$
γ_{il}^{mn}	$\leftarrow$	$\sin m\beta P_l^m(\Phi) \cos n\gamma P_l^n(\Psi)$
δ_{il}^{mn}	$\leftarrow$	$\sin m\beta P_l^m(\Phi) \sin n\gamma P_l^n(\Psi)$

or, much more efficiently, by using a Rietveld-type program. Programs providing stabilized (smoothed) solutions are preferred. Furthermore, by using the fitted coefficients the whole macrostrain/stress state of the sample can be determined. For easy handling and coding of these operations, it is useful to define the *parameter vectors* and the *generalized spherical harmonics of real type* associated with these vectors.

Denoting the pair m, n by ν, $\nu \in [1, (2l + 1)2]$, and the coefficients $\alpha_{il}^{mn}, \ldots, \delta_{il}^{mn}$ by g_{il}^ν, the vectors of the parameters are

$$\begin{aligned}\mathbf{g}_{il} = (g_{il}^\nu) = (&\alpha_{il}^{0,0}, \alpha_{il}^{0,1}, \beta_{il}^{0,1}, \ldots, \alpha_{il}^{0,n}, \beta_{il}^{0,n}, \ldots, \alpha_{il}^{0,l}, \beta_{il}^{0,l}; \ldots \\ &\alpha_{il}^{m,0}, \alpha_{il}^{m,1}, \beta_{il}^{m,1}, \ldots, \alpha_{il}^{m,n}, \beta_{il}^{m,n}, \ldots, \alpha_{il}^{m,l}, \beta_{il}^{m,l}; \\ &\gamma_{il}^{m,0}, \gamma_{il}^{m,1}, \delta_{il}^{m,1}, \ldots, \gamma_{il}^{m,n}, \delta_{il}^{m,n}, \ldots, \gamma_{il}^{m,l}, \delta_{il}^{m,l}; \ldots) \\ &(m = 1, \ldots, l). \end{aligned} \tag{5.2.92}$$

The sequence of vector elements in (5.2.92) is imposed by the sequence of the sums over the harmonic indices m, n in (5.2.89) and (5.2.90), with n varying faster than m. Using (5.2.92), equations (5.2.89) and (5.2.90) become

$$t_{il}(\mathbf{h}, \mathbf{y}) = \sum_{\nu=1}^{(2l+1)^2} g_{il}^\nu T_l^\nu(\Phi, \beta; \Psi, \gamma), \tag{5.2.93}$$

with the functions T_l^ν being paired with the coefficients g_{il}^ν according to Table 5.2.3.

To find the set of real generalized spherical harmonics associated with $\mathbf{g}_{il}$ one starts from equation (5.2.81). The sums are rearranged to have only positive indices, with n varying faster than m; furthermore, we use (5.2.83) and the properties (5.2.82*a*,*b*,*c*) of the Legendre functions P_l^{mn}, which are replaced by the following real functions: $Q_l^{mn} = P_l^{mn}$ for $m + n$ = even and $Q_l^{mn} = iP_l^{mn}$ for $m + n$ = odd. Note that the properties (5.2.82*b*,*c*) of P_l^{mn} are transferred to Q_l^{mn},

$$Q_l^{-m,-n}(x) = Q_l^{m,n}(x); \quad Q_l^{-m,n}(x) = (-1)^{l+m+n} Q_l^{m,n}(-x).$$

Finally, by using (5.2.92) and Table 1 from Popa & Balzar (2001, 2014), equation (5.2.81) becomes

$$f(g)\varepsilon_i(g) = \sum_{l=0}^{\infty} \sum_{\nu=1}^{(2l+1)^2} g_{il}^\nu R_l^\nu(g). \tag{5.2.94}$$

Here, R_l^ν are the generalized spherical harmonics of real type, explicitly given in Table 5.2.4. For every l they form a complete and orthogonal basis in Euler space with the following orthogonality condition:

$$(8\pi^2)^{-1} \textstyle\iiint \mathrm{d}g \, R_l^\nu(g) R_{l'}^{\nu'}(g) = r_l^\nu \delta_{ll'} \delta_{\nu\nu'}. \tag{5.2.95}$$

Finally, R_l^ν and T_l^ν fulfil the following equation similar to (5.2.84):

$$\frac{1}{2\pi} \int_{\mathbf{h}\|\mathbf{y}} \mathrm{d}\omega \, R_l^\nu(\varphi_1^+, \Phi_0^+, \varphi_2^+) = \frac{2}{2l+1} T_l^\nu(\Phi, \beta; \Psi, \gamma). \tag{5.2.96}$$

The texture index was introduced by Bunge (1982) to obtain a measure of the texture strength. Similarly, we can introduce a *WSODF index* that should be defined as follows:

$$J = \sum_{i=1}^{6} (8\pi^2)^{-1} \textstyle\iiint \mathrm{d}g \, [f(g)\varepsilon_i(g)]^2 \Big/ \sum_{i=1}^{6} (\overline{\varepsilon}_i)^2. \tag{5.2.97}$$

Inserting (5.2.94), truncating, and taking account of (5.2.95) and that $g_{i0}^1 = \overline{\varepsilon}_i$, one obtains

$$J = 1 + \sum_{i=1}^{6} \sum_{l=2}^{l_0} \sum_{\nu=1}^{(2l+1)^2} r_l^\nu (g_{il}^\nu)^2 \Big/ \sum_{i=1}^{6} (\overline{\varepsilon}_i)^2. \tag{5.2.98}$$

Beside its role as a measure of the WSODF strength, the index can be used to find a stabilized solution for the strain parameters g_{il}^ν by minimizing the Lagrange function $\chi^2 + \lambda(J - 1)$ in place of χ^2.

5.2.7.4. *Determining the macrostrain/stress state of the sample*

Once the strain parameters g_{il}^ν have been determined, the whole macrostrain/stress state can be calculated. Hence, inserting (5.2.94) truncated at $l = l_0$ into (5.2.16*b*), one obtains the WSODF for e_i:

$$f(g)e_i(g) = \sum_{j=1}^{6} \sum_{l=0}^{l_0} \sum_{\nu=1}^{(2l+1)^2} R_l^\nu(g) P_{ij}(g) g_{jl}^\nu. \tag{5.2.99}$$

If (5.2.94) is inserted into (5.2.25*a*), and (5.2.25*a*) into (5.2.16*d*), one obtains a similar expression for the WSODF as for s_i, but with the vector $\mathbf{g}_{jl}$ being replaced by $\mathbf{g}'_{jl}$, which is defined as

$$(g')_{jl}^\nu = \sum_{k=1}^{6} C_{jk} \rho_k g_{kl}^\nu. \tag{5.2.100}$$

According to (5.2.30), to determine $\overline{e}_i$, equation (5.2.99) must be integrated in Euler space. Only terms with $l = 0$ and $l = 2$ can

Table 5.2.4
The real generalized spherical harmonics

g_{il}^ν	$\leftarrow$	$R_l^\nu(\varphi_1, x, \varphi_2); \quad x = \cos\Phi_0$	
α_{il}^{mn}	$\leftarrow$	$[\cos(m\varphi_2) + n\varphi_1) Q_l^{mn}(x) + (-1)^{l+n} \cos(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{even}$
		$[\sin(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) - (-1)^{l+n} \sin(m\varphi_2) - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{odd}$
β_{il}^{mn}	$\leftarrow$	$[\sin(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) - (-1)^{l+n} \sin(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{even}$
		$[-\cos(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) - (-1)^{l+n} \cos(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{odd}$
γ_{il}^{mn}	$\leftarrow$	$[-\sin(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) - (-1)^{l+n} \sin(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{even}$
		$[\cos(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) - (-1)^{l+n} \cos(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{odd}$
δ_{il}^{mn}	$\leftarrow$	$[\cos(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) - (-1)^{l+n} \cos(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{even}$
		$[\sin(m\varphi_2 + n\varphi_1) Q_l^{mn}(x) + (-1)^{l+n} \sin(m\varphi_2 - n\varphi_1) Q_l^{mn}(-x)]/2,$	$m + n = \text{odd}$

have contributions that differ from zero. This is the consequence of the fact that the elements of the matrix **P** can be written as a linear combination of R_0^1 and R_2^ν combined with the orthogonality condition (5.2.95). There are 936 integrals of the type $w_{ijl}^\nu = (1/8\pi^2)\iiint \mathrm{d}g\, P_{ij}(g) R_l^\nu(g)$. Although an analytical calculation is possible, they were calculated numerically. Only 73 differ from zero. The macroscopic averaged strain tensor is as follows:

$$\begin{aligned}
\overline{e}_1, \overline{e}_2 &= (1/3)(g_{10}^1 + g_{20}^1 + g_{30}^1) + (1/30)(g_{12}^1 + g_{22}^1 - 2g_{32}^1)\\
&\mp (1/10/\sqrt{6})(g_{12}^4 + g_{22}^4 - 2g_{32}^4) - (1/5/\sqrt{6})g_{52}^6\\
&\pm (1/10)g_{52}^9 - (1/5/\sqrt{6})g_{42}^{11} \pm (1/10)g_{42}^{14}\\
&- (1/10/\sqrt{6})(g_{12}^{16} - g_{22}^{16}) \pm (1/20)(g_{12}^{19} - g_{22}^{19})\\
&- (1/5/\sqrt{6})g_{62}^{21} \pm (1/10)g_{62}^{24}, \qquad (5.2.101a)\\
\overline{e}_3 &= (1/3)(g_{10}^1 + g_{20}^1 + g_{30}^1) - (1/15)(g_{12}^1 + g_{22}^1 - 2g_{32}^1)\\
&+ (2/5/\sqrt{6})g_{52}^6 + (2/5/\sqrt{6})g_{42}^{11} + (1/5/\sqrt{6})(g_{12}^{16} - g_{22}^{16})\\
&+ (2/5/\sqrt{6})g_{62}^{21}, \qquad (5.2.101b)\\
\overline{e}_4 &= -(1/10/\sqrt{6})(g_{12}^3 + g_{22}^3 - 2g_{32}^3) + (1/10)g_{52}^8\\
&+ (1/10)g_{42}^{13} + (1/20)(g_{12}^{18} - g_{22}^{18}) + (1/10)g_{62}^{23}, \qquad (5.2.101c)\\
\overline{e}_5 &= -(1/10/\sqrt{6})(g_{12}^2 + g_{22}^2 - 2g_{32}^2) + (1/10)g_{52}^7\\
&+ (1/10)g_{42}^{12} + (1/20)(g_{12}^{17} - g_{22}^{17}) + (1/10)g_{62}^{22}, \qquad (5.2.101d)\\
\overline{e}_6 &= -(1/10/\sqrt{6})(g_{12}^5 + g_{22}^5 - 2g_{32}^5) + (1/10)g_{52}^{10}\\
&+ (1/10)g_{42}^{15} + (1/20)(g_{12}^{20} - g_{22}^{20}) + (1/10)g_{62}^{25}. \qquad (5.2.101e)
\end{aligned}$$

The elements of the macroscopic averaged stress tensor $\overline{s}_i$ have exactly the same expressions except that $\mathbf{g}_{jl}$ is replaced by $\mathbf{g}'_{jl}$ given by (5.2.100).

5.2.7.5. *Simplified ('short') harmonics representation of the peak shift, and the 'mixed' representation*

When it is not necessary to find WSODFs and the averaged strain and stress tensors are not of interest, one can choose a different representation for I_l^M with fewer parameters that corrects only for the line shifts caused by stress. For this reason we call this representation 'short', in contrast to the 'full' representation of I_l^M given by equations (5.2.88) and (5.2.93). Besides correcting for the line shifts, the 'full' representation provides the whole macrostrain/stress state of the sample.

To derive the 'short' representation, the quantities E_i in equation (5.2.88) and the angles (Φ, β) in equation (5.2.89) are replaced by the direction cosines a_i and one obtains

$$I_l^M(\mathbf{h}, \mathbf{y}) = \sum_{i=1}^{6} t_{il}(\mathbf{h}, \mathbf{y}) \rho_i j_{i2}(a_1, a_2, a_3), \qquad (5.2.102a)$$

$$t_{il}(\mathbf{h}, \mathbf{y}) = \sum_{\mu=1}^{\mu_l} C_{il}^\mu(\mathbf{y}) j_{\mu l}(a_1, a_2, a_3). \qquad (5.2.102b)$$

The functions $C_{il}^\mu(\mathbf{y})$ are linear combinations of $A_{il}^m(\mathbf{y})$ and $B_{il}^m(\mathbf{y})$, while $j_{\nu l}(a_1, a_2, a_3)$ are the following monomials of degree l in the variables (a_1, a_2, a_3):

$$j_{\mu l}(a_1, a_2, a_3) = a_1^{l_1} a_2^{l_2} a_3^{l_3} \quad (l_1 + l_2 + l_3 = l,\ l_i \geq 0). \qquad (5.2.103)$$

For a given value of the harmonic number l there are μ_l monomials. The complete set of monomials for l = 2, 4, 6 is given in Table 5.2.5.

Substituting (5.2.102*b*) into (5.2.102*a*) and taking into account that $j_{\nu l} j_{\mu l'} = j_{\lambda, l+l'}$, where $\lambda \in [1, \mu_{l+l'}]$, one obtains

Table 5.2.5
The monomials $j_{\mu l}(a_1, a_2, a_3)$ for l = 2, 4, 6

μ_l is the number of monomials for harmonic index l.

l, μ_l	Monomials
$l = 2$, $\mu_2 = 6$	$a_1^2, a_2^2, a_3^2, a_2a_3, a_1a_3, a_1a_2$
$l = 4$, $\mu_4 = 15$	$a_1^4, a_2^4, a_3^4, a_2^3a_3, a_2a_3^3, a_1^3a_3, a_1a_3^3, a_1^3a_2, a_1a_2^3, a_2^2a_3^2, a_1^2a_3^2, a_1^2a_2^2, a_1^2a_2a_3, a_1a_2^2a_3, a_1a_2a_3^2$
$l = 6$, $\mu_6 = 28$	$a_1^6, a_2^6, a_3^6, a_2^5a_3, a_2a_3^5, a_1^5a_3, a_1a_3^5, a_1^5a_2, a_1a_2^5, a_2^4a_3^2, a_2^2a_3^4, a_1^4a_3^2, a_1^2a_3^4, a_1^4a_2^2, a_1^2a_2^4, a_2^3a_3^3, a_1^3a_3^3, a_1^3a_2^3, a_1a_2^3a_3^2, a_1a_2^2a_3^3, a_1^3a_2a_3^2, a_1^2a_2a_3^3, a_1^3a_2^2a_3, a_1^2a_2^3a_3, a_1^4a_2a_3, a_1a_2^4a_3, a_1a_2a_3^4$

$$I_l^M(\mathbf{h}, \mathbf{y}) = \sum_{\mu=1}^{\mu_{l+2}} E_{\mu l}(\mathbf{y}) j_{\mu, l+2}(a_1, a_2, a_3). \qquad (5.2.104)$$

The functions $E_{\mu l}(\mathbf{y})$ are linear combinations of $C_{il}^\mu(\mathbf{y})$ and thus are linear combinations of $A_{il}^m(\mathbf{y})$ and $B_{il}^m(\mathbf{y})$. Consequently, according to (5.2.90) we have

$$E_{\mu l}(\mathbf{y}) = \eta_{\mu l}^0 P_l^0(\Psi) + \sum_{n=1}^{l} \left(\eta_{\mu l}^n \cos n\gamma + \zeta_{\mu l}^n \sin n\gamma\right) P_l^n(\Psi). \qquad (5.2.105)$$

Equations (5.2.104) and (5.2.105) are valid for triclinic crystal symmetry and for triclinic sample symmetry, respectively. If the crystal symmetry is higher than triclinic then (5.2.104) should be replaced by

$$I_l^M(\mathbf{h}, \mathbf{y}) = \sum_{\mu=1}^{M_{l+2}} E_{\mu l}(\mathbf{y}) J_{\mu, l+2}(a_1, a_2, a_3). \qquad (5.2.106)$$

Here, $J_{\mu,l}$ are homogenous polynomials of degree l in the variables a_1, a_2, a_3, invariant to the symmetry operations of the crystal Laue group, and M_l is their number. They are derived by setting these invariance conditions on the function $I_l^M(\mathbf{h}, \mathbf{y})$ expressed by (5.2.104) (Popa & Balzar, 2001, 2014). The polynomials for l = 2, 4, 6 are listed in Table 5.2.6 for all Laue classes. For sample symmetry higher than triclinic the coefficients $\eta_{\mu l}^n$ and $\zeta_{\mu l}^n$ in (5.2.103) follow the selection rules of the texture with the same sample symmetry. For non-cubic Laue groups these selection rules can be found, for example, in Table 3 in Popa (1992).

The number M_{l+2} in (5.2.106) must be equal to or smaller than the total number of functions A_{il}^m, B_{il}^m in (5.2.90); for crystal symmetry higher than triclinic it is frequently much smaller. For example, if the Laue class is $\overline{3}$ and l = 4, the total number of A_{il}^m, B_{il}^m is 18 (Table 6 of Popa & Balzar, 2001, 2014) but M_6 = 10; this means that there are 90 refinable parameters in place of 162. Unfortunately, it is not possible to obtain the WSODF and the averaged strain and stress tensors from the coefficients $\eta_{\mu l}^n$ and $\zeta_{\mu l}^n$.

Finally, it is possible to have a 'mixed' representation of the peak shift if I_l^M in (5.2.87) is taken as in the full representation for l = 0, 2 and as in the short representation for $l \geq 4$. In this mixed representation, besides correcting for peak shift, it is possible to calculate the averaged macroscopic strain and stress tensors $\overline{e}_i$ and $\overline{s}_i$, but not the WSODF for e_i and s_i. Like the full and the short representations, the mixed representation is implementable in Rietveld programs.

5.2.7.6. *Implementation in Rietveld codes*

In the practical applications reported to date by Behnken (2000), by Wang *et al.* (2001, 2003) and recently by Balzar *et al.*

Table 5.2.6
The complete set of polynomials $J_{\mu l}$ for $l = 2, 4, 6$ for all Laue groups

M_l is the number of polynomials in a complete set. In parts (*a*) to (*d*) the list in square brackets should be added to the complete set of polynomials for the dihedral Laue group to obtain the complete set of the cyclic Laue group. For cubic Laue groups in part (*e*), the sets are identical for some values of l and different for other l. Polynomials common to cubic Laue groups may also exist in the second case but they do not form a complete set, completeness being realized by adding the two different lists in square brackets.

(*a*) Laue groups *mmm* and 2/*m*.

l, M_l	Polynomials

(2010), the least-squares method was used to fit the calculated peak shifts to the measured peak shifts. As mentioned in Section 5.2.4, finding the peak shift presumes prior accurate determination of the peak positions. Because of peak overlap this can be accomplished for only a small number of peaks, and a large part of the information contained in the diffraction pattern is thus lost. As a consequence, a reasonably good set of data that could be processed using full representation of the peak shift may become a set only supported by a less powerful representation. This and other drawbacks are eliminated by implementing the peak-shift representation into Rietveld programs. All WSODF representations discussed previously are appropriate for such implementation.

5.2.7.7. *An application: determining the averaged macroscopic strain and stress tensors in a rolled uranium plate from time-of-flight neutron diffraction data*

An application of the WSODF model was reported quite recently by Balzar *et al.* (2010). The article is based on time-of-flight diffraction data measured on two identically shaped uranium plates on the SMARTS diffractometer at Los Alamos Neutron Science Center (LANSCE). One plate was cold-rolled in order to determine the residual strain and stress after plastic deformation; the second was annealed for use as a reference for the first one. With the sample mounted on an Eulerian cradle, measurements were performed for 18 specimen orientations, all with the cradle rotation angle fixed at 130° and for four scattering angles ($2\theta = \pm 98.4^\circ, \pm 81.6^\circ$), which gave 72 histograms in total. Separating 19 Bragg reflections in every histogram by pattern decomposition with peak positions as free parameters, 1368 experimental peak shifts become available. As the peak positions of the annealed sample were used as references, the strain/stress state reported by Balzar *et al.* (2010) is relative to the state of this sample. The texture was determined by *GSAS* (Von Dreele, 1997) and, surprisingly, the texture sample symmetry *mmm* expected for the cold-rolled sample was not confirmed, with the pole figures rather showing a triclinic symmetry. Consequently, the sample Laue group is $\overline{1}$, with the crystal Laue group being *mmm* (the space group of uranium is *Cmcm*). For numerical calculations an 'in-house' least-squares program without a stabilizer was adapted. As the sample and crystal symmetries were low, the number of parameters becomes too large at large l, and to avoid unreliable refined parameters the series (5.2.87) was interrupted at $l_0 = 4$. Inspection of the data set suggested using a mixed rather than a full representation of the peak shift. The expression used in least squares was then

$$\langle\varepsilon_{\mathbf{h}}(\mathbf{y})\rangle P_{\mathbf{h}}(\mathbf{y}) = 2\sum_{i=1}^{3} E_i T_0^1 g_{i0}^1 + \frac{2}{5}\sum_{i=1}^{6} E_i \rho_i \sum_{\nu\in[\nu]_i} T_2^\nu g_{i2}^\nu + \frac{2}{9}\sum_{\mu=1}^{10} E_{\mu2} J_{\mu6}.$$

All quantities have already been defined except for $[\nu_i]$. These are the ranges of the index ν for which $g_{i2}^\nu \neq 0$, thus representing the selection rules for these parameters. Looking in Table 9 from Popa & Balzar (2001, 2014) with the aid of (5.2.92), one finds $[\nu]_i = [1, 5] \cup [16, 20]$ for $i = 1, 2, 3$, $[\nu]_4 = [11, 15]$, $[\nu]_5 = [6,10]$ and $[\nu]_6 = [20, 25]$. The necessary values of $P_{\mathbf{h}}(\mathbf{y})$ were 'picked' from the *GSAS* output. There are 90 parameters for $l = 4$ with the role of ensuring a good fit and 48 for $l = 0, 2$, from which the averaged macroscopic strain and stress tensors were calculated using the expressions (5.2.101) and (5.2.102) and literature data for the single-crystal stiffness elastic constants. Taking $\mathbf{y}_1$ as the transverse direction, $\mathbf{y}_2$ as the rolling direction and $\mathbf{y}_3$ as the normal direction, these tensors are

$$\mathbf{e} = \begin{bmatrix} 1.55\,(22) & -5.41 & -6.16 \\ -5.41 & 6.42 & -0.19 \\ -6.16 & -0.19 & -1.05 \end{bmatrix} \times 10^{-4},$$

$$\mathbf{s} = \begin{bmatrix} 63\,(2) & -65 & -87 \\ -65 & 135 & -2 \\ -87 & -2 & 4 \end{bmatrix} \text{ MPa.}$$

The standard uncertainties, which are approximately constant for all tensor elements, are given in parentheses only for e_{11} and s_{11}. The tensile strain and stress in the rolling and transverse directions, with the former being much higher (approximately four times in strain and two times in stress), and a compressive strain in the normal direction accompanied by practically zero stress (within the limits of two standard deviations) confirm the expectations. Unexpected results before the experiment, but in concordance with the texture sample symmetry found from the measurements, are the strong, compressive shear components in both the strain and stress tensors. This may be caused by the slippage of rollers or/and the existence of a strong texture before rolling. Unfortunately, the texture before rolling was not investigated.

5.2.7.8. *Limitations of the spherical-harmonics approach and possible further developments*

The coefficients g_{jl}^{ν} from (5.2.93) refined in a least-squares program (Rietveld included) could be unreliable if the number of terms in the truncated series (5.2.87) is too large. One expects there to be a large number of terms in three cases: for low sample and crystal symmetry, if the peak shift is a strongly varying function in its arguments and if the strain/stress state is far from the ground state. For the approach presented here the ground state is the hydrostatic strain/stress state of an isotropic polycrystal. It is possible to derive at least two other spherical-harmonics representations of the WSODF having the Voigtian and the Reussian strain/stress state of an anisotropic polycrystal as a ground state, respectively.[6] Compared to the approaches of Wang *et al.* (1999) and Behnken (2000), these new representations will extend to any sample and crystal symmetry and will be implementable in Rietveld programs. The best representation from the hydrostatic, Voigtian and Reussian ground-state representations can be determined by trials. It must be noted that searching for representations with different ground states makes sense only because the corresponding series are interrupted. Finally, for low crystal and sample symmetries and strongly varying WSODFs the number of parameters may still remain large. It will then be useful to examine the possibility of finding a direct method to invert the strain pole distributions similar to the WIMW (Williams, Imhof, Matthies and Vienel) direct method used in texture analysis to determine the ODF from the texture pole distribution.

5.2.8. The spherical-harmonics approach to strain broadening

5.2.8.1. *Ignoring the macrostrain variance*

The strain diffraction line integral breadth in WPPF calculated with one of the equations (5.2.48) is proportional to the square root of the variance of the strain. According to equations (5.2.45) this quantity has two components: the microstrain variance $V_{\mathbf{h}}^{m}(\mathbf{y})$ and the macrostrain variance $V_{\mathbf{h}}^{M}(\mathbf{y})$. As in Section 5.2.7, the strain tensors on the right-hand side of these functions are defined in the crystallite reference system. As it is determined only by the intergranular strain, the macrostrain variance is small if the macrostrain/stress state is not too far from the hydrostatic state. Starting from the fact that the first term in the spherical-harmonics representation of intergranular strain has the harmonic index $l = 2$, it is easy to show that the macrostrain variance can be represented as a series of polynomials in a_1, a_2, a_3 beginning with degree 8, thus anticipating that the microstrain variance can be represented as a series of polynomials beginning with degree 4. The macrostrain variance has a contribution to the high-order terms (≥ 8) which is ignored in practice; thus, we can set $V_{\mathbf{h}}(\mathbf{y}) \simeq V_{\mathbf{h}}^{m}(\mathbf{y})$.

5.2.8.2. *The double-dependent anisotropic strain breadth (DDASB)*

The variance of microstrains $V_{\mathbf{h}}^{m}(\mathbf{y})$ is susceptible to analysis by generalized spherical harmonics similar to those developed previously for the peak shift [equation (5.2.44)]. The functions to be expanded in generalized spherical harmonics are the elements of the microstrain correlation matrix $\Delta_{ij}(g)$ defined by (5.2.41), weighted by the ODF. An expansion of $\Delta_{ij}(g)f(g)$ in generalized spherical harmonics similar to (5.2.81) but with the index i replaced by the pair ij is inserted in (5.2.45*c*). Following the derivation from Section 5.2.7.1 and ignoring the macrostrain variance, the variance of observable strains becomes

$$V_{\mathbf{h}}(\mathbf{y})P_{\mathbf{h}}(\mathbf{y}) = \sum_{l=0}^{\infty}[2/(2l+1)]I_l^m(\mathbf{h},\mathbf{y}) \quad (l = \text{even}), \tag{5.2.107}$$

$$I_l^m(\mathbf{h},\mathbf{y}) = \sum_{i=1}^{6}\sum_{j=1}^{6} E_i E_j \rho_i \rho_j t_{ijl}(\mathbf{h},\mathbf{y}), \tag{5.2.108}$$

$$\begin{aligned} t_{ijl}(\mathbf{h},\mathbf{y}) = {} & A_{ijl}^{0}(\mathbf{y})P_l^0(\Phi) \\ & + \sum_{m=1}^{l}\left[A_{ijl}^{m}(\mathbf{y})\cos m\beta + B_{ijl}^{m}(\mathbf{y})\sin m\beta\right]P_l^m(\Phi). \end{aligned} \tag{5.2.109}$$

Expressions similar to (5.2.90) can be written for the coefficients $A_{ijl}^{m}(\mathbf{y})$ and $B_{ijl}^{m}(\mathbf{y})$.

Although similar, there are important differences between the spherical-harmonics representations of $\varepsilon_i(g)$ and of $\Delta_{ij}(g)$. Firstly, the symmetrical tensor Δ_{ij} has 21 distinct elements while ε_i has only six, and thus the number of harmonic coefficients is much greater for the former. Secondly, the selection rules for $A_{ijl}^{m}(\mathbf{y})$ and $B_{ijl}^{m}(\mathbf{y})$ resulting from the crystal symmetry operations should be different from those for $A_{il}^{m}(\mathbf{y})$ and $B_{il}^{m}(\mathbf{y})$ for the problem of the peak shift. Finally, if the determination of the strain orientation distribution functions $\varepsilon_i(g)$ is frequently required, there is no practical interest in determining the function $\Delta_{ij}(g)$. Only the dependence on $\mathbf{h}$ and $\mathbf{y}$ of the strain broadening is required and, for this purpose, an alternative representation of $I_l^m(\mathbf{h},\mathbf{y})$ with a smaller number of parameters can be derived, similar to the 'short' representation of $I_l^M(\mathbf{h},\mathbf{y})$ for the peak shift. In this case, deriving the selection rules for $A_{ijl}^{m}(\mathbf{y})$ and $B_{ijl}^{m}(\mathbf{y})$ becomes useless.

To arrive at the 'short' representation of the strain variance, one replaces the quantities E_i in (5.2.108) and the angles (Φ, β) in (5.2.109) by the direction cosines (a_1, a_2, a_3). After replacement these equations become

$$I_l^m(\mathbf{h},\mathbf{y}) = \sum_{\nu=1}^{15} t_{\nu l}(\mathbf{h},\mathbf{y})\, j_{\nu 4}(a_1, a_2, a_3), \tag{5.2.110}$$

$$t_{ijl}(\mathbf{h},\mathbf{y}) = \sum_{\mu=1}^{\mu_l} C_{ijl}^{\mu}(\mathbf{y})\, j_{\mu}(a_1, a_2, a_3). \tag{5.2.111}$$

The functions $t_{\nu l}(\mathbf{h},\mathbf{y})$ in (5.2.110) are linear combinations of $t_{ijl}(\mathbf{h},\mathbf{y})$, while $C_{ijl}^{\mu}(\mathbf{y})$ in (5.2.111) are linear combinations of $A_{ijl}^{m}(\mathbf{y})$ and $B_{ijl}^{m}(\mathbf{y})$. Substituting (5.2.111) into (5.2.110), one obtains

---

[6] WSODF representations with Voigtian and Reussian ground states have been reported by Popa *et al.* (2014, 2015) and by Popa (2017), respectively.

$$I_l^m(\mathbf{h}, \mathbf{y}) = \sum_{\mu=1}^{\mu_{l+4}} E_{\mu l}(\mathbf{y})\, j_{\mu,l+4}(a_1, a_2, a_3). \qquad (5.2.112)$$

For crystal symmetries higher than triclinic the monomials in (5.2.112) should be replaced by symmetrized polynomials and we then have

$$I_l^m(\mathbf{h}, \mathbf{y}) = \sum_{\mu=1}^{M_{l+4}} E_{\mu l}(\mathbf{y})\, J_{\mu,l+4}(a_1, a_2, a_3), \qquad (5.2.113)$$

Equations (5.2.48), (5.2.107), (5.2.113) and (5.2.105) describe the dependence of the strain diffraction line breadth on both the crystal and sample directions. These equations are appropriate for implementation in WPPF programs, including Rietveld, if (5.2.107) is truncated, keeping a dependence on both **h** and **y**, but not increasing the number of refinable parameters too much; truncating at $l = 2$ may be a reasonable choice.

5.2.8.3. *The 'classical' limit of the DDASB*

If $\Delta_{ij}(g) = \overline{\Delta}_{ij}$, where $\overline{\Delta}_{ij} = \iiint \mathrm{d}g\, f(g)\, \Delta_{ij}(g)$, and the sample is isotropic, then in the right-hand side of equation (5.2.113) there is only the term with harmonic index $l = 0$. This condition is similar to (5.2.72) defining the hydrostatic macrostrain/stress state. The coefficients in (5.2.105) become constants and the strain variance is independent of sample direction. We then have

$$V_{\mathbf{h}} = \sum_{\mu=1}^{M_4} \eta_{\mu 0}\, J_{\mu,4}(a_1, a_2, a_3). \qquad (5.2.114)$$

This is the phenomenological model of strain broadening anisotropy reported by Popa (1998) and independently by Stephens (1999). This model is implemented today in all popular Rietveld programs. In *GSAS* (Larson & Von Dreele, 2004) to simultaneously process a number of diffraction patterns recorded in different sample directions, the same number of independent sets of Popa/Stephens model parameters are necessary (R. B. Von Dreele, personal communication), while only one set of strain broadening parameters of the DDASB model is required if this model was implemented in the Rietveld method.

This work was performed with financial support from the Romanian National Authority for Scientific Research through contract PCE 102/2011.

5.3. Quantitative texture analysis and combined analysis

D. Chateigner, L. Lutterotti and M. Morales

5.3.1. Introduction

For many solids, the growth of single crystals with sufficiently perfect crystallinity is not easy to manage, and is sometimes impossible. On the other hand, a perfectly randomly oriented powder is often impossible to obtain, or may even be undesirable if the anisotropic character of the sample is to be maintained. Consequently, any nondestructive characterization technique (for example diffraction) faces the difficulty of analysing textured samples, which are in a state between a perfect single crystal and a perfect powder. Such 'real samples' are obtained by complex techniques (alignment under uniaxial pressure, magnetic or electric fields, thermal gradients, flux or substrate growth, and combinations of these), and sample preparation is often difficult and time consuming. Unfortunately, when samples are crystallographically oriented to benefit from the intrinsic anisotropic properties of the constituent crystals, many characterization techniques (*i.e.* Rietveld analysis; Rietveld, 1969) are not appropriate or require sample grinding. Very often this grinding is not acceptable, as in the case of rare samples (for example fossils or comets), when grinding modifies the physical properties of the samples themselves (residually stressed materials), or when grinding is simply not possible (thin films).

It then becomes crucial to quantitatively take the textured character of the measured samples into account, either independently of other parameters that are accessible to diffraction (phase content, stresses, particle sizes and shapes), as in quantitative texture analysis (QTA), or to take these parameters into account by refining them all together, as in the combined-analysis (CA) methodology.

In this chapter, we introduce the various aspects of QTA and describe the additional information that CA can yield for the full characterization of real materials. QTA is most commonly applied because the existence of texture often determines the characteristics of the sample.

5.3.2. Crystallographic quantitative texture analysis (QTA)

Even though QTA was developed in the 1960s, the current literature shows that some qualitative information can still be usefully obtained by the simple 'classical' scans used by diffractionists. Such classical scans can be the usual one-dimensional θ–2θ or ω scans (rocking curves) in reflection mode, using point or position-sensitive detectors, or even single images in transmission. We should not forget that such scans can provide (depending on the texture itself) very restricted textural information, which has been thoroughly discussed in Chateigner (2010). There is then *a priori* no justification for using such limited views of texture, particularly with the recent technical advancements in sources and detectors that make the rapid acquisition of full texture scans available.

5.3.2.1. *Orientation distribution (OD)*

5.3.2.1.1. *The orientation space H*

Defining the orientation of a crystal requires the location of at least two directions of the crystal in a macroscopic reference frame. The definition of two reference frames (Fig. 5.3.1), one linked to the sample, $K_A = (\mathbf{x}_A, \mathbf{y}_A, \mathbf{z}_A)$, or (**100**, **010**, **001**), and the other to each of the crystals in the sample, K_B, is thus required. In order to make these two frames coincident (Fig. 5.3.2), one needs three Euler angles, α_c, β_c, γ_c, forming a triplet called the orientation component $g = \{\alpha_c, \beta_c, \gamma_c\}$. The angles β_c and α_c determine the orientation of the [001]* crystallite direction in K_A and are called the co-latitude (or pole distance) and azimuth, respectively, while γ_c defines the location of another crystallographic

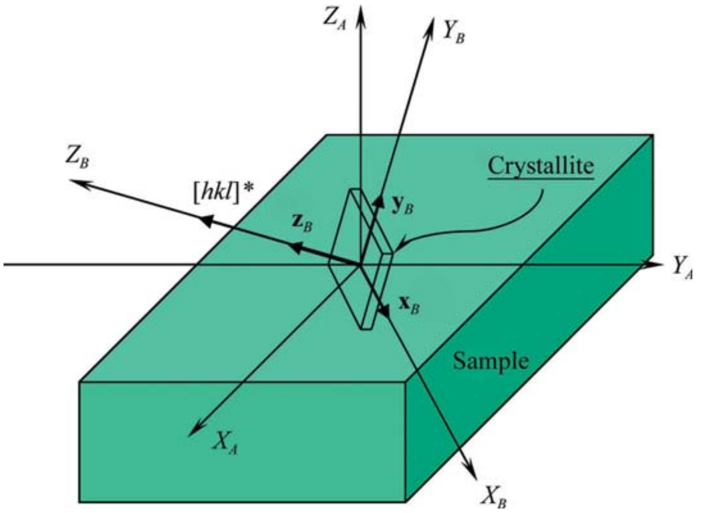

Figure 5.3.1
Crystal and sample reference frames $K_B = (\mathbf{x}_B, \mathbf{y}_B, \mathbf{z}_B)$ and $K_A = (\mathbf{x}_A, \mathbf{y}_A, \mathbf{z}_A)$. Only one crystallite is shown.

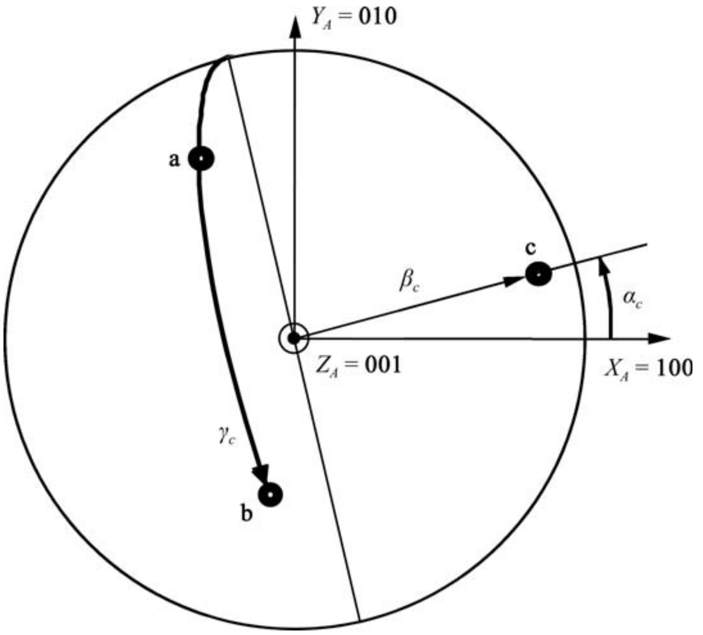

Figure 5.3.2
Definition of the three Euler angles α_c, β_c and γ_c that define the orientation of one crystallite frame $K_B = (\mathbf{a}, \mathbf{b}, \mathbf{c})$ of an orthogonal crystal cell in the sample coordinate system K_A. Note that **100**, **010** and **001** are not Miller indices but are vectors referring to an orthonormal frame aligned with K_A.

direction, chosen as [010]* [in the (**a**, **b**) plane for orthogonal crystal cells].

The ensemble of all possible values of g defines the orientation space, or H space. Note that we use H here (rather than the usual 'G space' for QTA) after the description of orientation symmetry of Curien (1971). An infinite number of possibilities for the choice of Euler angles exist, but the two most commonly used are those of Roe–Matthies (Roe, 1965; Matthies *et al.*, 1987) and Bunge (Bunge, 1969). We use the former here, for which K_A is brought coincident to K_B by the operation g: $[K_A \mapsto K_B]$ using the three following rotations:

(i) rotation of K_A about the axis Z_A through the angle α_c: $[K_A \mapsto K'_A]$; associated rotation $g_1 = \{\alpha_c, 0, 0\}$,
(ii) rotation of K'_A about the axis Y'_A through the angle β_c: $[K'_A \mapsto K''_A]$; associated rotation $g_2 = \{0, \beta_c, 0\}$,
(iii) rotation of K''_A about the axis Z''_A through the angle γ_c: $[K''_A \mapsto K'''_A \parallel K_B]$; associated rotation $g_3 = \{0, 0, \gamma_c\}$.

Finally, we obtain

$$g = g_1\, g_2\, g_3 = \{\alpha_c, 0, 0\}\,\{0, \beta_c, 0\}\,\{0, 0, \gamma_c\} = \{\alpha_c, \beta_c, \gamma_c\}.$$

The choice of K_A has historically been dependent on the field of science. In metallurgy, in dealing with the rolling of metals and alloys (Coulomb, 1982), the normal to the rolling plane (ND), the rolling direction (RD) and its transverse (TD) are typically chosen. For geologists, the sample axes are aligned with respect to the lineation direction and foliation plane, with the track from the latter generally being aligned with the lineation on the pole figures (Wenk, 1985). The use of QTA in molluscan studies (Chateigner *et al.*, 2000) imposed the choice of a frame linked to the mollusc shell growth, margin and normal directions (**G**, **M** and **N**, respectively). In thin-film analyses (Chateigner & Erler, 1997), for which a heteroepitaxial relationship between the film and the underlying single-crystal substrate is generally desired, the sample frame is aligned with the main crystallographic directions of the substrate. In the case of unidirectional experimental environments such as magnetic fields (Morales *et al.*, 2003), fibre spinning, axial pressure (Wenk *et al.*, 1996), hot forging (Guilmeau *et al.*, 2003), spin coating (Ricote & Chateigner, 1999) and self-deposition in a liquid (Manceau *et al.*, 1998), the unique axis (of loading, field or spinning) is generally aligned with the $\mathbf{z_A}$ pole-figure axis. When a combination of several loads is applied, such as a magnetic field and a perpendicular thermal gradient (Durand *et al.*, 1995), the axis of one load is aligned with $\mathbf{z}_A$ while the other is parallel to $\mathbf{x}_A$ or $\mathbf{y}_A$. Using centrifugation, the axis of rotation of the centrifugation is not generally the axis along which the crystal orientation is forced (Gridi-Bennadji *et al.*, 2009), because the pressure axis resulting from centrifugation is radially distributed and is often placed along $\mathbf{z}_A$ in the pole figures, and there is no in-plane alignment in the sample.

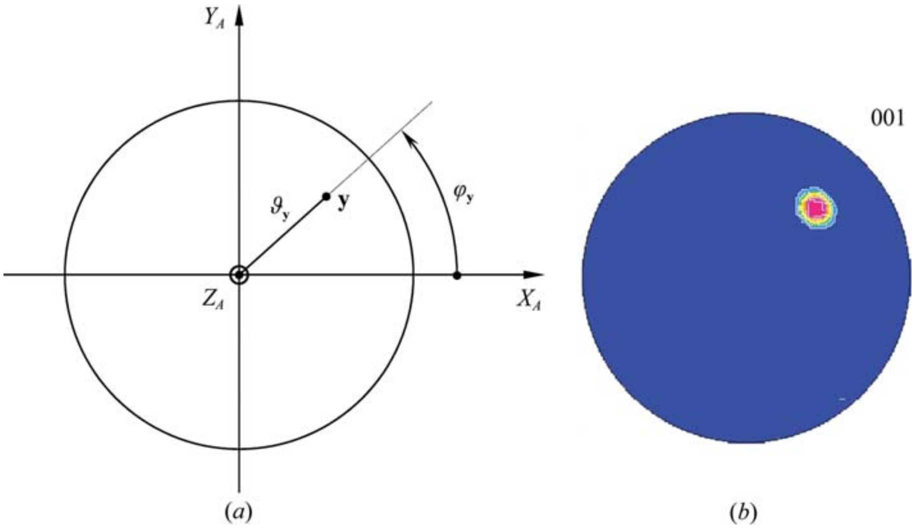

Figure 5.3.3
(*a*) $P_{\mathbf{h}}(\mathbf{y})$ diffraction pole figure for one crystallite. The direction **y** is associated with the [*hkl*]* vector. (*b*) Pole figure of a texture component centred on the previous **y**, with a Gaussian shape with 10° FWHM, for **h** = ⟨001⟩* of an orthorhombic crystal structure.

5.3.2.1.2. *The orientation distribution (OD) or orientation distribution function (ODF)*

Another concept is needed when dealing with an assembly of many crystals: the orientation distribution of crystallites (or OD), $f(g)$. This function, which can either be represented by an analytical function (ODF) or not (OD), represents the statistical distribution of the orientations of the crystallites in a polycrystalline aggregate. It is defined by

$$\frac{\mathrm{d}V(g)}{V} = \frac{1}{8\pi^2} f(g)\,\mathrm{d}g, \qquad (5.3.1)$$

where $\mathrm{d}g = \sin\beta_c\,\mathrm{d}\beta_c\,\mathrm{d}\alpha_c\,\mathrm{d}\gamma_c$ is the orientation element (Fig. 5.3.2) in the orientation space. The H space is constructed from the rotation groups of the crystallographic and sample symmetry (and the inversion centre in normal diffraction). V is the irradiated volume and $\mathrm{d}V(g)$ is the volume of crystallites which have an orientation between g and $g + \mathrm{d}g$.

$f(g)$ is consequently the volume density of crystallites oriented in dg. It is measured in m.r.d. (multiples of a random distribution) and normalized to the value $f_r(g) = 1$ for a sample without any preferred orientation (random). The $f(g)$ values are orientation distribution densities, and range from 0 (an absence of crystallites oriented in dg around g) to infinity (for some of the H-space values of single crystals). Since V is by definition 100%, the normalization condition of $f(g)$ over the whole orientation space is

$$\int\limits_{\alpha_c=0}^{2\pi} \int\limits_{\beta_c=0}^{\pi} \int\limits_{\gamma_c=0}^{2\pi} f(g)\,\mathrm{d}g = 8\pi^2. \qquad (5.3.2)$$

5.3.2.1.3. *Pole figures*

5.3.2.1.3.1. *Mathematical expression*

Pole figures, $P_{\mathbf{h}}(\mathbf{y})$, are representations of the distribution of a given **h** = ⟨*hkl*⟩* direction in K_A located in Y space (Fig. 5.3.3*a*). They represent the volume density of crystallites oriented in d**y**, *i.e.* between $(\vartheta_{\mathbf{y}}, \varphi_{\mathbf{y}})$ and $(\vartheta_{\mathbf{y}} + \mathrm{d}\vartheta_{\mathbf{y}}, \varphi_{\mathbf{y}} + \mathrm{d}\varphi_{\mathbf{y}})$,

$$\frac{\mathrm{d}V(\mathbf{y})}{V} = \frac{1}{4\pi} P_{\mathbf{h}}(\mathbf{y})\,\mathrm{d}\mathbf{y}, \qquad (5.3.3)$$

where V is the irradiated volume and $\mathrm{d}V(\mathbf{y})$ is the volume of crystallites which have an orientation with a direction **h** between **y** and **y** + d**y**, with $\mathrm{d}\mathbf{y} = \sin\vartheta_{\mathbf{y}}\mathrm{d}\vartheta_{\mathbf{y}}\mathrm{d}\varphi_{\mathbf{y}}$. The factor $1/4\pi$ arises from the normalization of the pole figures into distribution densities,

$$\int_{\varphi_{\mathbf{y}}=0}^{2\pi}\int_{\vartheta_{\mathbf{y}}=0}^{\pi} P_{\mathbf{h}}(\vartheta_{\mathbf{y}},\varphi_{\mathbf{y}})\sin\vartheta_{\mathbf{y}}\,\mathrm{d}\vartheta_{\mathbf{y}}\,\mathrm{d}\varphi_{\mathbf{y}} = 4\pi. \qquad (5.3.4)$$

Every pole figure of a random sample will exhibit the same density $P_{\mathbf{h}}(\mathbf{y})$ = 1 m.r.d., whatever the value of $\mathbf{y}$.

5.3.2.1.3.2. *Diffraction pole figures and orientation of planes*

At a Bragg angle corresponding to the $\{hkl\}$ planes and for a direction $\mathbf{y}$ of the sample, all of the planes such that $\mathbf{h}\|\mathbf{y}$ are in the diffraction condition, whatever their rotation around $\mathbf{y}$. Consequently, diffraction only probes a direction, not an orientation, and we need at least to determine the location of two directions of a plane to know its orientation. Diffraction only probes $P_{\mathbf{h}}(\mathbf{y})$, not $f(g)$ directly, and we need to measure at least several pole figures $P_{\mathbf{h}}(\mathbf{y})$ to determine $f(g)$.

Again, using normal diffraction Friedel's law applies and one cannot differentiate the diffracted intensity $I_{\mathbf{h}}$ from $I_{-\mathbf{h}}$. Consequently, the measured (reduced) pole figures are centrosymmetric and even objects, such that

$$\tilde{P}_{\mathbf{h}}(\mathbf{y}) = \tfrac{1}{2}[P_{\mathbf{h}}(\mathbf{y}) + P_{-\mathbf{h}}(\mathbf{y})]. \qquad (5.3.5)$$

5.3.2.1.3.3. *From diffraction measurements to pole figures and ODs*

Diffraction pole figures are usually measured using a four-circle diffractometer with regular increments in tilt (χ) and azimuth (φ) rotation axes, or in kappa geometry. Both reflection (Schulz, 1949*a*) and transmission (Schulz, 1949*b*; Field & Merchant, 1949) modes can be used, with point, one-dimensional or two-dimensional detectors, which can be either linear, flat or curved.

Prior to any measurement, it is necessary to know whether the data available from a given instrument can provide a correct OD characterization (*i.e.* how many pole figures are necessary and over which range each pole figure has to be measured) in order to permit an OD refinement. Helming (1992) addressed the question with the minimum pole-figure range, using the minimum pole density set concept of Vadon (1981). Such an approach defines as a necessary condition that the number and range of pole figures must be large enough such that any crystal orientation can be determined unambiguously. Using discrete data points, this requires that at least three projection paths $\tilde{\varphi}$ from pole figures pass through every OD cell. Complete OD coverage requires quite a large amount of data (typically 1300 measured points per pole figure, with several pole figures being necessary for low resolution using a 5° grid), which is nowadays accessible using multiple detectors.

The goniometer setting for each point can be described by three angles: ω, χ and φ. Additionally, if the diffraction point that we consider (the detector or pixel position) is outside the usual 2θ diffraction plane, another angle η is necessary along the Debye ring. We can define the resulting rotation matrix $\mathbf{R}$ as the product of the corresponding 3×3 matrices,

$$\mathbf{R} = -\boldsymbol{\Theta}\mathbf{H}\boldsymbol{\Omega}\mathbf{X}\boldsymbol{\Phi}, \qquad (5.3.6)$$

and the pole-figure angles can be obtained:

$$\begin{aligned}\cos\vartheta_{\mathbf{y}} &= R_{33},\\ \tan\varphi_{\mathbf{y}} &= R_{31}/R_{32}.\end{aligned} \qquad (5.3.7)$$

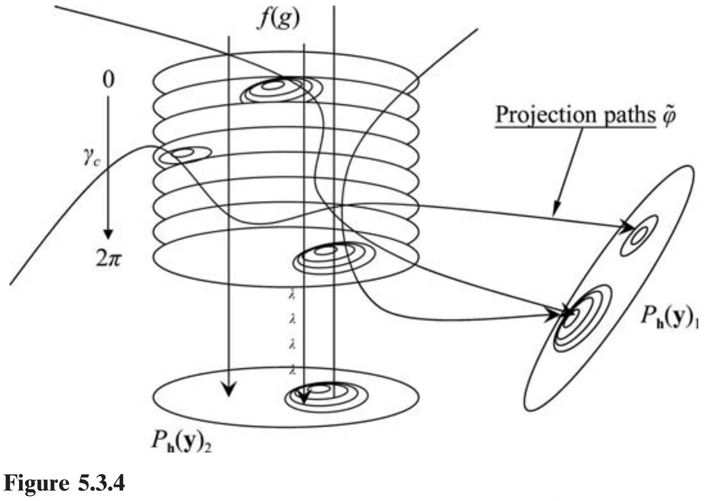
Depending on the experimental setup, various corrections have to be applied to the data. Localization corrections are those that transform the angular coordinates of the data from the diffractometer space S, where the scattered intensities are measured, to the space in which modelling occurs, for instance the pole-figure space Y (Bunge *et al.*, 1982; Heizmann & Laruelle, 1986; Heidelbach *et al.*, 1999; Chateigner, 2010). Also, depending on the sample itself, proper corrections for defocusing and background (Chernock & Beck, 1952; Gale & Griffiths, 1960; Holland, 1964; Feng, 1965; Tenckhoff, 1970; Couterne & Cizeron, 1971; Huijser-Gerits & Rieck, 1974), fluorescence, absorption and volume changes (Chateigner *et al.*, 1992, 1994*a*,*b*, 1995; Liu *et al.*, 2003) have to be carried out during sample rotations. The representation of pole figures is usually by stereographic (or equal-angular) projections. The main drawback of such a representation is that the density levels at the centre of the pole figures appear to be overrepresented compared with those near the equator. We then prefer to plot pole figures using Schmidt (or Lambert) projections (or equal-area projections), which offer representations with nearly equal surface elements at the centres and peripheries of pole figures (Kocks *et al.*, 1998).

After the previous corrections, one obtains the so-called diffraction (direct) pole figures, $I_{\mathbf{h}}(\mathbf{y})$. However, these depend on the porosity, crystalline state and other features of the sample, and to compare textures between samples the normalized pole figure $P_{\mathbf{h}}(\mathbf{y})$ has to be calculated.

Such normalization, calculations and refinements of the ODs using various algorithms are implemented in software such as the *Berkeley Texture* (*BEARTEX*) package (Wenk *et al.*, 1998), the *Preferred Orientation Package – Los Alamos* (*popLA*) package (Kocks *et al.*, 1994), the *LaboTex* texture-analysis software (Pawlik & Ozga, 1999) and the *MATLAB* toolbox for quantitative texture analysis (*MTEX*; Hielscher & Schaeben, 2008). The last is freeware. Two other programs, *Material Analysis Using Diffraction* (*MAUD*; Lutterotti *et al.*, 1999) and the *General Structure Analysis System* (*GSAS*; Von Dreele, 1997; Larson & Von Dreele, 2000), are furthermore able to carry out Rietveld analysis on large sets of data, giving access to many more material characteristics.

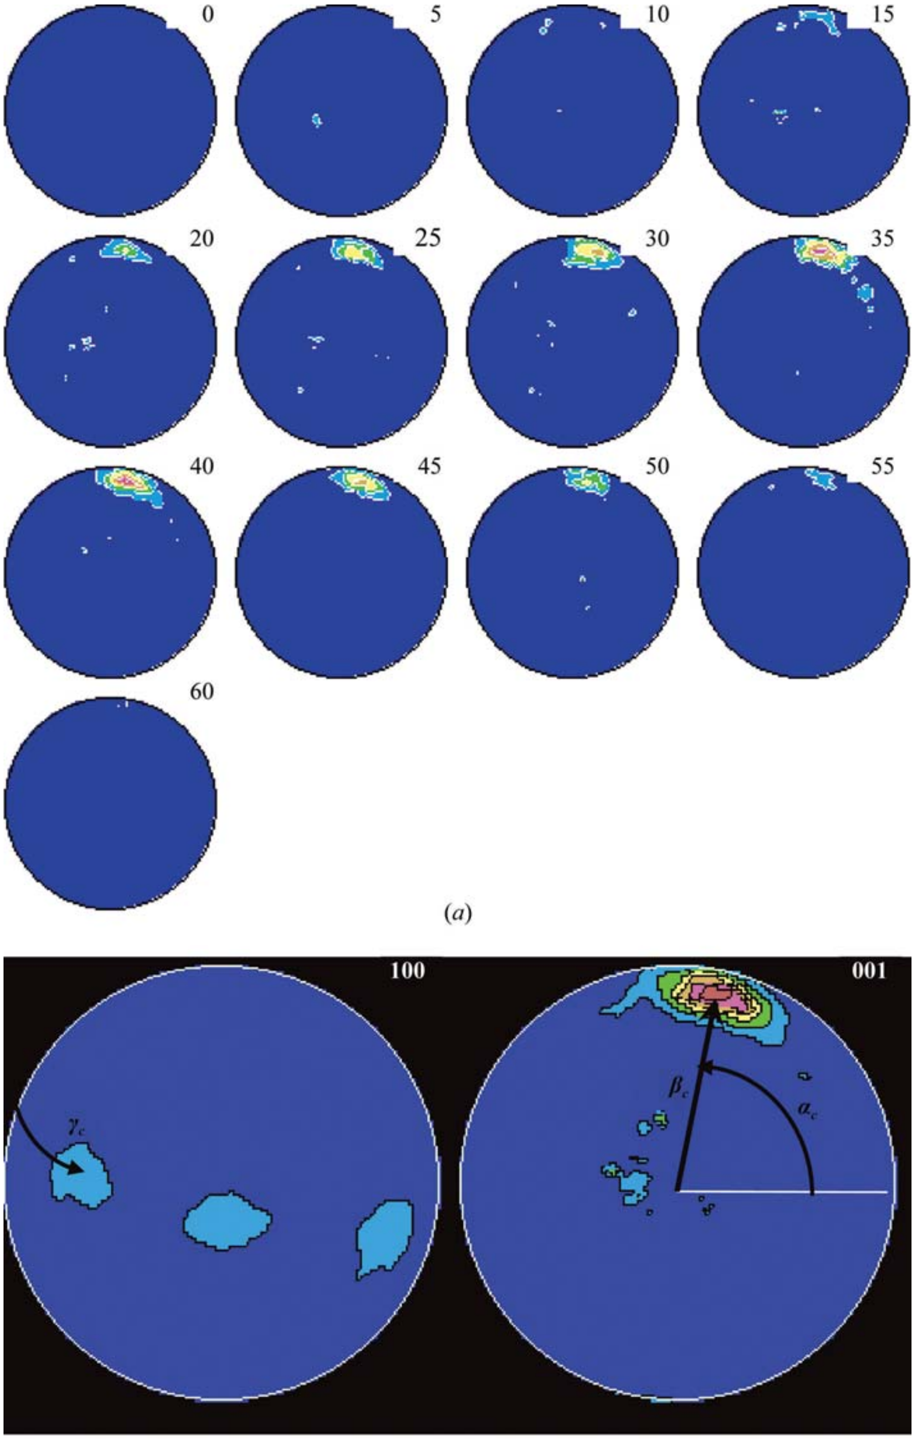
5.3.2.1.3.4. *Pole-figure normalization*

If a given $I_{\mathbf{h}}(\mathbf{y})$ pole figure has been measured completely (all of the $\mathbf{y}$ values could be obtained), it can be normalized



$f(g)$
0
γ_c
2π
Projection paths $\tilde{\varphi}$
λ
λ
λ
λ
$P_{\mathbf{h}}(\mathbf{y})_1$
$P_{\mathbf{h}}(\mathbf{y})_2$

Figure 5.3.4
Relationship between the three-dimensional object $f(g)$ and the pole figures $P_{\mathbf{h}}(\mathbf{y})$. Several OD boxes correspond to each pole figure cell, and each OD box is linked to several pole-figure cells.



(*a*)

(*b*)

Figure 5.3.5
(*a*) An OD as γ_c sections and (*b*) as {100} and {001} pole figures.

directly. Since whatever the texture state of a given sample is (*i.e.* whether the sample exhibits a texture or is randomly oriented) the total intensity scattered by the sample $I^t_{\mathbf{h}}$ must be the same, the sum of all intensities $I_{\mathbf{h}}(\mathbf{y})$ collected on the hemisphere is the same, all other sample characteristics being constant:

$$I^t_{\mathbf{h}} = \int_{\varphi_{\mathbf{y}}=0}^{2\pi} \int_{\vartheta_{\mathbf{y}}=0}^{\pi/2} I_{\mathbf{h}}(\vartheta_{\mathbf{y}}, \varphi_{\mathbf{y}}) \sin\vartheta_{\mathbf{y}} \, \mathrm{d}\vartheta_{\mathbf{y}} \, \mathrm{d}\varphi_{\mathbf{y}}. \qquad (5.3.8)$$

One can then obtain the intensity $N_{\mathbf{h}}$ that would diffract from this sample for the $\mathbf{h}$ pole figure if it was randomly oriented,

$$N_{\mathbf{h}} = I^t_{\mathbf{h}} \Big/ \int_{\varphi_{\mathbf{y}}=0}^{2\pi} \int_{\vartheta_{\mathbf{y}}=0}^{\pi/2} \sin\vartheta_{\mathbf{y}} \, \mathrm{d}\vartheta_{\mathbf{y}} \, \mathrm{d}\varphi_{\mathbf{y}}, \quad (5.3.9)$$

which is necessary for calculation of the normalized pole figure (expressed in m.r.d. units),

$$P_{\mathbf{h}}(\mathbf{y}) = \frac{I_{\mathbf{h}}(\mathbf{y})}{N_{\mathbf{h}}}. \qquad (5.3.10)$$

However, experimental considerations mean that the pole figures are generally not measured completely, and the $N_{\mathbf{h}}$ factors are usually refined during the OD calculation (see Section 5.3.2.3.1).

5.3.2.2. *The fundamental equation of quantitative texture analysis*

Since a pole figure measures the distribution of only one direction type $\langle hkl \rangle^*$, it does not probe an orientation directly. Phrased differently, any rotation around this specific vector by an angle $\tilde{\varphi}$ results in the same diffracted intensity. From (5.3.1) and (5.3.3), one can obtain the fundamental equation of QTA,

$$P_{\mathbf{h}}(\mathbf{y}) = \frac{1}{2\pi} \int_{\mathbf{h}\parallel\mathbf{y}} f(g) \, \mathrm{d}\tilde{\varphi}, \qquad (5.3.11)$$

which represents the fact that each pole figure (which is a two-dimensional object) is a projection along a certain path $\tilde{\varphi}$ of the OD (a three-dimensional object) which depends on the crystal symmetry (Fig. 5.3.4). Each cell of a given pole figure will then be an average over several cells of the OD, and each cell of the OD will be measured by one or more cells from the pole figures. The larger the number of pole-figure cells that measure a specific OD cell, the more statistically reliable the measurement of this OD is. In practice, one has to measure the largest number possible of reliable (sufficiently intense) pole figures to define the OD with the best resolution available.

For instance, an OD of a hexagonal system represented by a series of γ_c sections (Fig. 5.3.5*a*) may reveal a maximum pole density for a γ_c value of 35°. The corresponding {100} and {001} pole figures (Fig. 5.3.5*b*) illustrate the meaning of γ_c in the pole-figure space for this single-component texture. In the {001} pole figure, the pole maximum is located at $(\varphi_{\mathbf{y}}, \vartheta_{\mathbf{y}}) = (\alpha_c, \beta_c) = (85°, 80°)$. Since γ_c locates the $\mathbf{b}$ axis, with this latter being represented by the {100} pole figure, $\gamma_c = 35°$ is the angle between the equator and $\mathbf{b}$ in this pole figure. Users should not be afraid to build a three-dimensional model of the unit-cell axes to assist in interpreting such pole figures.

Let us mention at this point that the pole figures that are obtained using normal diffraction methods are so-called reduced pole figures, $\tilde{P}_{\mathbf{h}}(\mathbf{y})$. Friedel's law requires that the measured pole figures are superpositions of $+\mathbf{h}$ and $-\mathbf{h}$ true pole figures. This fact (which is even the case for anomalous scattering in the case of centrosymmetric crystals) leads to the presence of 'ghost' phenomena (Matthies & Vinel, 1982; Matthies *et al.*, 1987). The true, unreduced or 'complete' pole figure is defined as

$$P_{\mathbf{h}}(\mathbf{y}) = \tilde{P}_{\mathbf{h}}(\mathbf{y}) + \tilde{\tilde{P}}_{\mathbf{h}}(\mathbf{y}), \tag{5.3.12}$$

in which $\tilde{\tilde{P}}_{\mathbf{h}}(\mathbf{y})$ is the nonmeasured part of the pole figures. We will not take account of this here since ghost suppression, if possible, would require anomalous diffraction and very intense beams. Instead, theoretically derived ghost-correcting approximations can be used. However, it should be strongly emphasized here that in the case of noncentrosymmetric crystal symmetry the ODF will not be determined completely.

5.3.2.3. *Resolution of the fundamental equation*

5.3.2.3.1. *Generalized spherical-harmonics expansion*

The solution proposed by Bunge & Esling (1982) consists of describing the OD and the pole figures as series of generalized spherical harmonics,

$$f(g) = \sum_{\lambda=0}^{\infty} \sum_{m=-\lambda}^{\lambda} \sum_{n=\lambda}^{\lambda} C_{\lambda}^{mn} T_{\lambda}^{mn}(g), \tag{5.3.13}$$

$$P_{\mathbf{h}}(\mathbf{y}) = \sum_{\lambda=0}^{\infty} \frac{4\pi}{2\lambda+1} \sum_{n=-\lambda}^{\lambda} k_{\lambda}^{n}(\mathbf{y}) \sum_{m=-\lambda}^{\lambda} C_{\lambda}^{mn} k_{\lambda}^{*m}(\Theta_{\mathbf{h}}\phi_{\mathbf{h}}). \tag{5.3.14}$$

(5.3.11) still holds, and in this approach one has to determine the C_{λ}^{mn} coefficients, which are the proportions of the respective $T_{\lambda}^{mn}(g)$ and depend on the texture, from the experiments. The $T_{\lambda}^{mn}(g)$ are known generalized spherical harmonics which depend on the crystal and texture symmetries. The series expands on both even and odd values of λ. In practice, the expansion on λ cannot be infinite and is limited to a value L, the maximum degree of series expansion, which fixes the angular resolution of the expansion. k_{λ}^{n} and k_{λ}^{*m} are spherical harmonics based on Legendre polynomials (Bunge & Esling, 1982). The angles $\Theta_{\mathbf{h}}$ and $\phi_{\mathbf{h}}$ are the spherical coordinates of the **h** direction in the crystal reference frame. The number of C_{λ}^{mn} coefficients and the extension L to which the series in (5.3.14) has to be expanded in λ are also dependent on the crystal and texture symmetries.

If a certain number of pole-figure values are measured for different crystallographic directions **h**, then a set of linear equations can be set up using (5.3.14) and solved. There are three commonly used methods to obtain the C_{λ}^{mn} coefficients.

The first method can be used only if complete pole figures are measured, in which case (5.3.14) can be written

$$P_{\mathbf{h}}(\mathbf{y}) = \sum_{\lambda=0}^{\infty} \sum_{n=-\lambda}^{\lambda} F_{\lambda}^{n}(\mathbf{h}) k_{\lambda}^{n}(\mathbf{y}) \tag{5.3.14a}$$

and

$$F_{\lambda}^{n}(\mathbf{h}) = \frac{4\pi}{2\lambda+1} \sum_{m=-\lambda=0}^{\lambda} C_{\lambda}^{mn} k_{\lambda}^{*m}(\Theta_{\mathbf{h}}, \phi_{\mathbf{h}}) \sum_{n=-\lambda}^{\lambda} F_{\lambda}^{n}(\mathbf{h}) k_{\lambda}^{n}(\mathbf{y}). \tag{5.3.14b}$$

Multiplying both sides of (5.3.14*a*) by $k_{\lambda}^{*m}(\mathbf{y})$ and integrating over the whole sphere then yields

$$\begin{aligned} F_{\lambda}^{n}(\mathbf{h}) &= \int P_{\mathbf{h}}(\mathbf{y}) k_{\lambda}^{*n}(\mathbf{y})\, \mathrm{d}\mathbf{y} \\ &= \int_{\vartheta_y}^{\pi} \int_{\varphi_{\mathbf{y}}}^{2\pi} P_{\mathbf{h}}(\vartheta_{\mathbf{y}}, \varphi_{\mathbf{y}}) k_{\lambda}^{*n}(\vartheta_{\mathbf{y}}, \varphi_{\mathbf{y}}) \sin\theta_{\mathbf{y}}\, \mathrm{d}\vartheta_{\mathbf{y}}\, \mathrm{d}\varphi_{\mathbf{y}}. \end{aligned} \tag{5.3.14c}$$

The first step of the procedure is to compute the quantities $F_{\lambda}^{n}(\mathbf{h})$ from (5.3.14*c*) using the measured pole-figure values. In the second step (transformation of coefficients), the system of linear equations (5.3.14*b*) solved for the variables C_{λ}^{mn} and $f(g)$ is determined.

The second method is used when it is not possible to measure complete pole figures and consequently the quantities in (5.3.14*c*) cannot be computed. In such a case, we refer the reader to Chapter 7 of Bunge & Esling (1982) for a complete exposition. The method also solves a system of linear equations to obtain the harmonic coefficients:

$$\sum_{\lambda=0}^{L} \sum_{m=1}^{M(\lambda)} \sum_{n=1}^{N(\lambda)} C_{\lambda}^{mn} \left[\alpha_{\lambda\lambda'}^{mm'} \zeta_{\lambda\lambda'}^{nn'} - \sum_{\mathbf{h}} \frac{a_{\lambda}^{mn}(\mathbf{h}) a_{\lambda'}^{m'n'}(\mathbf{h})}{P_{\mathbf{h}}} \right] = 0 \tag{5.3.14d}$$

and

$$P_{\mathbf{h}} = 2 \int_{B} [I_{\mathbf{h}}(\mathbf{y})]^2\, \mathrm{d}\mathbf{y},$$

where B is the measured range in the pole figure,

$$a_{\lambda}^{mn}(\mathbf{h}) = 2 \frac{4\pi}{2\lambda+1} \overset{\vdots}{k}{}_{\lambda}^{*m}(\Theta_{\mathbf{h}}, \phi_{\mathbf{h}}) \int_{B} I_{\mathbf{h}}(\mathbf{y}) \dot{k}_{\lambda}^{n}(\mathbf{y})\, \mathrm{d}\mathbf{y},$$

$$\zeta_{\lambda\lambda'}^{nn'} = 2 \int_{B} \dot{k}_{\lambda'}^{n'}(\mathbf{y}) \dot{k}_{\lambda}^{n}(\mathbf{y})\, \mathrm{d}\mathbf{y},$$

$$a_{\lambda\lambda'}^{mm'} = \frac{4\pi}{2\lambda+1} \frac{4\pi}{2\lambda'+1} \sum_{\mathbf{h}} \overset{\vdots}{k}{}_{\lambda}^{*m}(\Theta_{\mathbf{h}}, \phi_{\mathbf{h}}) \overset{\vdots}{k}{}_{\lambda'}^{*m'}(\Theta_{\mathbf{h}}, \phi_{\mathbf{h}}).$$

The third method uses the minimization procedure of (5.3.15) to refine the harmonic coefficients by a least-squares method, through which the $P_{\mathbf{h}}(\mathbf{y})$ are expressed using (5.3.14):

$$\sum_{\mathbf{h}} \oint [I_{\mathbf{h}}(\mathbf{y}) - N_{\mathbf{h}} P_{\mathbf{h}}(\mathbf{y})]^2\, \mathrm{d}\mathbf{y} = \min. \tag{5.3.15}$$

The integral is substituted by a summation over the entire measured range of the pole figures (complete or uncomplete).

For strongly textured samples, the harmonics formulation creates strong negative density values, in particular if the expansion is restricted to too low an L value (which unfortunately can be the case experimentally if insufficient pole figures can be measured), and has been proved to be less adequate than other discrete methods. Several methods have been developed to correct for this artifact, all of which force negative densities to zero (Wenk *et al.*, 1988). However, forcing densities to zero wherever they appear to be negative (if physically more reasonable) may appear to be a little arbitrary. This feeling may be reinforced by the fact that ghosts can also be positive, with these latter not being subject to the same 'correction' possibilities. However, one advantage of using a harmonic series is that it provides the necessary material for the simplest approximation of the mechanical property simulations with a limited number of coefficients to be refined (the C_{λ}^{mn} values). These coefficients can also be computed from the OD obtained by other methods.

Since $f(g)$ is a density, one should observe $f(g) \geq 0$ for all g values, or 'positivity'. From (5.3.5) we know that the measured or reduced pole figures are centrosymmetric, and as a consequence of (5.3.14) only the even-order coefficients can be determined by diffraction. On the other hand there are even and odd coefficients in $f(g)$, and two different ODs have then to be considered, depending on the parity of the λ terms,

$$f(g) = f^{e}(g) + f^{o}(g), \tag{5.3.16}$$

and here $f(g)$ and $f^o(g)$ are two unknowns, with the even part of the harmonic series $f^e(g)$ being the part that is accessible to normal diffraction; the odd part is measurable in certain cases using anomalous scattering. This phenomenon creates ghosts (negative, unphysical distribution densities) in the OD (Matthies, 1979; Matthies & Vinel, 1982), which are undesirable for a quantitative description of $f(g)$. An approximate 'ghost correction' by estimating the odd coefficients is more or less complicated in the harmonic formalism (Esling *et al.*, 1982). Some approaches for this correction have been developed such as the 'positivity method' (Dahms & Bunge, 1988; Wagner & Dahms, 1991) or the 'GHOST' and 'quadratic' methods (Van Houtte, 1983, 1991), all of which still permit some residual negative densities (see Section 5.3.2.3.8).

5.3.2.3.2. *Vector method*

This discrete method (Ruer, 1976; Ruer & Baro, 1977; Vadon, 1981) works in direct space. Here, $f(g)$ is represented by a vector called the 'texture vector' $\mathbf{f}_j$, $j = 1, \ldots, J$, with J the number of cells in which $f(g)$ is discretized. This number, of course, depends on the resolution of the measurement scans of the pole figures. Each pole figure is represented by $\mathbf{P}_i(\mathbf{h})$, $i = 1, \ldots, N$, with N being the number of cells of the pole figure. The fundamental equation of QTA becomes

$$P_i(\mathbf{h}) = [\boldsymbol{\sigma}_{ij}(\mathbf{h})]\mathbf{f}_j, \qquad (5.3.17)$$

in which $\boldsymbol{\sigma}_{\rm ij}(\mathbf{h})$ is a rectangular matrix. The fundamental problem therefore consists of finding the solution to the system of linear equations (5.3.17).

5.3.2.3.3. *WIMV method*

The WIMV approach [where WIMV is an acronym from Williams (1968), Imhof (1982) and Matthies & Vinel (1982)] is an iterative method which ensures a conditional ghost correction. It is based on the numerical refinement of $f(g)$ at step $n + 1$,

$$f^{n+1}(g) = \hat{N} \frac{f^n(g) f^0(g)}{\prod_{i=1}^{I} \left[\prod_{m=1}^{M_{\mathbf{h}i}} P^n_{\mathbf{h}_{im}}(\mathbf{y}) \right]^{1/IM_{\mathbf{h}i}}}, \qquad (5.3.18)$$

where the product extends over the I experimentally measured pole figures and the multiplicity is $M_{\mathbf{h}}$ for all the poles. $f^n(g)$ and $P^n_{\mathbf{h}}(\mathbf{y})$ represent the refined values of $f(g)$ and $P_{\mathbf{h}}(\mathbf{y})$ at the nth step, respectively. $\hat{N}$ is the normalization operation. The $P^n_{\mathbf{h}_{im}}(\mathbf{y})$ values are calculated at each cycle with (5.3.12). The first step in this procedure is to evaluate $f^0(g)$,

$$f^0(g) = \hat{N} \prod_{i=1}^{I} \left[\prod_{m=1}^{M_{\mathbf{h}i}} P^{\rm exp}_{\mathbf{h}_{im}}(\mathbf{y}) \right]^{1/IM_{\mathbf{h}i}}, \qquad (5.3.19)$$

in which $P^{\rm exp}_{\mathbf{h}}(\mathbf{y})$ represents the measured pole figures. The WIMV algorithm maximizes the so-called 'phon' (orientation background or minimum value of the OD which represents the randomly oriented fraction of the sample) and the texture sharpness. While in the previous methods of OD resolution low texture and crystal symmetries give rise to large amounts of data to store and long computation times, the WIMV approach does not depend greatly on these symmetries. Other methods have been derived from WIMV and they maintain the same iteration structure as depicted in (5.3.18); they are described in Sections 5.3.2.3.4, 5.3.2.3.5 and 5.3.2.3.6.

5.3.2.3.4. *Arbitrarily defined cells (ADC) method*

Essentially based on a WIMV-like algorithm (Pawlik, 1993), the ADC method uses projection tubes instead of projection paths. Each cell volume is then taken into account in the calculations, which gives a better smoothing scheme. A similar concept is also used in the EWIMV approach and is described in Section 5.3.2.3.6.

5.3.2.3.5. *Entropy-maximization method*

This method (Schaeben, 1988, 1991*a*,*b*) is based on the maximization of the texture 'disorder' or texture entropy, *i.e.* trying to obtain the maximum texture phon from a set of experiments. Following information theory (Shannon, 1948), the entropy estimator in texture can be described by

$$S = -\sum_i f(g_i) \ln f(g_i), \qquad (5.3.20)$$

which results in the iterative procedure

$$f^{n+1}(g) = f^n(g) \prod_{i=1}^{I} \prod_{m=1}^{M_{\mathbf{h}i}} \left[\frac{P_{\mathbf{h}}(\mathbf{y})}{P^n_{\mathbf{h}}(\mathbf{y})} \right]^{r_n/IM_{\mathbf{h}i}}, \qquad (5.3.21)$$

in which r_n is a relaxation parameter such that $0 < r_n < 1$.

5.3.2.3.6. *EWIMV method*

When the WIMV calculation is inserted into the Rietveld refinement procedure, it requires two additional steps:

(i) the extraction of the pole-figure or texture weights,

(ii) the interpolation of these weights to fit a regular grid (imposed by the original WIMV algorithm).

The latter yields non-optimized values of the OD, particularly for sharp textures and coarse irregular coverage of the OD. The entropy-modified WIMV (EWIMV) method has proved to be effective as an extension of the WIMV method (Lutterotti *et al.*, 2004; Morales *et al.*, 2002). In this latter the OD cell values are computed through an entropy iteration algorithm as in (5.3.21), with incorporation of the reflection weights $w_{\mathbf{h}}$:

$$f^{n+1}(g) = \hat{N} f^n(g) \prod_{h=1}^{I} \prod_{m=1}^{M_{\mathbf{h}i}} \left[\frac{P_{\mathbf{h}_{im}}(\mathbf{y})}{P^n_{\mathbf{h}_{im}}(\mathbf{y})} \right]^{r_n w_{\mathbf{h}}/IM_{\mathbf{h}i}}. \qquad (5.3.22)$$

$w_{\mathbf{h}}$ is introduced to take into account the different accuracy of the more intense and less overlapped reflections with respect to the smaller reflections, and is calculated analogously to the weight factors in the Rietveld analysis. In (5.3.22), the integration path is computed using a similar concept to the tube projection introduced by the ADC method (Section 5.3.2.3.4). In the case of EWIMV the projection for each integration point is calculated using all of the neighbouring cells in the OD to that in which the integration point falls, and the cell contribution is weighted using the reciprocal of the distance between the centre of the cell and the exact integration-point position. This has also a positive effect on smoothing out the noise from the OD and increases the experimental 'coverage' of the OD.

5.3.2.3.7. *Component method*

For very strong textures most of the orientation space cells have zero values, while a few cells exhibit very large distribution densities. In such cases the number of data to be acquired can be tremendously large and tends to an unacceptable limit. However, since the OD is described by a small number of orientations g, simple functions can be used to represent it, and the g values are easily handled. Let a specific texture component (Helming, 1992) centred at the orientation $g = g^c$ be represented by the model function $f^c(g)$. The total OD can be represented by

$$f(g) = F + \sum_c I^c f^c(g), \tag{5.3.23}$$

where the intensity I^c is the volume fraction of crystallites belonging to the component g^c of distribution $f^c(g)$, and F represents the volume fraction of randomly oriented crystallites. For consistency, the components have to respect the normalization conditions

$$F + \sum_c I^c = 1 \text{ and } \sum_c f^c(g) = 1. \tag{5.3.24}$$

The $f^c(g)$ components can be represented by any function, *i.e.* Gaussian, Lorentzian or elliptical distributions (Matthies *et al.*, 1987), that is normalized. Generally, two types of components are used: spherical (Matthies, 1980, 1982) and fibre (Matthies *et al.*, 1988). Each component may then have a Gaussian or Lorentzian character.

Spherical components are described by an orientation position g_0 in the OD space and a half-width at half-maximum, b, to characterize the shape of the distribution ($0 \leq b \leq 2\pi$). Taking $\tilde{\omega}$ as the angular distance between an orientation g and g_0, the Gaussian spherical component can be written as

$$f(g_0, b, g) = f(S, \tilde{\omega}) = N(S)\exp(S\cos\tilde{\omega}), \tag{5.3.24a}$$

with $0 \leq \tilde{\omega} = \tilde{\omega}\,(g_0, g) \leq \pi$, $0 \leq S \leq \infty$, $S = \ln 2/[2\sin^2(b/4)]$;

$$N(S) = [I_0(S) - I_1(S)]^{-1} \tag{5.3.24b}$$

is the normalization factor and $I_n(x)$ are the modified Bessel functions:

$$I_n(x) = \frac{1}{\pi}\int_0^{\pi} \exp[x\cos(t)]\cos(nt)\,\mathrm{d}t. \tag{5.3.24c}$$

Now the unreduced pole-figure value by integration using (5.3.9) becomes

$$P_{\mathbf{h}}(g_0, b, \mathbf{y}) = P(S, z) = N(S) I_0\left[\frac{S(z+1)}{2}\right]\exp\left[\frac{S(z-1)}{2}\right], \tag{5.3.25}$$

with $z = \mathbf{h} \cdot g_0 \cdot \mathbf{y}$.

Since the reduced pole figure is the measured one (Section 5.3.2.3.1), it must be computed as (using equation 5.3.5),

$$\bar{P}(S, z) = \frac{P(S, z) - P(S, -z)}{2}. \tag{5.3.26}$$

Similarly, for a Lorentzian spherical component

$$f(g_0, b, g) = f(t, \tilde{\omega}) = (1 - t^2)\frac{(1 + t^2)^2 + 4t^2\cos^2(\tilde{\omega}/2)}{[(1 + t^2)^2 - 4t^2\cos^2(\tilde{\omega}/2)]^2}, \tag{5.3.27}$$

where

$$\begin{aligned}
t &= \tau^{1/2} - (\tau - 1)^{1/2},\\
c &= \cos^2(b/4),\\
w &= (19c^2 - 34c + 19)^{1/2},\\
\tau &= \frac{2w}{3}\cos\left[\frac{1}{3}\cos^{-1}\left(\frac{-82c^3 + 240c^2 - 246c + 80}{w^3}\right)\right] + \frac{5 - 4c}{3},
\end{aligned}$$

and the unreduced pole-figure value becomes

$$P_{\mathbf{h}}(g_0, b, y) = P(t, z) = \frac{1 - t^4}{(1 - 2t^2 z + t^4)^{3/2}}. \tag{5.3.28}$$

A Gaussian-like fibre component is defined by two vectors ($\mathbf{h}_0$, $\mathbf{n}_0$) and the half-width b. $\mathbf{n}_0$ is the fibre direction in the sample coordinates and $\mathbf{h}_0$ is the fibre direction in the crystal coordinate system. Then,

$$f(\mathbf{h}_0, \mathbf{n}_0, b, g) = f(S, z) = \left[\frac{S}{\sinh(S)}\right]\exp(Sz), \tag{5.3.29}$$

in which z and S have been already defined for the Gaussian component. The unreduced pole figures can now be computed as

$$P(S, z_1, z_2) = \frac{S}{\sinh(S)} I_0\left[S(1 - z_1^2)^{1/2}(1 - z_2^2)^{1/2}\right]\exp(Sz_1z_2), \tag{5.3.30}$$

where

$$z_1 = \mathbf{h} \cdot \mathbf{h}_0, \quad z_2 = \mathbf{y} \cdot \mathbf{n}_0.$$

In the case of a Lorentzian fibre component, using the same definitions as for the Gaussian fibre component the equations are

$$f(\mathbf{h}_0, \mathbf{n}_0, b, g) = f(t_f, z) = \frac{1 - t_f}{(1 - 2t_f z + t_f^2)^{3/2}}, \tag{5.3.31}$$

where

$$\begin{aligned}
t_f &= R - (R^2 - 1)^{1/2},\\
R &= \frac{2^{2/3} - \cos(b/4)}{2^{2/3} - 1}
\end{aligned}$$

and the reduced pole figure is

$$\begin{aligned}
P(t_f, z_1, z_2) &= \frac{2}{\pi}\frac{1 - t_f^2}{(C - D)(C + D)^{1/2}} E\left(\frac{2D}{C + D}\right),\\
C &= 1 + t_f^2 - 2t_f z_1 z_2,\\
D &= 2t_f(1 - z_1^2)^{1/2}(1 - z_2^2)^{1/2}
\end{aligned}$$

and $E(k)$ is the complete elliptic integral of the second kind,

$$E(k) = \int_0^{\pi/2} (1 - k^2\sin^2\theta)^{1/2}\,\mathrm{d}\theta.$$

5.3.2.3.8. *Positivity and exponential harmonics*

In the positivity and exponential method the idea is to use and determine the odd coefficients that may ensure a positive $f(g)$. In the positivity method the even coefficients are not modified (as they are linked to the experimental pole figures) and the odd coefficients do not affect the computation. For a detailed description of the positivity algorithm, we refer to the original articles (Dahms & Bunge, 1988; Van Houtte, 1991). The goal of the algorithm is to determine the odd coefficients corresponding to an OD equal to (with sign inverted) the negative part of the OD found from the experimental data, $f_0(g)$,

$$C_\lambda^{mn} = -(2\lambda + 1)\int_{\forall g \in Z-} f_0(g) T_\lambda^{mn}(g)\,\mathrm{d}g, \tag{5.3.32}$$

where $Z-$ is the orientation space over which the $f_0(g)$ values are negative or lower than a given threshold α defining the OD background. Moreover, it has been recognized that most of the time there are a set of odd coefficients that are able to completely eliminate all negative parts of the OD, maintaining the even coefficients constant. Another way to ensure OD positivity (Van

Houtte, 1991) is to express it with functions that result in values that are always positive, such as exponentials with real function arguments $h(g)$. For instance, using $f(g) = \exp[h(g)] \geq 0$, (5.3.13) and (5.3.14) become

$$\exp[h(g)] = \sum_{\lambda=0}^{L} \sum_{m=1}^{M(\lambda)} \sum_{n=1}^{N(\lambda)} C_\lambda^{mn} T_\lambda^{mn}(g)$$
$$C_\lambda^{mn} = (2\lambda + 1) \textstyle\int \exp[h(g)] T_\lambda^{mn}(g)\,\mathrm{d}g. \qquad (5.3.33)$$

The first OD approximation is now obtained by the positivity method described above (or the GHOST version as described in Van Houtte, 1983). Calling this latter $f_0(g)$, the first approximation for $h_0(g)$ is imposed as

$$h_0(g) = \begin{cases} \ln[f_0(g)] & \text{if } f_0(g) > \alpha, \\ f_0(g) - \alpha + \ln\alpha & \text{if } f_0(g) \leq \alpha. \end{cases}$$

An iterative refinement is carried out using

$$h_{k+1}(g) = h_k(g) + \sum_{\lambda=0}^{L} \sum_{m=1}^{M(\lambda)} \sum_{n=1}^{N(\lambda)} \exp[-h_k(g)](C_\lambda^{mn} - C_{\lambda,k}^{mn}) T_\lambda^{mn}(g).$$

C_λ^{mn} are the initial coefficients obtained by the positivity or GHOST method and the $C_{\lambda,k}^{mn}$ before each iteration are computed using (5.3.14*b*) and the $h_k(g)$ values of the OD. A normalization of $h_k(g)$ is performed at each step. At the end the always-positive OD is computed as $f(g) = \exp[h_k(g)]$.

5.3.2.3.9. *Radon transform and Fourier analysis*

The fundamental equation of QTA (5.3.11) can be recognized as the Radon transform (Radon, 1986) of $f(g)$ as proposed by Schaeben & van den Boogaart (2003),

$$\mathscr{R}f(\mathbf{h}, \mathbf{y}) = \frac{1}{2\pi} \int\limits_{\tilde{\varphi}(\mathbf{h},\mathbf{y})} f(g)\,\mathrm{d}\tilde{\varphi}. \qquad (5.3.34)$$

The integration path $\tilde{\varphi}(\mathbf{h}, \mathbf{y})$ takes all of the equivalents of **h** into account, *i.e.* all of the rotations that represent the **h** multiplicity (such that $g\mathbf{h} = \mathbf{y}$). Because the Radon and the Fourier transforms are closely related, computationally efficient inversion formulas are available and $f(g)$ can be retrieved by fast Fourier inversion techniques. The biggest advantage is then that, unlike generalized spherical harmonics, both odd and even coefficients can be accessed from the inversion of the Radon transform.

5.3.2.4. *Inverse pole figures*

In a pole figure $P_\mathbf{h}(\mathbf{y})$ (5.3.11), all of the given **h** directions from all of the diffracting crystals are located using the **y** coordinates relative to K_A, the sample reference frame. In this way, one looks at only one of the equivalent **h** directions, and **y** varies in the pole figure. In some cases such as axially symmetric textures or when only some macroscopic directions **y** are of importance, it can be useful to represent which of the **h** directions align with the given **y**. For instance, one can aim to see which crystal directions are aligned with a uniaxial pressure axis ($\boldsymbol{\sigma}$). This time **y** is fixed ($\boldsymbol{\sigma}$, or Z_A if the pressure is applied along Z_A) and **h** varies, and an easy way to represent such a distribution of **h** directions *versus* **y** is an inverse pole figure, or $R_\mathbf{y}(\mathbf{h})$. Similarly to (5.3.9), one can calculate every inverse pole figure $R_\mathbf{y}(\mathbf{h})$ from $f(g)$,

$$R_\mathbf{y}(\mathbf{h}) = \frac{1}{2\pi} \int\limits_{\mathbf{y}\parallel\mathbf{h}} f(g)\,\mathrm{d}\overset{\approx}{\varphi}, \qquad (5.3.35)$$

in which $\overset{\approx}{\varphi}$ is an orientation path in $f(g)$ which takes account of the crystal symmetry. Inverse pole figures are represented in the crystal reference frame K_B (Fig. 5.3.6). Different sectors are equivalent by symmetry, from one for triclinic crystal symmetry to 24 for cubic symmetry. Only one sector is necessary to portray the unique information, and inverse pole figures are generally represented in the sector frame.

Similar to pole figures, inverse pole figures exhibit pole-density distributions. For instance, the inverse pole figure for the drawing axis of an aluminium wire shows that the ⟨111⟩ and ⟨001⟩ directions are the main alignment components, with a major ⟨111⟩

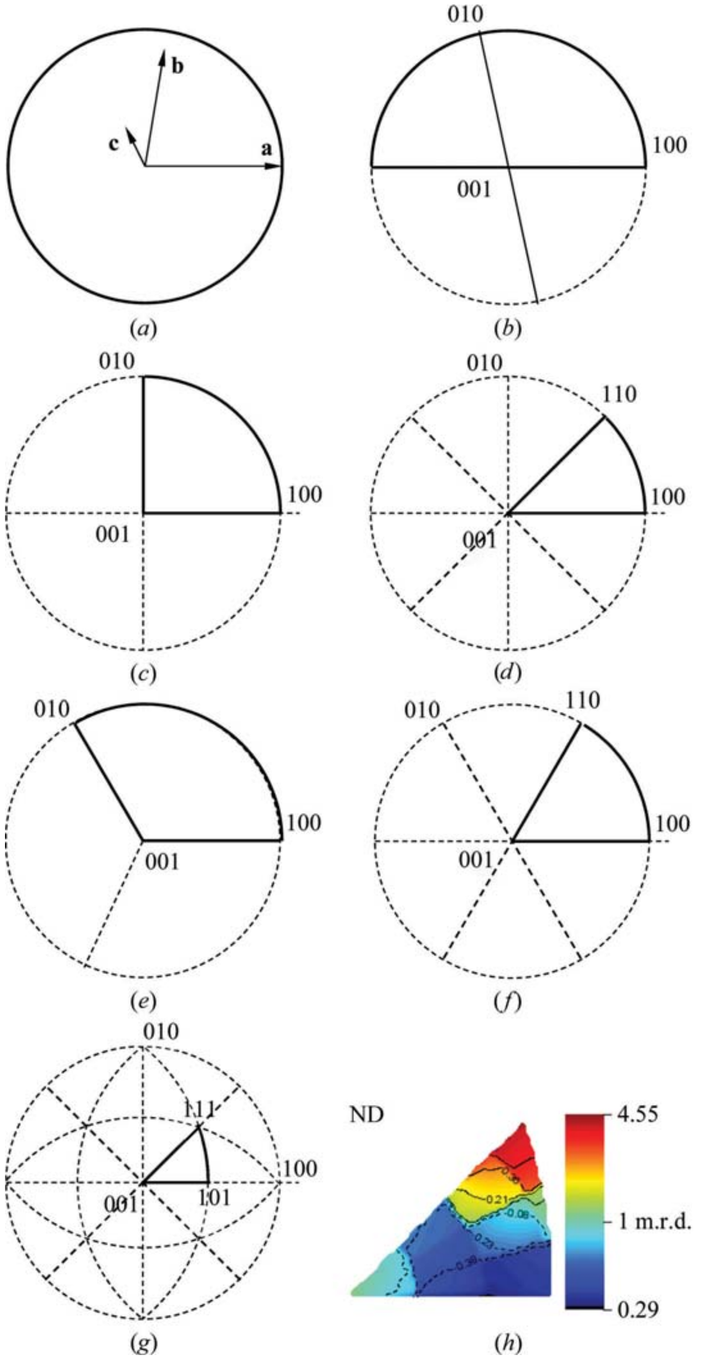


Figure 5.3.6
The inverse pole-figure sectors as a function of the crystal symmetry. The nonredundant sectors are indicated by bold edges. (*a*) Triclinic, (*b*) monoclinic (the *b*-axis unique setting has been used), (*c*) orthorhombic, (*d*) tetragonal, (*e*) rhombohedral using a hexagonal unit cell, (*f*) hexagonal and (*g*) cubic crystal systems. (*h*) An inverse pole figure for the drawing axis of an aluminium wire elaborated by cold drawing (linear density scale, cubic sector, equal-area projection).

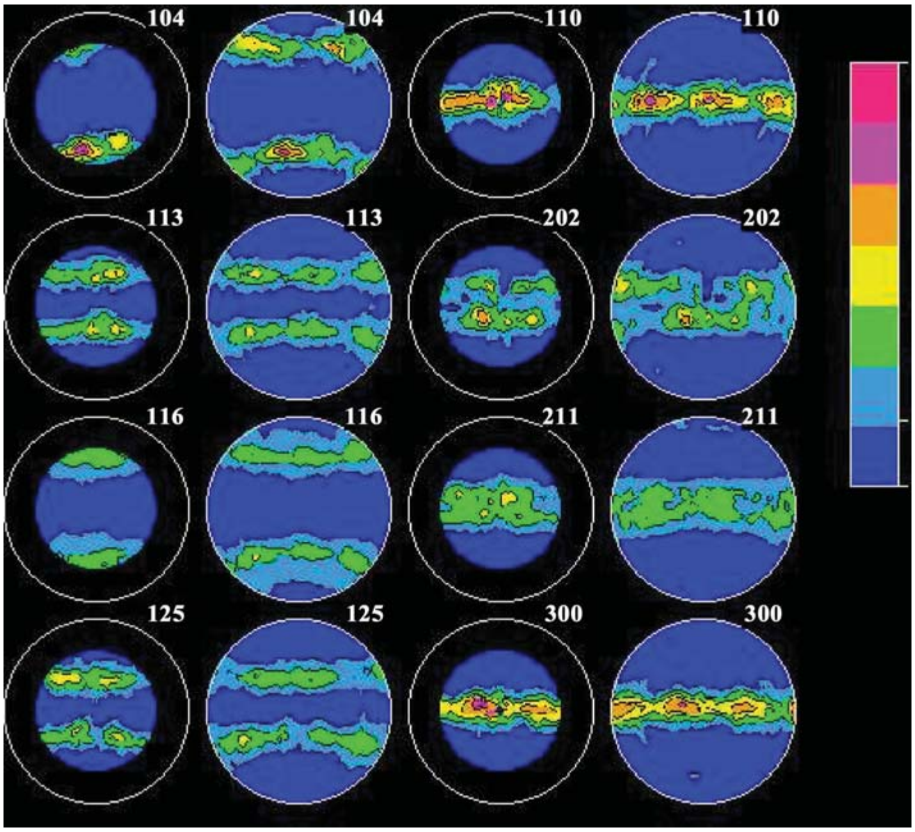

Figure 5.3.7
Visual examination of the OD refinement reliability using experimental and recalculated normalized {104}, {110}, {113}, {202}, {116}, {211}, {125} and {300} pole figures (in successive order). WIMV refinements are from *BEARTEX*. Linear density scale, equal angular projections. The sample is the calcite outer prismatic layer of the deep-ocean mussel *Bathymodiolus thermophilus*, maximum density 6.3 m.r.d., minimum density 0 m.r.d. Here, $\mathrm{RP}_{0.05}$ = 25% and RP_1 = 17%.

component, resulting from the gliding systems activated in the crystals (Fig. 5.3.6*h*).

5.3.2.5. *OD refinement reliability estimators*

As in Rietveld analysis, several factors are used to evaluate the reliability of the solution for $f(g)$. In most programs the RP_x factors are used,

$$\overline{\mathrm{RP}}_x = \frac{1}{I}\sum_i \sum_j \frac{\left|P^c_{\mathbf{h}_i}(\mathbf{y}_j) - P^o_{\mathbf{h}_{ii}}(\mathbf{y}_j)\right|}{P^o_{\mathbf{h}_i}(\mathbf{y}_j)}, \qquad (5.3.36)$$

where $\mathbf{h}_i$, $i = 1, \ldots, I$, are the measured pole figures, $\mathbf{y}_j$, $j = 1, \ldots, J$, are the measured points of the pole figures, a superscript 'o' indicates observed normalized values and a superscript 'c' indicates recalculated normalized values, $P_{\mathbf{h}_i}(\mathbf{y}_j)$ is the pole density at $\mathbf{y}_j$ on pole figure $\mathbf{h}_i$, and $x = 0, \varepsilon, 1, 10, \ldots$ is the criterion to estimate the accuracy *versus* the density level.

The value x is a criterion that is used to indicate the quality of the refinement for the low- and high-density levels. We use x = 0.05 to reveal the global quality and x = 1 to show this quality for density values higher than 1 m.r.d. However, RP factors depend on the texture strength since they are not weighted by the density level, and consequently make the comparison of refinement quality between samples ambiguous (Chateigner, 2005). In other words, one should compare the refinement quality with RP factors only for similar texture strengths and types. Working out reliability factors on individual pole figures helps to detect whether some pole figures are particularly badly reproduced after the refinement, in order to devise a correction strategy.

In order to avoid texture-strength dependence of the reliability factors, surface-weighted factors (Matthies *et al.*, 1987) and several arithmetic mean averaging schemes have been described (Chateigner, 2005). Bragg-like factors also can be calculated, either weighted by density levels or not (Chateigner, 2005). However, using full patterns, Rietveld-like analysis provides 'intensity-weighted' factors, which exhibit less overall variation with texture strength and are better indicators for comparing OD refinement quality among samples,

$$\mathrm{Rw}^z_x = \frac{\sum_{i=1}^{I}\sum_{j=1}^{J}\left[w^o_{ij} I^o_{\mathbf{h}_i}(\mathbf{y}_j) - w^c_{ij} I^c_{\mathbf{h}_i}(\mathbf{y}_j)\right]^2}{\sum_{i=1}^{I}\sum_{j=1}^{J}\left[w^z_{ij} I^z_{\mathbf{h}_i}\right]^2(\mathbf{y}_j)}\,\theta[x, P^o_{\mathbf{h}_i}(\mathbf{y}_j)], \qquad (5.3.37)$$

where

$$I^z_{\mathbf{h}_i}(\mathbf{y}_j) = P^o_{\mathbf{h}_i}(\mathbf{y}_j) N_{\mathbf{h}_i}$$

is the diffracted intensity, $N_{\mathbf{h}_i}$ is the refined normalizing factor,

$$w^z_{ij} = \frac{1}{[I^z_{\mathbf{h}_i}(\mathbf{y}_j)]^{1/2}}$$

is the diffracted intensity weight and

$$\theta(x, t) = \begin{cases} 1 & \text{for } P_{\mathbf{h}_i}(\mathbf{y}_j) > x, \\ 0 & \text{for } P_{\mathbf{h}_i}(\mathbf{y}_j) \le x. \end{cases}$$

Whatever the reliability factors, one of the best estimates of a physically reasonable solution remains visual (Fig. 5.3.7). If the OD has been satisfactorily refined, any pole figure recalculated from this OD should compare well with the experimental pole figure.

5.3.2.6. *Texture-strength factors*

Once $f(g)$ has been satisfactorily obtained, some factors can give an estimate of the overall texture strength. These factors are used to compare samples with the same crystal symmetries and similar texture components.

5.3.2.6.1. *Texture index*

5.3.2.6.1.1. *OD texture index*

The first overall texture-strength parameter is the so-called ‘texture index’ (Bunge, 1982; expressed in units of m.r.d.^{2}),

$$F^2 = \frac{1}{8\pi^2}\sum_i [(g_i)]^2 \Delta g_i, \qquad (5.3.38)$$

where Δg_i is the OD cell volume. This index varies from 1 (random powder) to infinity (perfect texture or single crystal). It represents the mean-square value of the OD. Using harmonics, this factor is calculated from the C_λ^{mn} coefficients:

$$F^2 = 1 + \sum_{\lambda=2}^{L}\left(\frac{1}{2\lambda+1}\right)\sum_{m=-\lambda}^{\lambda}\sum_{n=-\lambda}^{\lambda}|C_\lambda^{mn}|^2. \qquad (5.3.39)$$

5.3.2.6.1.2. *Pole-figure texture index*

To compare the texture strengths of different samples, the texture index associated with given pole figures may be used,

$$J_{\mathbf{h}}^2 = \frac{1}{4}\sum_i [P_{\mathbf{h}}(\mathbf{y}_i)]^2 \Delta \mathbf{y}_i, \qquad (5.3.40)$$

with $\Delta\mathbf{y} = \sin\vartheta_{\mathbf{y}}\Delta\vartheta_{\mathbf{y}}\Delta\varphi_{\mathbf{y}}$.

5.3.2.6.2. *Texture entropy*

The second overall texture strength parameter is a measure of the texture disorder, evaluated by the calculation of the entropy (Shannon, 1948),

$$S = -\frac{1}{8\pi^2}\sum_i f(g_i)\ln f(g_i)\Delta g_i. \qquad (5.3.41)$$

5.3.2.6.3. *Pole-figure and ODF strengths*

Both OD and pole-figure indexes are expressed in units that are not homogeneous with distribution density units (m.r.d.). To help with comparison and interpretation, it is more convenient to compare the square roots of these values, *i.e.* the OD and pole-figure strengths, respectively (Kocks *et al.*, 1998),

$$F = (F^2)^{1/2} \text{ and } J_{\mathbf{h}} = (J_{\mathbf{h}}^2)^{1/2}. \qquad (5.3.42)$$

The texture entropy can also serve as another texture-strength definition, called F_S:

$$F_S = [\exp(-S)]^{1/2}. \qquad (5.3.43)$$

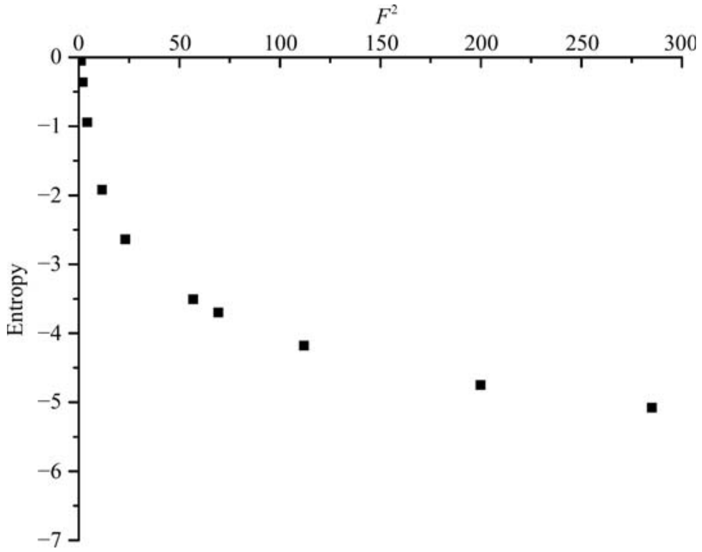

Figure 5.3.8
Entropy variation with texture index for modelled $f(g)$ functions.

5.3.2.6.4. *Correlation between F^2 and S*

From the definitions of F^2 and S, their variations are restricted to the $(1, \infty)$ and $(0, -\infty)$ domains, respectively. Entropy and texture index are correlated, but it is not possible to obtain a general analytical expression for this correlation, which depends on $f(g)$. To appreciate it, one can represent $f(g)$ functions as points in the (F^2, S) plane. In this plane there is a lower bound for $f(g)$, which can be visualized by the $f(g)$ functions of strongly textured samples with no random component (Fig. 5.3.8). This lower bound for the H space (Hielscher *et al.*, 2007) is defined by

$$S = -\ln F^2. \qquad (5.3.44)$$

No $f(g)$ function can be located below this bound, but *a priori* all of the space between it and the S = 0 axis of this graph corresponds to possible $f(g)$ functions. For instance, an OD composed of two components, one very sharp and corresponding to part of the sample volume and the other random and corresponding to the remaining volume fraction, would be positioned at the point (300, −0.5). On the S = 0 axis only the point (1, 0) corresponds to a valid point for $f(g)$, since if S = 0 then F^2 is automatically 1 m.r.d.^{2}.

5.3.2.7. *Texture types*

5.3.2.7.1. *Random texture*

A random texture (or random sample) belongs to the $\infty\infty/m$ Curie (limit) group and is simply a name given to the texture exhibited by a sample that has no preferred orientation. Its crystallites are randomly oriented. The same number of grains are diffracting at any $\mathbf{y}$, and the orientation density for any point $\mathbf{y}$ in a given $\mathbf{h}$ pole figure is the same. Consequently, all crystalline $\{hkl\}$ planes are randomly oriented, and $P_{\mathbf{h}}(\mathbf{y})$ = 1 m.r.d. for any $\mathbf{h}$ and $\mathbf{y}$, *i.e.* all pole figures exhibit homogeneous 1 m.r.d. densities. In such a texture, each crystallite has three degrees of freedom (rotations around three orthogonal axes) to orient K_B relative to K_A. Consequently, all of the OD values correspond to $f(g)$ = 1 m.r.d. distribution densities, whatever the value of g.

However, in some samples only a fraction of the total volume, V_r, is randomly oriented; the rest, $V_c(g)$, is the oriented fraction volume with orientation component or components $f_c(g)$. The random part produces a background level in the OD, sometimes called ‘fon’ or ‘phon’, and one can decompose the OD as

$$f(g) = f_r + f_c(g), \qquad (5.3.45)$$

with the mandatory conditions $0 \le f_r \le 1$ and $f_r = \min[f(g)]$.

By integrating (5.3.1) and taking into account (5.3.35), one obtains

$$\frac{V_r + V_c(g)}{V}\frac{1}{8\pi^2}\oint [f_r + f_c(g)]\,\mathrm{d}g,$$

which verifies that

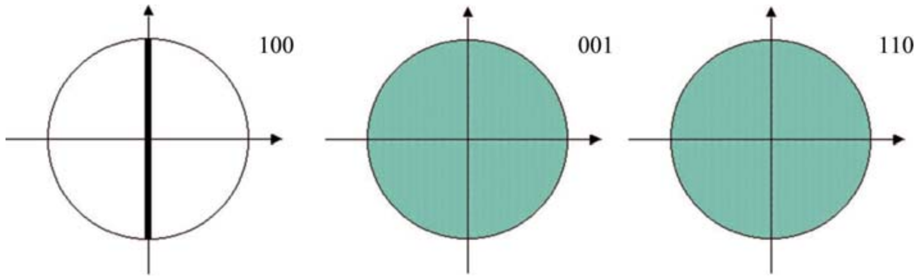

Figure 5.3.9
{100}, {001} and {110} pole figures of a planar texture in an orthorhombic crystal system. The rotation axis of the planar texture is with ⟨100⟩* directions perpendicular to X_A.

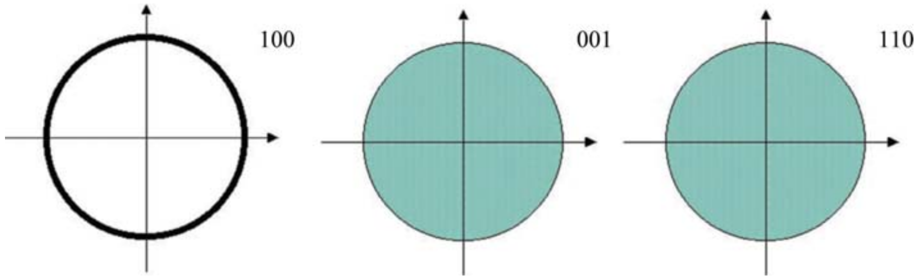

Figure 5.3.10
{100}, {001} and {110} pole figures of a cyclic-planar texture in an orthorhombic crystal system. The rotation axis of the cyclic-planar texture is with ⟨100⟩* directions perpendicular to Z_A.

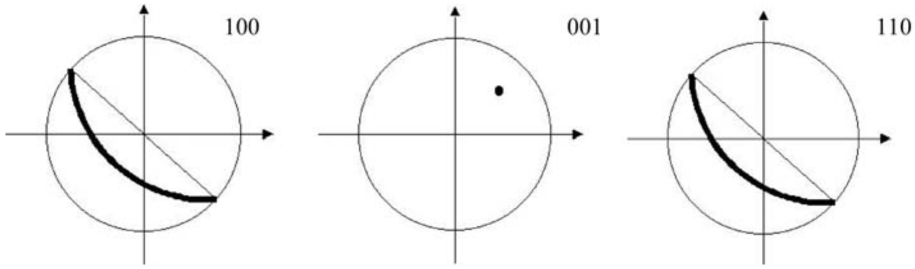

Figure 5.3.11
{100}, {001} and {110} pole figures of a fibre texture in an orthorhombic crystal system. The fibre axis is with ⟨001⟩* directions at ($\vartheta_{\mathbf{y}} = 45°$, $\varphi_{\mathbf{y}} = 45°$).

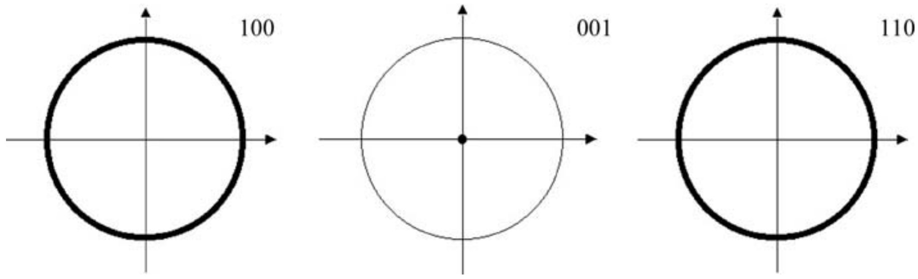

Figure 5.3.12
{100}, {001} and {110} pole figures of a cyclic-fibre texture in an orthorhombic crystal system. The fibre axis is with ⟨001⟩* directions along Z_A.

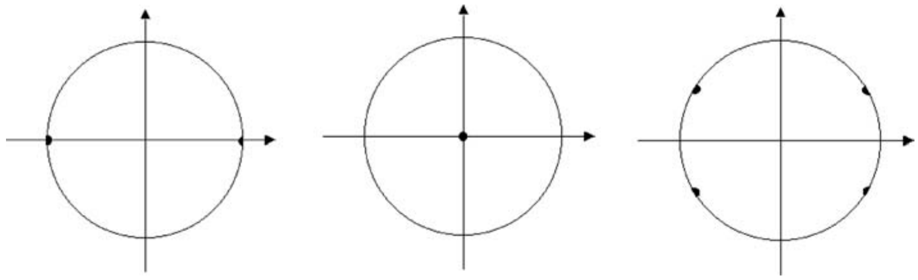

Figure 5.3.13
{100}, {001} and {110} pole figures of a three-dimensional texture in an orthorhombic crystal system, with ⟨001⟩* directions along Z_A and ⟨100⟩* directions along X_A.

$$V_r/V = f_r \text{ for the random part, and}$$
$$\frac{\mathrm{d}V_c(g)}{V} = \frac{1}{8\pi^2} f_c(g)\,\mathrm{d}g \text{ for the textured part.} \qquad (5.3.46)$$

This strictly means that the minimum value of the OD (*e.g.* f_r = 0.3 m.r.d.) defines the random volume fraction, *i.e.* 30% of the material is randomly oriented in this case.

5.3.2.7.2. *Planar textures*

This kind of texture is exhibited by samples in which the crystallites have two degrees of freedom to orient and belong to the $\infty\infty$ Curie group. One specific ⟨*hkl*⟩* direction family is allowed to rotate around one sample axis. The ⟨*hkl*⟩* directions are then located at random in a K_A plane perpendicular to the rotation axis. For instance, if the rotation axis is X_A with the direction family ⟨100⟩* of an orthorhombic crystal system (Fig. 5.3.9), the the ⟨100⟩* directions are then distributed in the (Y_A, Z_A) plane. However, since the other directions are at random around ⟨100⟩*, their pole figures remain quite homogeneous.

Of course, it is a special case that the rotation axis is along a major axis of the sample, and that the ⟨100⟩* (**a** axes) are the directions concerned. There could have been an inclined axis of rotation and reflections with a larger multiplicity, giving rise to more complex pole figures. Planar textures with the rotation axis around Z_A are called a 'cyclic-planar' texture (Fig. 5.3.10).

5.3.2.7.3. *Fibre textures*

If the crystallites lose another degree of freedom in their orientation (∞, ∞m, ∞/m, $\infty 2$ or ∞/mm Curie groups), they are forced to align one of their ⟨*hkl*⟩* directions with one direction **y** of K_A, with all other directions being at random around ⟨*hkl*⟩*. Such a texture is called 'fibre texture'. For instance, if all of the ⟨001⟩* directions from an orthorhombic crystal system are located along **y** = ($\vartheta_{\mathbf{y}} = 45°$, $\varphi_{\mathbf{y}} = 45°$) (Fig. 5.3.11), then the ⟨100⟩* and ⟨110⟩* directions will be located at random in a plane perpendicular to this **y**. As above, if the ⟨001⟩* directions are aligned with Z_A then the texture is called a 'cyclic-fibre texture' (Fig. 5.3.12). Such a texture has the ⟨100⟩* and ⟨110⟩* poles located on the periphery of the pole figures.

5.3.2.7.4. *Three-dimensional textures*

Samples composed of crystallites which have had no opportunity to orient themselves in K_A (zero degrees of freedom) will exhibit point poles for all of their pole figures. The pole figures will be similar to those of a single crystal. We call this a 'three-dimensional' or 'single-crystal-like' texture. For instance if the

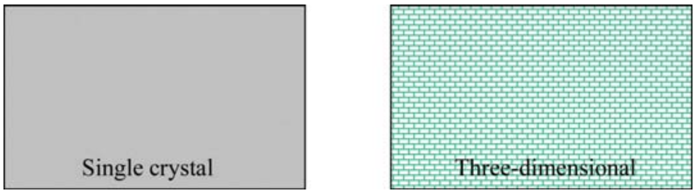

Figure 5.3.14
The difference between a perfect single crystal and a polycrystal with perfect three-dimensional crystallite orientations. The normalized pole figures should be identical.

$\langle 001\rangle^*$ directions are aligned with Z_A and the $\langle 100\rangle^*$ directions with X_A, the pole figures will look like those in Fig. 5.3.13, and the φ_y angles to which the $\langle 110\rangle^*$ poles are localized will depend on the b/a ratio of the orthorhombic structure.

One should avoid confusion between real single crystals and polycrystals exhibiting three-dimensional textures (Fig. 5.3.14). A single crystal, as usually understood in single-crystal crystallography, exhibits a 'mosaicity', itself composed of a mosaic spread and size. The mosaic spread is often measured using a so-called 'rocking curve', *i.e.* a limited view of the complete texture, and in this sense is a 'three-dimensional texture' with very small crystallite misorientation. The mosaic size represents the coherent domains (crystallites) of the mosaic in the single crystal. A perfect three-dimensional texture can correspond either to an ensemble of coherent domains with respective crystal reference frames perfectly parallel to one another (*i.e.* with no spread) but with no wave coherence between them, or to a large single crystal that diffracts as a single coherent domain. The diffracted intensity is much larger in the latter case and the direct pole figures will show very large intensities compared with the former. However, the normalized pole figures will be the same in both cases, as all effects other than crystal orientation are eliminated by normalization.

5.3.2.7.5. *Typical OD components*

Each of the previous texture types has corresponding OD descriptions as components of orientations, which can be represented, for example, using a Cartesian coordinate system for H space (Fig. 5.3.15) and isodensity surfaces for simplicity. An individual point g in this space represents an individual orientation located at $\{\alpha_c, \beta_c, \gamma_c\}$. A spherical component (b in Fig. 5.3.15) consists of concentric spheres with increasing radii for lower densities, with the level of these latter depending on the choice of the function representing the component. An elliptical component (c) shows an elongation in one or two directions (here along the α_c rotation axis). A tube around a given (α_c, β_c) couple that is elongated over the whole γ_c range represents a fibre texture with a fibre axis that is inclined with respect to the main K_A axis (a in Fig. 5.3.15). Isolated components respecting specific relationships between their coordinates can also exist; for instance, a tube around $\gamma_c = 0$ with $\alpha_c + \beta_c =$ constant (d in Fig. 5.3.15) or $\alpha_c^2 + \beta_c^2 =$ constant (e in Fig. 5.3.15).

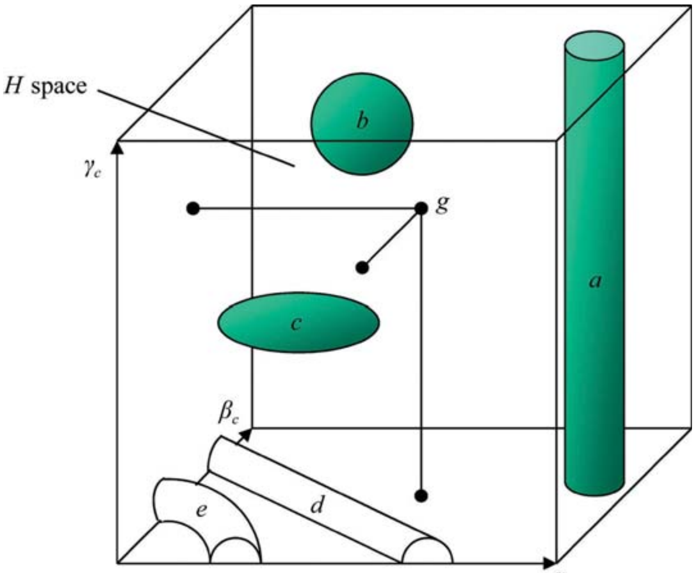

Figure 5.3.15
Isodensity surfaces representing isolated OD components in a Cartesian coordinate system in H space.

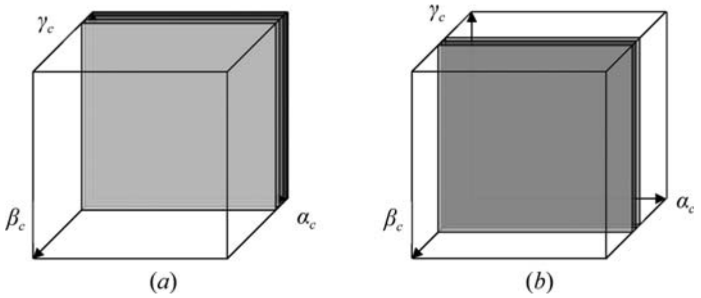

Figure 5.3.16
Several isodensity surfaces representing a cyclic-fibre OD (a) and a cyclic-planar OD (b) in H space.

For cyclic-fibre components $\beta_c = 0$ and α_c is distributed on 2π. In this configuration, a γ_c rotation or an α_c rotation have the same effect and the whole (α_c, γ_c) plane is filled by density (Fig. 5.3.16*a*). In a cyclic-planar texture (Fig. 5.3.16*b*), on the contrary, $\beta_c = 90^\circ$. However, in this case both α_c and γ_c are distributed on 2π, since the cyclic-planar axis Z_B is distributed in the (X_A, Y_A) plane and since all directions are at random Z_B. The result is an ODF representation that looks very similar to that of a cyclic-fibre texture, except for the coordinate of the high density levels along the β_c axis of rotation.

5.3.2.8. *Reciprocal-space mapping*

Reciprocal-space mapping (RSM) represents the localization of the momentum transfer in the sample reference frame (K_A). The momentum-transfer vector $\mathbf{q}$ is defined by

$$\mathbf{q} = (\mathbf{k}_o - \mathbf{k}_i),$$
$$\|\mathbf{q}\| = \frac{4\pi}{\lambda}\sin\theta = 2\|\mathbf{k}\|, \qquad (5.3.47)$$

in which $\mathbf{k}_i$ and $\mathbf{k}_o$ are the incident and outgoing wavevectors, respectively. The goal of RSM is then to locate a reciprocal vector, defined in reciprocal space $\mathbf{R}$, in a reference frame defined in the sample direct space. Since $\mathbf{q}$ is perpendicular to the diffracting plane (hkl), it is also parallel to the normal $\mathbf{h}$ of this latter. Consequently, RSM first determines the ensemble of $I_{\mathbf{h}}(\mathbf{y})$ diffracted intensities for the $\mathbf{y}$ orientations of a given reciprocal node corresponding to the extension of the Bragg peak $\mathbf{h}$ on the pole sphere. At this point one should notice that RSM is generally performed on strongly oriented samples such as epitaxial layers or single crystals. Each $\mathbf{y}$ set of measured orientations is then restricted in sample space on the pole sphere for a given $\mathbf{h}$. However, this does not avoid the measurement of a large number of points for each **h** to correctly describe the reciprocal-space node.

Secondly, one has to transform measured **y** directions of Y space to their corresponding values in R by multiplying them by the norm $\|\mathbf{q}\|$ of the **q** vector. This results in a set of $I_{\mathbf{h}}(\mathbf{q})$ values represented in K_A.

From the pole-figure definitions, the **q** coordinates are

$$\begin{aligned} q_{X_A} &= \frac{4\pi}{\lambda}\sin\theta\sin\vartheta_{\mathbf{y}}\cos\varphi_{\mathbf{y}} \\ q_{Y_A} &= \frac{4\pi}{\lambda}\sin\theta\sin\vartheta_{\mathbf{y}}\sin\varphi_{\mathbf{y}} \\ q_{Z_A} &= \frac{4\pi}{\lambda}\sin\theta\cos\vartheta_{\mathbf{y}}. \end{aligned} \qquad (5.3.48)$$

5.3.3. Magnetic quantitative texture analysis (MQTA)

5.3.3.1. *Magnetization curves and magnetic moment distributions*

The measurement of magnetic pole figures using neutron diffraction is sparsely documented and only a few attempts at refining magnetic ODs have been carried out to date (Birsan *et al.*, 1996), although knowledge of the anisotropic distribution of magnetic moments in a sample has been shown to be of crucial importance to predict macroscopic magnetic behaviours (Morales *et al.*, 2003). Anisotropic magnetic behaviour is usually probed using magnetization curves measured in only two perpendicular macroscopic directions of the sample, and is then intrinsically subjected to strong biases if the sample magnetic moment distribution does not respect some symmetry, adapted to the magnetization measurement (Fig. 5.3.17). Magnetic moment distribution characterization is thus a prerequisite for checking the validity of magnetization measurements for a given sample-measurement configuration.

Neutron diffraction is perfectly suited for the examination of macroscopic magnetic moment distributions, provided that one can measure the same sample with and without the application of an external magnetic field during the measurements (Chateigner *et al.*, 2010).

5.3.3.2. *Magnetic pole figures and magnetic ODs*

5.3.3.2.1. *Magnetic pole figures and ODs*

Using neutron diffraction, pole figures are composed of a nuclear (n; the usual crystallographic pole figures) and a magnetic (m) part in zero field or under the application of an external magnetic field **B**,

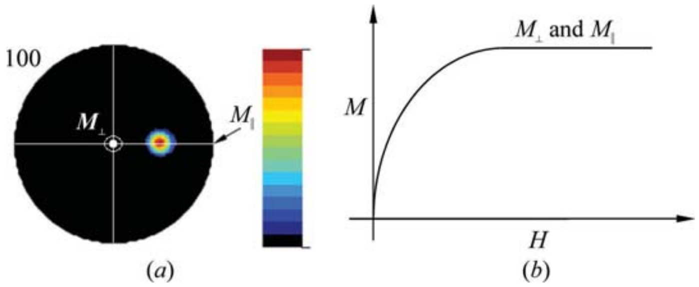

Figure 5.3.17
Illustration of a case for which a magnetization measurement in two perpendicular directions cannot reveal the macroscopic magnetic anisotropy. (a) Virtual distribution of the magnetic moments, with magnetic moments at 45° from both magnetization measurement directions, and (b) the corresponding magnetization curves.

$$\begin{aligned} I_{\mathbf{h}}(\mathbf{y}) &= I^n_{\mathbf{h}}(\mathbf{y}) + I^m_{\mathbf{h}}(\mathbf{y}), \\ I_{\mathbf{h}}(\mathbf{y},\mathbf{B}) &= I^n_{\mathbf{h}}(\mathbf{y},\mathbf{B}) + I^m_{\mathbf{h}}(\mathbf{y},\mathbf{B}). \end{aligned} \qquad (5.3.49)$$

For crystallites that are not free to rotate under **B**, for example in the solid state without phase transformation,

$$\begin{aligned} I^n_{\mathbf{h}}(\mathbf{y},\mathbf{B}) &= I^n_{\mathbf{h}}(\mathbf{y}), \ \text{hence} \\ I_{\mathbf{h}}(\mathbf{y},\mathbf{B}) &= I^n_{\mathbf{h}}(\mathbf{y}) + I^m_{\mathbf{h}}(\mathbf{y},\mathbf{B}). \end{aligned} \qquad (5.3.50)$$

This latter equation is of interest because it can serve for the determination of the magnetic part from an independent determination of the nuclear part, for example using X-ray diffraction. The application of a field **B** eventually induces a reorientation of magnetic moments in the sample, or magnetic polarization, which is seen using neutron diffraction as variations of intensities, $\Delta I^m_{\mathbf{h}}(\mathbf{y},\mathbf{B})$, in the pole figures, and (5.3.49) becomes

$$I_{\mathbf{h}}(\mathbf{y},\mathbf{B}) = I^n_{\mathbf{h}}(\mathbf{y},\mathbf{B}) + I^m_{\mathbf{h}}(\mathbf{y},0) + \Delta I^m_{\mathbf{h}}(\mathbf{y},\mathbf{B}). \qquad (5.3.51)$$

As for crystallographic QTA, total magnetic scattering normalized pole figures $[P^m_{\mathbf{h}}(\mathbf{y},\mathbf{B})]$, normalized magnetic scattering polarization pole figures $[\Delta P^m_{\mathbf{h}}(\mathbf{y},\mathbf{B})]$ and their respective magnetic ODs $[f_m(g,\mathbf{B})$ and $f^p_m(g,\mathbf{B})]$ have to respect normalization with their respective normalization factors (random intensities),

$$\begin{aligned} &\int_{\mathbf{y}} P^m_{\mathbf{h}}(\mathbf{y},\mathbf{B})\,\mathrm{d}\mathbf{y} = 2\pi, \\ &\int_{\mathbf{y}} \Delta P^m_{\mathbf{h}}(\mathbf{y},\mathbf{B})\,\mathrm{d}\mathbf{y} = 0, \\ &I^{n,r}_{\mathbf{h}} = \frac{\int_{\mathbf{y}} I^n_{\mathbf{h}}(\mathbf{y},\mathbf{B})\,\mathrm{d}\mathbf{y}}{\int_{\mathbf{y}}\mathrm{d}\mathbf{y}}, \\ &I^{m,r}_{\mathbf{h}} = \frac{\int_{\mathbf{y}} I^m_{\mathbf{h}}(\mathbf{y},\mathbf{B})\,\mathrm{d}\mathbf{y}}{\int_{\mathbf{y}}\mathrm{d}\mathbf{y}} = I^{m,r}_{\mathbf{h}}(\mathbf{y},0) = I^{m,r}_{\mathbf{h}}(\mathbf{y},\mathbf{B}), \\ &\int_g f_m(g)\,\mathrm{d}g = 4\pi^2, \\ &\int_g f^p_m(g)\,\mathrm{d}g = 0. \end{aligned} \qquad (5.3.52)$$

5.3.3.2.2. *Fundamental equations of MQTA*

Since two different magnetic scattering pole figures and ODs have been constructed, there are two corresponding fundamental equations:

$$P^m_{\mathbf{h}}(\mathbf{y},\mathbf{B}) = \frac{1}{2\pi}\int_{\mathbf{h}\|\mathbf{y}} f_m(g,\mathbf{B})\,\mathrm{d}\tilde{\varphi} \qquad (5.3.53)$$

for the total magnetic scattering, with $\tilde{\varphi}$ in general different from that of the crystallographic (nuclear) part since magnetic and nuclear cells can have different rotation groups, and

$$\Delta P^m_{\mathbf{h}}(\mathbf{y},\mathbf{B}) = \frac{1}{2\pi}\int_{\mathbf{h}\|\mathbf{y}} f^p_m(g,\mathbf{B})\,\mathrm{d}\tilde{\varphi} \qquad (5.3.54)$$

for the polarization part. Because the normalization of the polarization part requires us to work in the 'positive' and 'negative' spaces of the polarization pole figures, this latter equation is in fact composed of two parts:

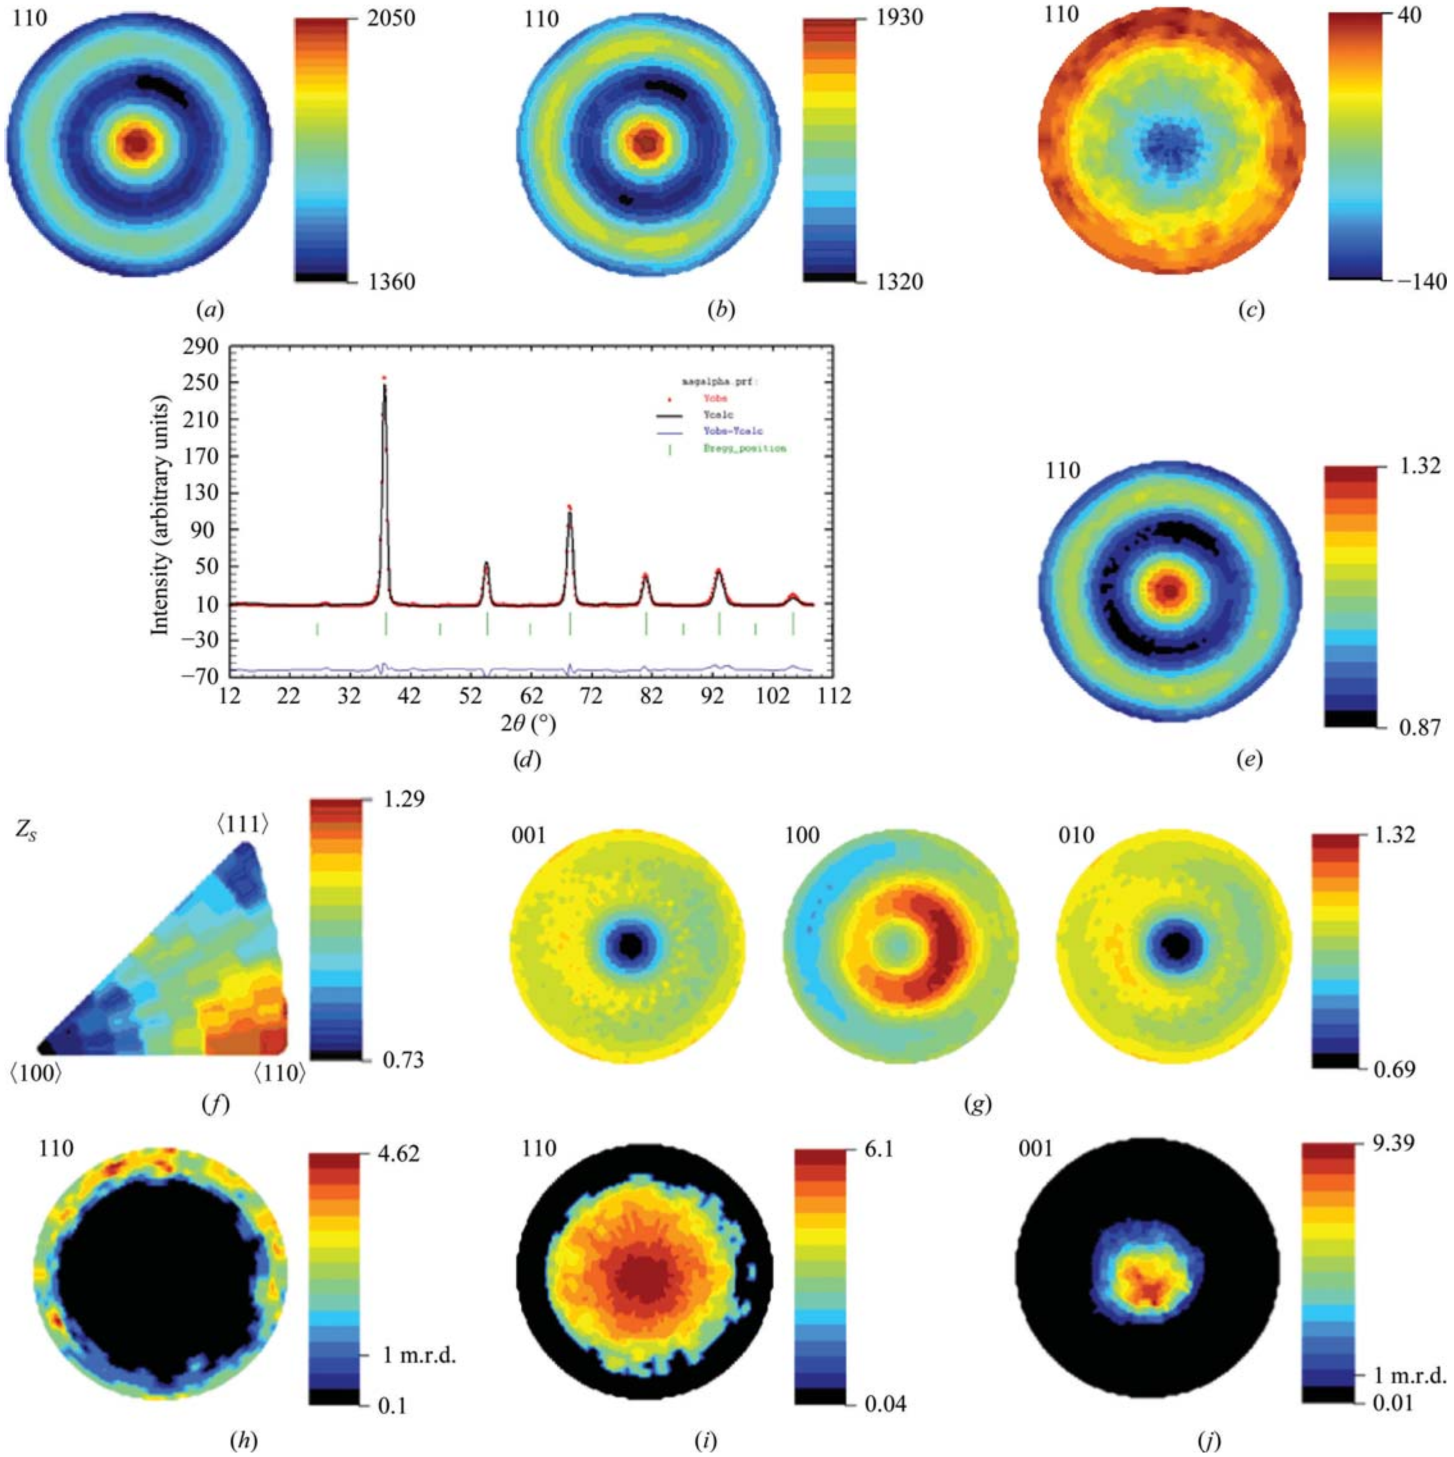

Figure 5.3.18

{110} pole figures at zero field (*a*), under 0.3 T (*b*) and the difference (*c*). (*d*) Fit of the sum of all diagrams at zero field using the orthorhombic magnetic subgroup in *FullProf*; (*e*) WIMV recalculated/normalized nuclear {110} pole figure. (*f*) Inverse nuclear pole figure for the cylinder sample-axis direction and (*g*) WIMV recalculated/normalized magnetic scattering contribution for the main orthorhombic axes. (*h*–*j*) Recalculated/normalized magnetic scattering polarization pole figures for the positive (*h*) and negative (*i*) parts of the difference pole figures, and the corresponding positive {001} magnetic scattering pole figure illustrating the magnetic moment reorientation (*j*).

$$\Delta P_{\mathbf{h}}^{m+}(\mathbf{y},\mathbf{B}) = \frac{1}{2\pi}\int\limits_{\mathbf{h}\parallel\mathbf{y}} f_m^{p+}(g,\mathbf{B})\,\mathrm{d}\tilde{\varphi},$$

$$\Delta P_{\mathbf{h}}^{m-}(\mathbf{y},\mathbf{B}) = \frac{1}{2\pi}\int\limits_{\mathbf{h}\parallel\mathbf{y}} f_m^{p-}(g,\mathbf{B})\,\mathrm{d}\tilde{\varphi}. \qquad (5.3.55)$$

The correct normalizations and determinations of the various orientation quantities accessible to neutron diffraction depend on many factors. The possibilities of observing neutron peaks without magnetic contributions and the initial magnetic and crystallographic orientation states of the sample (isotropic or anisotropic) have been discussed elsewhere (Chateigner *et al.*, 2010).

5.3.3.3. *An example*

Here, we illustrate magnetic quantitative texture analysis on an iron sample exhibiting magnetic saturation around 0.5 T (Chateigner *et al.*, 2010) that was initially not magnetized. Measurements were carried out on the D19 beamline at ILL first without and then with an applied magnetic field of 0.3 T, which is sufficient to partly reorient the magnetic moments. At zero field (Fig. 5.3.18*a*) the sample exhibits a strong signal with a moderate $\langle 110\rangle$ crystallographic texture. Under a 0.3 T field (Fig. 5.3.18*b*), the maximum of the $\{110\}$ experimental pole figure decreases significantly at the benefit of the pole-figure equator. This is coherent with a magnetic field applied along the sample cylinder axis (Z_A), with which magnetic moments tend to align, giving rise to more magnetic diffraction signal 90° to it. The difference $\{110\}$ pole figure illustrates this more explicitly (Fig. 5.3.18*c*), with negative differences at its centre and positive values on its equator. We then calculated the random magnetic contribution of the isotropic magnetic sample using *FullProf* (Fig. 5.3.18*d*), using the sum of all diagrams measured at all of the sample orientations, taking into account the resolution characteristics of the D19 instrument. This random magnetic contribution provides the possibility of decoupling nuclear and magnetic contributions at zero field: $I_h^n(\mathbf{y}, 0)$ and $I_h^m(\mathbf{y}, 0)$, respectively (Chateigner *et al.*, 2010). These latter pole figures were used to refine the corresponding ODs, $f_n(g)$ and $f_m(g)$, using the body-centred cubic crystal symmetry and the orthorhombic magnetic symmetries, respectively, and the WIMV algorithm in *BEARTEX* (Wenk *et al.*, 1998). The nuclear $\langle 110\rangle$ fibre texture (Fig. 5.3.18*e*) culminates at 1.32 m.r.d. [$f_n^{\max}(g) = 1.8$ m.r.d., $f_n^{\min}(g) = 0.61$ m.r.d., $F^2 =$ 1.03 m.r.d.^{2}, RP$_0$ = 1.42%], and the fibre axis is aligned with Z_A as the sole textured component (Fig. 5.3.18*f*). Since the easy-axis direction for magnetization in iron is $\langle 100\rangle$, the actual $\langle 110\rangle$ fibre does not correspond to an easy-magnetization configuration. Consequently, the total normalized magnetic scattering pole figures of the main magnetic unit-cell axes (Fig. 5.3.18*g*) do not show a strong reorientation of densities, and exhibit a maximum of only 1.32 m.r.d. on the pole figures, but a larger OD maximum value [$f_n^{\max}(g) = 2.3$ m.r.d., $f_n^{\min}(g) = 0.64$ m.r.d., $F^2 = 1.03$ m.r.d.^{2}, RP$_0$ = 0.24%].

From the magnetic scattering polarization pole figures we refined the magnetic polarization OD, $f_m^{p+}(g)$ and $f_m^{p-}(g)$. Since the magnetic scattering difference pole figures show positive and negative values, we divided them into positive and negative zones, $\Delta I_{\mathbf{h}}^{m+}(\mathbf{y}, \mathbf{B})$ and $\Delta I_{\mathbf{h}}^{m-}(\mathbf{y}, \mathbf{B})$, respectively, assigning zeros to the negative cells of $\Delta I_{\mathbf{h}}^{m+}(\mathbf{y}, \mathbf{B})$ and *vice versa*. From $\Delta I_{\mathbf{h}}^{m+}(\mathbf{y}, \mathbf{B})$ and $|\Delta I_{\mathbf{h}}^{m-}(\mathbf{y}, \mathbf{B})|$ we refined the magnetic scattering polarization ODs, $f_m^{p+}(g)$ [$f_m^{p+,\max}(g) = 93$ m.r.d., $f_m^{p+,\min}(g) =$ 0 m.r.d., $F^2 = 12.4$ m.r.d.^{2}, RP$_0$ = 6.83%] and $f_m^{p-}(g)$ [$f_m^{p-,\max}(g) =$ 6.1 m.r.d., $f_m^{p-,\min}(g) = 0.04$ m.r.d., $F^2 = 2.70$ m.r.d.^{2}, RP$_0$ = 0.00%] in *BEARTEX*, which yielded the normalized $\Delta P_{110}^{m+}(\mathbf{y}, \mathbf{B})$ and $|\Delta P_{110}^{m-}(\mathbf{y}, \mathbf{B})|$ pole figures (Figs. 5.3.18*h* and 5.3.18*i*, respectively). These latter clearly show the reoriented part of the magnetic signal, with a large density created in the centre of $|\Delta P_{110}^{m-}(\mathbf{y}, \mathbf{B})|$, indicating a departure of intensities in this area to reach the periphery of $\Delta P_{110}^{m+}(\mathbf{y}, \mathbf{B})$, both pointing towards magnetic moment alignment with Z_A. The maximum densities observed in these latter pole figures measure the strength of the intensity reorientations, as also seen from the texture indexes and OD maxima. Most importantly, since the diffracted signal reveals magnetic moments that are located 90° to it, one can search in this case for a reflection at this angle from [110], which is, for instance, 001 in this space group. The $\Delta P_{110}^{m+}(\mathbf{y}, \mathbf{B})$ (Fig. 5.3.18*j*) then directly reveals the distribution of reoriented magnetic moments, which in this case indicates a 9.4 m.r.d. density of reorientation. Interestingly, in this case one can see a slight but significant deviation of these magnetic moments with respect to Z_A ($\langle 110\rangle$ crystallographic fibre axis), probably owing to difficulty in controlling the application of the magnetic field.

5.3.4. Modelling of preferred orientation in the Rietveld method

The modelling of preferred orientation in diffraction patterns was originally developed to facilitate structure determination. The presence of an unrecognized preferred orientation can be fatal to structure solution. Texture is particularly present in easily cleaved materials or materials with anisotropic habits, and when the samples are prepared by anisotropic techniques. X-ray diffraction specimen preparation often introduces preferred orientations, which have been mostly considered as an undesirable phenomenon in Rietveld analysis.

When textures have not been removed successfully by careful grinding and packing, the remaining texture has to be modelled during the analysis. There are two types of texture treatments in Rietveld analysis. If the texture is simple (smooth, fibre type and not too severe), it can be modelled using analytical formulae. If it is more complex (several texture components, sharp pole figures) the treatment requires a quantitative texture analysis (the subject of Section 5.3.2). In this section the simplest texture corrections are described, but the best way to characterize texture effects is to carry out QTA inside the Rietveld approach. The texture is roughly modelled using three parameters:

(i) a texture axis linked to the sample symmetry (the normal to the sample surface for a flat sample in Bragg–Brentano geometry or the cylinder axis in Debye–Scherrer geometry),
(ii) the crystallographic direction $\mathbf{h}$, which tends to align with the previous axis, and
(iii) a texture strength (angular dispersion, texture factor *etc.*).

5.3.4.1. *Rietveld and March approaches*

The preferred orientations are modelled in the original equation of Rietveld by the March function (March, 1932) using the function $P_{\mathbf{h}}$,

$$P_{\mathbf{h}} = \exp(-G_1\alpha_{\mathbf{h}}^2) \qquad (5.3.56)$$

or

$$P_{\mathbf{h}} = G_2 + (1 - G_1)\exp(-G_1\alpha_{\mathbf{h}}^2), \qquad (5.3.57)$$

where G_1 and G_2 are refinable parameters and $\alpha_{\mathbf{h}}$ is the angle between the texture direction $\mathbf{h}$ and the scattering vector.

5.3.4.2. *March–Dollase approach*

Dollase proposed an improvement to the March approach using the following function (Dollase, 1986):

$$P_{\mathbf{h}} = \left[G_1^2\cos^2\alpha_{\mathbf{h}} + \left(\frac{1}{G_1}\right)\sin^2\alpha_{\mathbf{h}}\right]^{-3/2}. \qquad (5.3.58)$$

Originally, the March correction assumed a Gaussian distribution of the preferred-orientation axis of the individual crystallites about an axis. G_1 is a refinable parameter that now controls the distribution shape and is an index of the preferred-orientation strength ($0 < G_1 \leq 1$; $G_1 = 1$ for a random orientation).

This model provides

(i) a preferred-orientation model with minimum or maximum at $\alpha_{\mathbf{h}} = 0°$,
(ii) a symmetric and smooth evolution in the (0, 90°) $\alpha_{\mathbf{h}}$ range,
(iii) a single parameter to be fitted, and

(iv) the possibility of normalization of the orientation,

$$\int_0^{\pi/2} P_{\mathbf{h}} \sin\alpha_{\mathbf{h}}\, d\alpha_{\mathbf{h}} = 1. \qquad (5.3.59)$$

This latter property is important in order to keep the total diffracted intensity in a diffraction diagram constant whatever the distribution shape $P_{\mathbf{h}}$. A point that is often not realized is that the March–Dollase approach assumes cylindrical sample symmetry.

5.3.4.3. *Modified March–Dollase models*

More recently, Brosnan *et al.* (2006) proposed a modification of the March–Dollase approach by including a 'random' orientation factor,

$$P_{\mathbf{h}} = f\left\{\left[G_1^2\cos^2\alpha_{\mathbf{h}} + \left(\frac{1}{G_1}\right)\sin^2\alpha_{\mathbf{h}}\right]^{-3/2}\right\} + (1-f). \qquad (5.3.60)$$

In this model, it is expected that the factor f provides the random part, *i.e.* the volume of randomly oriented crystallites. However, it must be noted that this factor is linked to the component of orientation that is described by the formula. Since this only describes one orientation component, *i.e.* a specific $\mathbf{h}$ distributed in a given distribution around the normal to the sample, f is in fact only the volume fraction of crystallites that have their $\mathbf{h}$ direction in this distribution component, with $(1-f)$ being the volume fraction of crystallites that are not in this component (oriented differently) but are not necessarily randomly oriented. Let us give an example to illustrate this point: imagine a sample containing tetragonal crystallites with a single orientation component, for example with their c axes distributed in a Gaussian around the normal. In this case, if $f = 0.5$, 50% of the crystallites have [001] directions inside the Gaussian component. However, there is no information, for instance, about the orientation of the a axes around the orientation component. Thus, $(1 - f)$ does not mean that 50% of the crystallites are necessarily randomly oriented; the a axes may possibly be strongly oriented along one specific direction in the plane perpendicular to the c axes. The parameter f hence does not represent the orientation distribution function $f(g)$, and one should not confuse them.

A second modification (Zolotoyabko, 2009) focuses on the estimation of an orientation degree parameter η_Z, defined on the basis of the Dollase parameter G_1:

$$\eta_Z\,(\%) = \left[\frac{(1-G_1)^3}{1-G_1^3}\right]^{1/2}. \qquad (5.3.61)$$

The η_Z parameter tends to zero as G_1 values reach 1 and to 100% for $G_1 = 0$. It can easily be introduced in Rietveld programs and intrinsically contains the normalization condition of (5.3.59).

5.3.4.4. *Donnet–Jouanneaux function*

This model for preferred orientation is purely empirical, with a parameter D controlling the preferred orientation ($D = 0$ for a random orientation) (Jouanneaux, 1999):

$$P_{\mathbf{h}} = 1 + \frac{D\cos 2\alpha_{\mathbf{h}}}{1+(G-1)\sin^2\alpha_{\mathbf{h}}}. \qquad (5.3.62)$$

5.3.4.5. *Modelling by spherical harmonics (and exponential)*

Järvinen and others (Ahtee *et al.*, 1989; Järvinen, 1993) initially proposed the use of a harmonic method to model preferred orientation in Rietveld refinement for cylindrical sample symmetry. The idea was expanded by Popa (1992) to all sample symmetries and implemented by Von Dreele in *GSAS* (Larson & Von Dreele, 2000).

Equation (5.3.13) is utilized to compute the preferred-orientation effect on intensities as a function of the coefficients. The sample symmetry must be imposed depending on the kind of measurement that is performed. In general, with only one pattern in either Bragg–Brentano or Debye–Scherrer geometry, a cylindrical symmetry (fibre texture) for the sample should be used. The fibre axis will be normal to the surface of the sample for the Bragg–Brentano case and along the capillary axis for the Debye–Scherrer case. Spinning the sample along this fibre axis will ensure the correct symmetry for the sample in cases where it is not correct. When a static specimen with known rolling or shear texture is measured (preferably in multiple orientations), the appropriate noncylindrical sample symmetry should be used, and the angles relating the different orientations must be considered.

Another remark should be made on the use of spherical harmonics with the Rietveld method. All spherical-harmonics descriptions and implementations (the same is also true for discrete methods such as WIMV, EWIMV and ADC) in the case of monoclinic crystal symmetry work only in the c-axis unique (Mattheis & Wenk, 2009) setting.

Different approaches have been used to ensure an OD that is always positive. The approaches used to force a positive OD, such as those described by Van Houtte (1991), do not have an effect in this case as the even coefficients are the only ones that are used in preferred-orientation correction and are not affected by positivity or similar methods. Constraints to force positive texture-correction factors are already provided by the experimental pattern. Additional constraints may be added to force the OD to also have positive texture factors or to remain inside the measured bounds.

An alternative approach is to write the OD as $f(g) = \exp[h(g)]$ (in a similar fashion to the exponential-harmonic method of Van Houtte, 1991) and to expand the function $h(g)$ in terms of spherical harmonics. This will retain all of the symmetries of the OD and ensure an OD that is always positive. The problem is that the texture factors can no longer be calculated using (5.3.13) and should be evaluated by numerical integration over the OD using (5.3.11), and in the Rietveld least-squares method only the numerical derivative must be adopted.

5.3.4.6. *The use of standard functions (or texture components)*

An alternative model for preferred orientation is to use standard components. In the case of only one pattern, fibre components should be used or fibre sample symmetry as described in Section 5.3.2.3.7. To compute a pole-figure value or texture model for a general fibre component having a partial Gaussian and Lorentzian character, (5.3.29) and (5.3.31) can be used by integrating around the fibre axis.

5.3.4.7. *Remarks*

In most of the previous models, the formulations are only valid for axially distributed, single-component textures (with a cylindrical symmetry around the scattering vector, and for a Bragg–Brentano symmetric geometry), for which efficient corrections are obtained (O'Connor *et al.*, 1991; Capková *et al.*,

Table 5.3.1

† In this case an exponential-harmonics method is claimed, but the particular implementation does not ensure compatibility between pole-figure and OD values.

1993; Cerný *et al.*, 1995). They have been implemented in many Rietveld programs, and some of them allow the modelling of two or more texture components of this type. For all other textures, measurements and formalisms to resolve the texture are required, unless the conversion of the sample to powder is acceptable. Furthermore, one should take particular care regarding the geometry used for the measurements. The previous formulae describe the orientations in the sample reference frame, while measurements are carried out in the spectrometer frame. The relationships between the two frames are straightforward when using classical θ–2θ scans, but for any other measurements, such as rocking curves or the use of area detectors, for instance, prior localization corrections have to be made to locate the plane normals in the sample frame.

The previous models do not allow the description of texture either in terms of orientations or of distribution densities (expressed in m.r.d. units), based on the absence of OD calculations implying normalization. Also, many Rietveld-based programs offer preferred-orientation modelling capabilities, but do not always include OD refinement, *i.e.* not reaching the QTA stage (Table 5.3.1).

In particular, working on whole patterns became mandatory with the growing demand for the characterization of nanocrystalline samples. In such samples, the tremendous inter-phase and intra-phase overlaps prevent any correct QTA characterization if proper deconvolutions are not carried out. A Rietveld-like approach becomes mandatory, with the advantage of then being able to access other material characteristics such as residual stresses, phase amounts and line broadening. This is the subject of combined analysis.

5.3.5. Combined analysis: structure, texture, microstructure, stress, phase, layering and reflectivity analyses in a single approach

5.3.5.1. *Problems*

Analysis by the diffraction/scattering of X-rays is presently facing a major problem: the nondestructive characterization of samples with increasing complexity (thin or massive heterostructures, polyphase materials, hybrids *etc.*), including as many as possible of their characteristics (structure, texture, crystallite sizes). These real samples often exhibit optimized properties because of their anisotropy, and this creates some problems in data analysis.

Problem 1. Anisotropic samples exhibit diffraction diagrams depending on the sample orientation because of the presence of texture. Refinement of crystal structures requires a model for the texture, as shown in Section 5.3.4. Texture factors depend on sample orientation, whereas structure factors do not. Also, texture factors integrate to unity over the entire pole figure. This indicates that with a proper approach to the problem (exploiting the full texture analysis), texture and structure are completely uncorrelated and can easily be decoupled. Full (and sharp) texture can actually be used as an advantage in structure solution (Wessels *et al.*, 1999).

Problem 2. Anisotropy is induced during production (*e.g.* heteroepitaxy, uniaxial pressing *etc.*), along with residual stresses in the sample. The diffraction peaks are then shifted relative to their unstressed positions, which biases on the one hand structural determination (unit-cell parameters) and on the other hand QTA, since the peak positions vary with the necessary rotations of the sample for texture measurements. It is then necessary to analyse the residual stresses in order to determine both the structure and texture correctly. However, differently oriented crystallites do not deform identically under the same macroscopic stress thanks to their tensorial elastic properties (anisotropic if texture is present), and a mutual influence exists between texture and residual stresses. Thus, there is a need to analyse both texture and stress simultaneously to obtain more accurate values of each.

Problem 3. Samples can be composed of several layers of different phases, which then have to be characterized individually in terms of structure/texture/stress. Volume and absorption variations are not the same for a covered layer, a top film or a substrate, and have an effect on intensities measured at different 2θ and $\mathbf{y}$ positions. These variations, if unaccounted for, bias structural, quantitative and textural analyses. The corrections to be applied depend on the effective thicknesses of the layers and their absorption coefficients, and thus depend on the phase composition.

Problem 4. In polyphase materials (completely or partially crystalline), quantitative phase analysis (QPA) can be biased if texture is present, and a suitable model is necessary in the analysis. Simple models such as the March–Dollase model should be avoided. The texture should be fully accounted for or removed by suitable sample preparation.

Problem 5. All of these results (structure, QTA, QPA, residual stress analysis and layering) depend on the microstructural states, crystallite sizes and shapes (isotropic or anisotropic), crystalline defects (point, linear, planar or volumetric), composition variations and microstrains, which in turn will be correctly determined only if the other parameters are satisfactorily known. Let us take the example that crystallite size effects are revealed in the line broadening and are then decoupled from (for instance) texture, which induces only intensity variations. This working hypothesis is, however, only valid if no peak overlap occurs. Indeed, if overlap is present the separation of each individual line broadening will depend on the convoluted intensities, which in turn depend on the texture (and/or other intensity effects). In a multi-component line, it will become dangerous to separate the components without somehow constraining the intensities, which can be performed using both $F_{\mathbf{h}}$ and $f(g)$ information. Conversely, the correct estimation of each intensity for subsequent QTA requires the separation step, implying some knowledge of the broadening.

Problem 6. All of the previous determinations rely on an *a priori* knowledge of the exact material composition to be characterized. Unfortunately, compositions may vary from sample to sample, giving rise to incorrect assignments of parameters during refinement. For instance, we may have the same atoms distributed over multiple phases in an unknown way, or multiple atoms occupying the same crystallographic site in one or more phases. In such a case one needs to constrain the problem, using for instance elemental compositions from energy-dispersive X-ray spectroscopy (EDX) or X-ray fluorescence (XRF). Also, for a quantitative XRF or EDX analysis a precise knowledge of the phase concentrations is fundamental to estimate the matrix effect or absorption. Chemical analysis by EDX or XRF may benefit from a quantitative analysis by diffraction, as well as the reverse. Thus, there is a need for a combined analysis, either based on independent *in situ* or *ex situ* measurements of the same samples.

The question arises after this list of problems as to whether one could benefit from the anisotropy of the material, and/or from the multiple independent measurements necessary to carry out a complete characterization of the real material. Such an approach needs to take account of all the effects visible in the diffracted signal, to measure a sufficient number of independent data with different techniques when necessary, and perform a single fitting of the full data by either least-squares or other suitable methods.

5.3.5.2. *Intensity of a pattern and general scheme*

If we consider a sample composed of N_L layers (a bulk sample is then equivalent to a single layer of infinite thickness) and N_Φ phases distributed in the layers, the intensity of a single data point $\mathbf{y}_c$ at 2θ and η (see Section 5.3.2.1.3.3 for angle definitions) in a diffractogram measured at a given sample orientation $\mathbf{y}_S$ ($\mathbf{y}_S$ represents the sample orientation in the spectrometer space S, *i.e.* defined by the goniometer angles ω, χ and φ) can be calculated as the sum of all reflections contributing to that point for all phases in all layers,

$$\begin{aligned} y_c(\mathbf{y}_S,\theta,\eta) &= y_b(\mathbf{y}_S,\theta,\eta) \\ &\quad + I_0\sum_{i=1}^{N_L}\sum_{\Phi=1}^{N_\Phi}\frac{\nu_{i\Phi}}{V_{c\Phi}^2}\sum_{\mathbf{h}}\mathrm{Lp}(\theta)j_{\Phi\mathbf{h}}|F_{\Phi\mathbf{h}}|^2\Omega_{\Phi\mathbf{h}}(\mathbf{y}_S,\theta,\eta) \\ &\quad \times P_{\Phi\mathbf{h}}(\mathbf{y}_S,\theta,\eta)A_{i\Phi}(\mathbf{y}_S,\theta,\eta), \end{aligned} \qquad (5.3.63)$$

in which y_b is the background contribution, I_0 is the incident intensity on the sample, $\nu_{i\Phi}$ is the volumetric fraction of phase Φ in layer i, $V_{c\Phi}$ is the unit-cell volume of phase Φ, Lp is the Lorentz polarization factor, $j_{\Phi\mathbf{h}}$ is the multiplicity of line $\mathbf{h}$ for phase Φ, $|F_{\Phi\mathbf{h}}|$ is the modulus of the structure factor (including thermal vibrations) for line $\mathbf{h}$ of phase Φ, $\Omega_{i\Phi\mathbf{h}}$ is the profile function of line $\mathbf{h}$ for phase Φ, taking account of instrumental and sample broadenings, $P_{\Phi\mathbf{h}}$ is the preferred orientation (pole-figure value) of phase Φ and $A_{i\Phi}$ is an absorption factor which takes into account the experimental and sample geometries.

In a similar way, we can write the intensity of a measured point in a pattern for reflectivity and XRF or EDX. We will explicitly write the equations for the diffraction part, but the procedure can be extended to every technique for which a measured intensity can be written in terms of the parameters describing the sample. The overall weighted sum of squares, as in Rietveld joint refinements, can then be written as a weighted sum between different techniques, each measuring a certain number of patterns and with each pattern t composed of N_t measured points:

$$\mathrm{WSS} = \sum_{t=1}^{N_p} u_t \sum_{i=0}^{N_t} w_{it}(y_{itc} - y_{ito})^2. \qquad (5.3.64)$$

The weight w_{it} is usually related to the inverse of the measured intensity for point i of pattern t and is equal to the inverse of the square of the standard deviation. Each pattern t is weighted using the quantity u_t, which should be used to adjust the importance that we want to give to a particular technique or pattern with respect to the others.

The quantity WSS must be minimized to find the optimized parameters. The minimization can be performed through standard nonlinear least-squares methods or other minimization schemes depending on the particular models that are used and the efficiency of the algorithm for a given problem.

5.3.5.3. *Minimum experimental requirements*

This methodology requires a large amount of data, however, and to be practical requires rapid acquisition using, for example, multiple detectors. The first experiment using such an approach was carried out with X-rays on a thin film (Ferrari & Lutterotti, 1994) on a laboratory texture instrument using a scintillator detector. The first experiment of this kind using neutron TOF data (Lutterotti *et al.*, 1997) was performed on the General Purpose Powder Diffractometer (GPPD) at the Intense Pulsed Neutron Source (IPNS). Since then, the methodology has been used for various purposes (Chateigner *et al.*, 1998; Lutterotti *et al.*, 2002, 2004; Morales *et al.*, 2002, 2005; Ricote *et al.*, 2004; Guilmeau *et al.*, 2005).

The required diffractometer has to be equipped with four circles in order to correspond to a texture experiment, *i.e.* at least one tilt rotation χ, one azimuthal rotation φ, an incidence circle ω and a detection circle 2θ. One circle (one scanning movement) can be eliminated by using a linear detector on the 2θ arm. Another circle and scan can be saved by using bidimensional detectors.

5.3.5.4. *Theoretical implementation*

5.3.5.4.1. *Instrumental broadening calibration*

The spectrometer space is multidimensional, with each rotation axis possibly giving rise to defocusing or misalignment effects. Each of these aberrations has to be measured and corrected for. For instance, in dealing with goniometer misalignments (which should be minimized as much as possible by careful alignment of the instrument and the sample) one can model them to a certain extent in the computation by reproducing all effects of sample displacements, precession errors and angle offsets. The fitting of instrument- and sample-misalignment errors should only be used as a last resort, and a well performed experiment is obviously always preferred. Fig. 5.3.19 is an illustration of such aberrations measured on a KCl standard powder using a four-circle diffractometer and a curved position-sensitive detector (CPS 120 from Inel).

Three major effects are visible: peak broadening, peak shift and background variation.

Broadening occurs when the incident beam illuminates the sample surface, producing variations in the irradiated area and the apparent Bragg-angle values. These were originally called

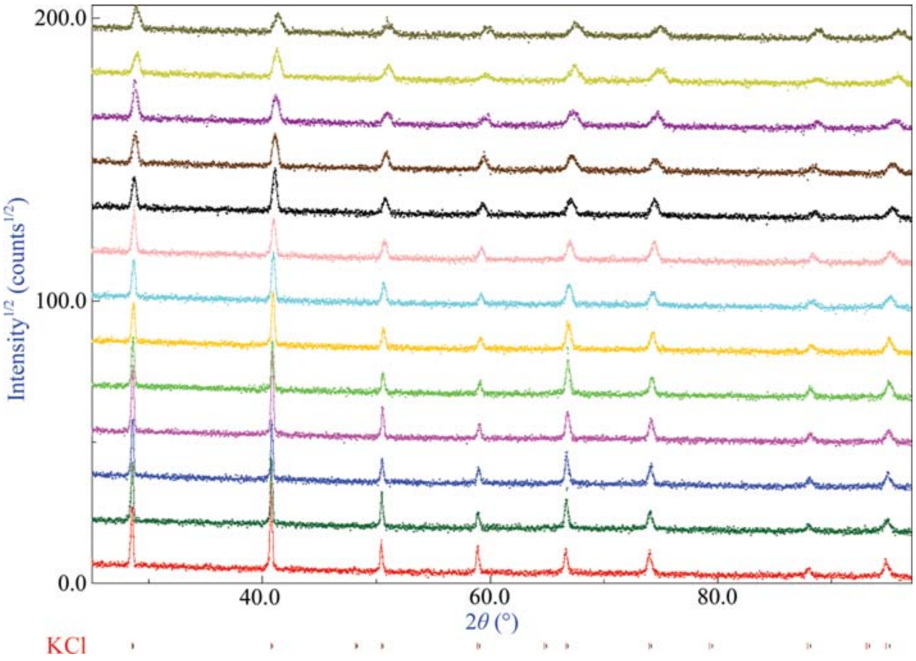

Figure 5.3.19
Illustration of the effects of defocusing and misadjustment on peak shapes and diffractometer resolution function. Measurements are on KCl powder. Diffractograms appear on top of each other from $\chi = 0°$ to $\chi = 60°$ in steps of 5° and were measured for $\omega = 20°$.

‘defocusing effects’, even if the experimental setup does not properly incorporate focusing optics (as in this case with the use of a parallel beam). They are dependent on the various angles of sample rotation.

When the sample tilt χ increases, the peaks broaden. For a square incident-beam cross section, the irradiated area on the flat sample is a rectangle at $\chi = 0°$ and becomes a parallelogram at $\chi > 0°$. The beam-footprint size then increases, giving rise to apparent θs and broadened peaks. For a bulk sample in symmetric reflection geometry the total integrated intensity remains constant whatever the value of χ (Schulz, 1949*a*). This implies that when using the full profile the defocusing effect is automatically taken into account since the total integrated area of the pattern is unchanged. However, at values of χ that are too large (typically >60°) the peak maxima decrease to values that are closer to the background, and even the integrated intensities are less reliable because of poorer counting statistics. This obviously depends on the instrumental setup, such as the detecting slit aperture, and can be partly compensated for by using larger counting times at larger χ values, but this always remains a compromise. For instance, increasing the detecting slit can provide a lower defocusing effect because of a larger integrating window, but as a result enhances the instrumental broadening and peak overlaps, and can prevent any microstructural analysis.

For a given diagram measured at ω, the peaks are broader at larger 2θ (Fig. 5.3.20). This effect is typical of flat specimen analyses; it does not occur, for instance, in transmission geometry using neutrons. For a given peak at 2θ, the full width at half maximum (FWHM) is smaller at larger ω angles owing to the smaller irradiated area of the sample. This effect also is typical of flat specimen analyses in reflection geometry and using a parallel beam.

In order to analyse the line broadening due to the characteristics of the sample, all of the various instrumental broadenings either have to be known from measuring the instrumental profiles using a standard sample with a known sample broadening or must be computed. The latter still requires the measurement of certain characteristics such as the tube focus.

A polynomial-like equation can then be used to represent the variations in the squared FWHM of the lines with the angles in a similar fashion to the Caglioti formula (Caglioti *et al.*, 1958),

$$\Delta_r \mathrm{FWHM}^2 = \sum_{u=0}^{U} p_{ru} r^u, \tag{5.3.65}$$

with r as a general rotation (χ, θ, $\tan\theta$, ω, $\eta, \ldots$) and with as many p_{ru} parameters as necessary, introducing them progressively in the refinement until they refine to negligible values.

5.3.5.4.2. *Peak-displacement errors*

Peak shifts arise from the misalignment of one or several of the rotation axes or sample displacement from the rotation centre. For instance, in Fig. 5.3.20 we clearly observe a 2θ peak shift for large χ values and this shift would not be the same at two different ω values. Depending on the experimental configuration, analytical formulae can be produced to fit these misalignments. If information about unit-cell parameters and/or residual strain are important, it is advisable to either have a perfectly aligned system or to use analytical formulae based on the geometrical features of the misalignment. Other empirical corrections are possible, based on polynomial fits or parametrizations per pattern, that are efficient for the correction of the peak position, but are more likely to cause a loss of positional information. These corrections are instrument dependent.

5.3.5.4.3. *Background fitting*

Furthermore, depending on many factors such as sample shape and absorption, the background B can also vary with the various angles of rotation. These variations have to be modelled, which is usually accomplished through a polynomial fit on all rotation axes,

$$\Delta_r B = \sum_{u=0}^{U} p'_{ru} r^u \tag{5.3.66}$$

or more complex functions such as Chebyshev polynomials (Larson & Von Dreele, 2000; Press *et al.*, 1988),

$$\Delta_r B = \sum_{u=0}^{U} p''_{ru} T_u(r^*), \qquad r^* = \frac{2(r - r_{\min})}{r_{\max} - r_{\min}} - 1, \tag{5.3.67}$$

where p'_{ru} and p''_{ru} are the factors to be determined. For Chebyshev polynomials the value of r must be substituted with r^* to be orthonormal, and $r_{\min}$ and $r_{\max}$ define the range of r.

Another option is to use an interpolated background which, instead of being applied to the original pattern (not advisable in Rietveld-like fitting), is applied to the residual pattern (the experimental data minus the computed profile) as in *MAUD* (Lutterotti, 2010). In this manner, the interpolation will not take intensity from the reflections as long as these are properly fitted.

In QTA with point detectors background subtraction is never easy; the evolution of background with rotation axes is not easily measured (because of defocusing from nearby peaks, for

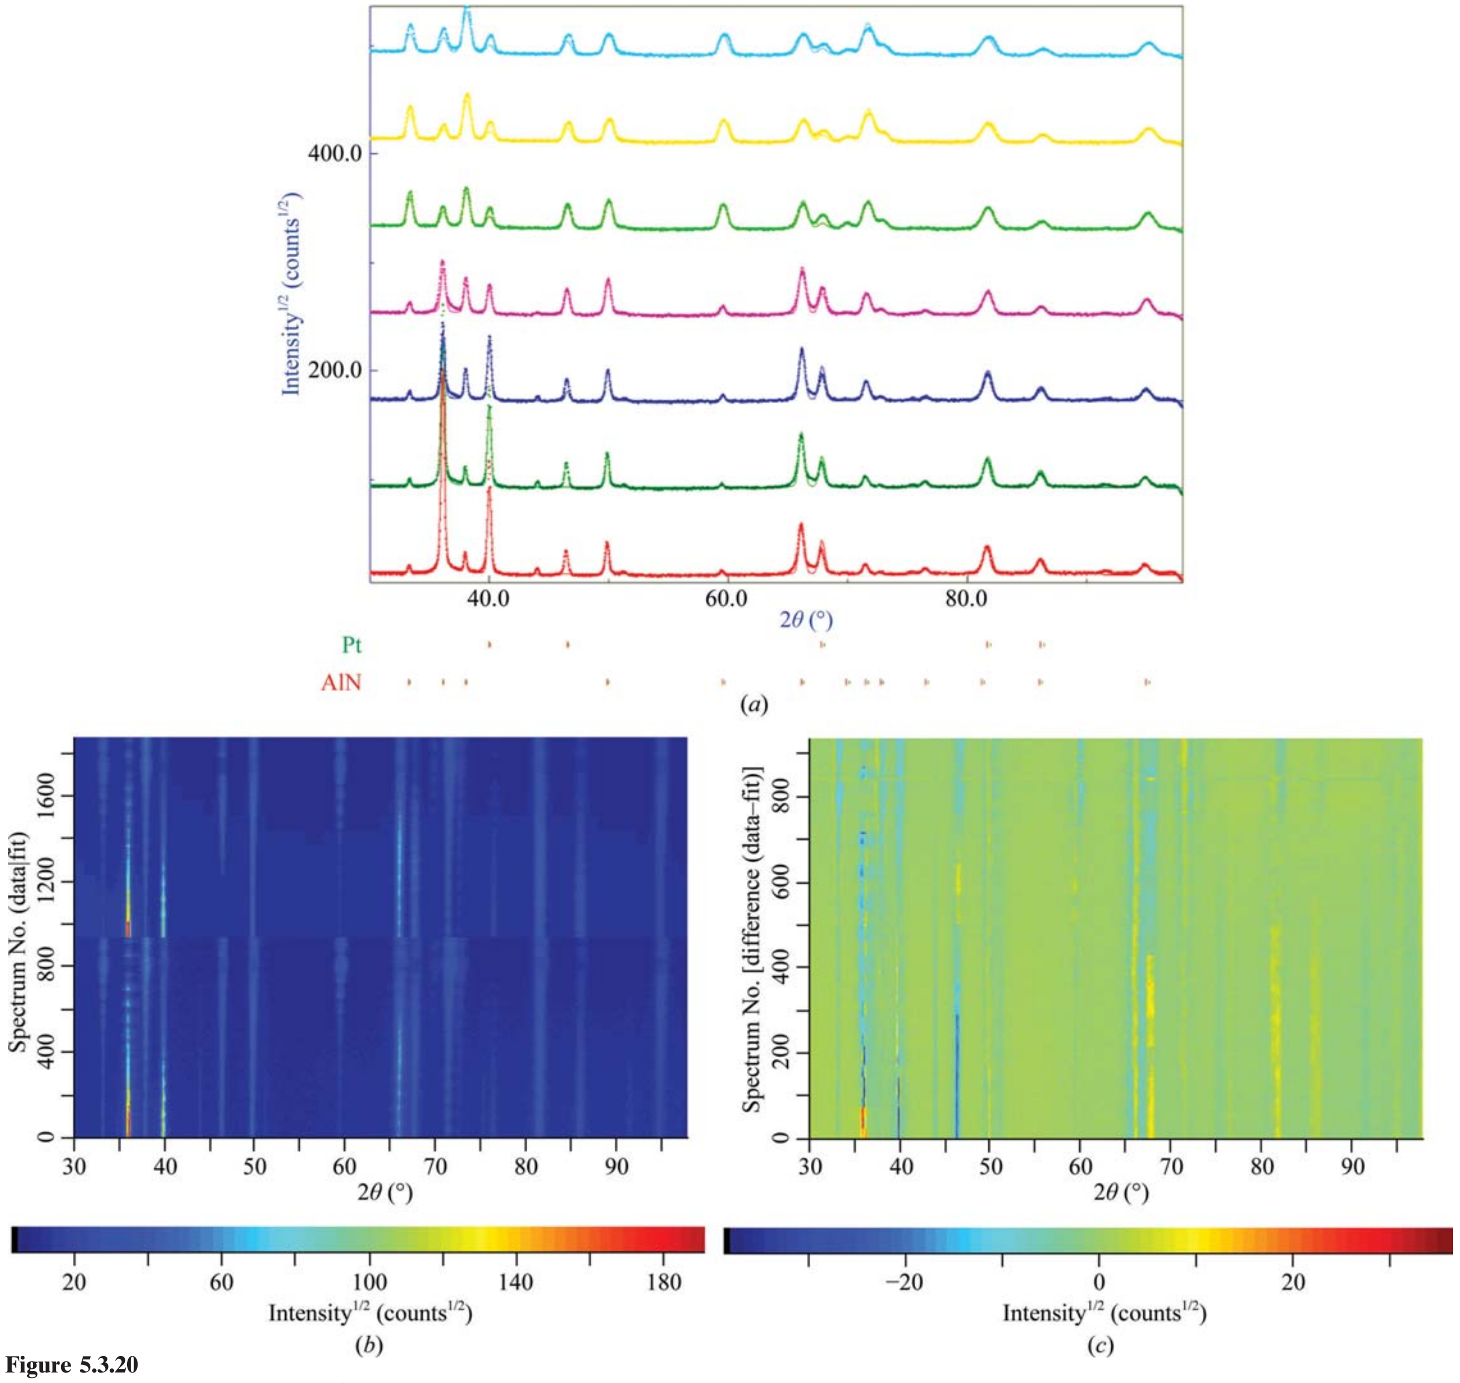

Figure 5.3.20

(*a*) Randomly selected diagrams (at increasing χ values and broadening due to defocusing from bottom to top) illustrating the quality of the fit, together with the textures of AlN and Pt. (*b*) Two-dimensional plots of the 936 experimental (lower half) and fitted (upper half) diagrams and (*c*) two-dimensional difference diagrams to reveal the errors.

instance) and is sample dependent. Here, one can see another advantage of full-profile analysis, where the background is not removed *a priori* but is modelled along with the reflection intensities.

5.3.5.4.4. *Reflection intensities*

Reflection intensities, as appearing in (5.3.63), depend mainly on the structure factors described elsewhere in this volume. Three different approaches are used to calculate them in the combined-analysis scheme.

The first approach calculates the structure factors from the atomic model with knowledge of the types and positions of the atoms in the unit cell. If an accurate crystal structure is not available for a particular phase, some information loss occurs (mainly phase concentrations and layer information), but we can still understand several other characteristics if at least an indexing of the phase is available. For most of the other properties (texture, stresses, anisotropic crystallite sizes and microstrains *etc.*) only the Laue group and an initial estimation of the unit-cell parameters are required. In this case, we can use the other two approaches.

The second approach starts from knowledge of the Laue group (or, better, the space group if available) and uses Le Bail or Pawley refinement for the intensities. In the case of Pawley refinement all of the reflection intensities become parameters to be refined (this is exactly equivalent to a whole-pattern fitting), and the exactly overlapped parameters should be treated as summed to achieve convergence. Normally this approach is rapid when the phase has a small number of reflections, but it becomes very difficult to carry out a fit when this number is very large. In this latter case the Le Bail approach is more efficient, and one can always switch to Pawley refinement just for the last iterations when the fitting is already satisfactory. These two methods are discussed in Chapter 3.5.

The third approach is a variant of the second, using an electron-density map (or a nuclear-density map for neutron diffraction) obtained from the extracted structure factors (using either one of the two methods mentioned above) at each iteration to calculate the intensities to be used in the fitting. This will force the structural intensities to be compatible with an electron-density map, providing a strong constraint for the severely overlapped peaks. It is assumed that by iteration the problem will converge toward the real electron-density map, but this cannot be ensured.

When associated with a strong texture of the sample, the second and third approaches can be used to obtain single-crystal-like structure factors that can be used to obtain the structure, as described by Wessels *et al.* (1999) and in a more recent variant in which texture and structure factors are extracted simultaneously from the same data (Lutterotti & Bortolotti, 2005; Grässlin *et al.*, 2015).

5.3.5.4.5. *Line profiles and sample broadening*

Profile functions are described as a convolution of two terms: the instrumental broadening and the sample broadening. In the combined approach we utilize the two explicitly separated contributions to perform refinement directly using the microstructural characteristics as parameters (Lutterotti & Scardi, 1990; Lutterotti & Gialanella, 1998; Lutterotti, 2010). If the instrumental broadening is known (see Section 5.3.5.4.1) we only need to refine the parameters concerning the sample broadening, and the best approach to ensure better convergence and more reliable results is to describe the sample broadening using physical quantities.

With respect to line-broadening theories, we note here that for this method we need equations and methods that allow computation of the sample-broadening profile from the microstructural characteristics and not the reverse.

These methods can be divided into two categories. The first category contains methods that describe the sample broadening using analytical functions, for which theory describes the variation of the parameters as a function of the scattering unit caused by the microstructural characteristics (Lutterotti & Scardi, 1990; Lutterotti & Gialanella, 1998). The second category does not impose analytical functions on the profile, but instead computes the profile directly from the crystallite size and microstrain distributions using the interference function (Lutterotti & Scardi, 1992), the Fourier transform (Ungár *et al.*, 2001; Lutterotti, 2010) or analytical approximations (Popa & Balzar, 2002). In the latter case it is the analytical shape of the distribution that is imposed. The crystallite and microstrain anisotropies, which cause anisotropy of the reflection broadenings, have been described previously by empirical formulae (Lutterotti & Scardi, 1990) or by taking into account the crystallographic symmetry restrictions (Popa, 1998), and can be coupled with the distribution-calculation method (Popa & Balzar, 2008).

In addition to crystallite sizes and microstrains, other microstructural characteristics have been included in the combined analysis as planar defects following Warren theory (Warren, 1969; Lutterotti & Gialanella, 1998) or turbostratic disorders (Ufer *et al.*, 2004; Lutterotti *et al.*, 2010); these are useful in the case of clay or graphitic materials.

5.3.5.4.6. *Texture computation*

The texture factors in (5.3.63) can be computed using one of the methods reported in Section 5.3.4 for Rietveld analysis, but only those associated with an OD computation, *i.e.* all but the empirical methods such as the March–Dollase and Donnet–Jouanneaux methods.

To ensure a physically meaningful texture analysis, two kinds of approach can be used in the combined analysis. The first is applicable when the pole figures can be computed through analytical functions containing the parameters to be refined. This is the case for the harmonic, exponential-harmonic and standard-components methods in Section 5.3.4. The implementation and the use of such methodologies is quite straightforward in the Rietveld framework.

A different case is the second approach (WIMV/EWIMV), in which there is no analytical function either to describe the OD or to compute the pole-figure values. This is performed through numerical integration using a discrete function with a very large number of unknowns. Therefore, by analogy to the electron-density case with structure factors, the method is to extract the texture values from patterns and use them to compute the OD, from which we can compute the texture value for the next Rietveld-like iteration step.

The extraction of the texture value (the difference between the random value and the measured value) can be performed using a modified Le Bail algorithm (Matthies *et al.*, 1997) working on the texture values instead of the structure factors. The resulting ‘experimental’ pole-figure values are used by the WIMV or EWIMV algorithms to compute the OD. After this, a final fitting of the patterns is performed using the quantities calculated from the OD as the texture values. In the case of WIMV an additional step is required before computing the OD, as WIMV requires the pole-figure data in a regular grid over the pole figures, and a cubic interpolation is used for this. On the other hand, EWIMV does not require such regular grids.

Much care is mandatory in using all of these methods in order to ensure that the measured data are sufficient to experimentally cover the entire OD. This can easily be checked using discrete methods such as WIMV/EWIMV, but not with others that may apparently work (output an OD) without having full coverage and thus with values for the uncovered part that depend on the assumptions made (for example, intrinsically when assuming an inappropriate specific texture symmetry as in the March–Dollase method or extrinsically when the unmeasured parts would have contained most of the texture information).

5.3.5.4.7. *Residual strains/stresses and evaluation of macroscopic tensors*

In the presence of residual stresses, diagrams measured at several tilt angles exhibit peak shifts that cannot be reproduced without correct modelling of the sample residual strains. These come from the macrostresses and microstresses in the sample and also depend on the crystallite orientations (ODs). There are two different methods to approach this problem in combined analysis. One makes use of elasticity theories and models the strains and thus the reflection shifts from the stresses; the other instead directly models the strains without any assumption about the relationship between strains and stresses.

In the first approach, defining $K_L = (X_L, Y_L, Z_L)$, a laboratory frame in which Z_L is coincident with the scattering vector, X_L lies in the plane defined by the incident and diffracted beams and is directed towards the detector, and $Y_L = (Z_L \times X_L)$, the deformation of the diffracting plane (direction 33 for the deformation tensor in K_L) is then

$$\begin{aligned}\overline{\varepsilon}_{33}^{L}(\overline{\sigma}; \mathbf{h}, \mathbf{y}) &= \frac{1}{4\pi\tilde{P}_{\mathbf{h}}(\mathbf{y})}\left[\int\limits_{\mathbf{h}\|\mathbf{y}} \varepsilon_{33}^{L}(\sigma; g) f(g)\,\mathrm{d}\tilde{\varphi} + \int\limits_{-\mathbf{h}\|\mathbf{y}} \varepsilon_{33}^{L}(\sigma; g) f(g)\,\mathrm{d}\tilde{\varphi}\right]\\ &\equiv S_{33kl}^{L}(\mathbf{h}, \mathbf{y})\overline{\sigma}_{kl}^{L}. \qquad (5.3.68)\end{aligned}$$

The crystallographic strain $\varepsilon_{33}^{L}(\sigma; g)$ depends on the macrostresses through the stress factor $S_{33kl}^{L}(\mathbf{h}, \mathbf{y})$ (Behnken & Hauk, 1991), and several schemes have been proposed to calculate it in the presence of texture using different averages over orientations as a theoretical basis. The most used are the Voigt (1928), Reuss (1929) and Hill (1952) models. In the Voigt case the stress factor does not depend on **h** and it imposes a linear behaviour in $\sin^2\psi$, whereas in the Reuss case it does not. The Voigt and Reuss models define upper and lower bounds, respectively, for the macrostresses, the macroscopic elastic constants (those of the real sample) and their average, but do not ensure the consistency of elastic properties (simultaneous stress and strain equilibria). Such consistency for elastic properties requires that the homogenized sample stiffness, $\langle C\rangle$, should be equal to the inverse of the homogenized compliance, $\langle S\rangle^{-1}$. Neither of the methods mentioned above meet this criterion. On the contrary, the geometric-mean approach guarantees such consistency.

Considering an ensemble of N grains, with each grain m having a volume fraction ν_m and with S_m being the single-crystal compliance tensor of the grain rotated in the sample reference frame, the arithmetic mean is then

$$\langle S\rangle_a^{-1} = \left[\sum_{m=1}^{N} \nu_m S_m\right]^{-1} \neq \sum_{m=1}^{N} \nu_m S_m^{-1} = \langle S^{-1}\rangle_a = \langle C\rangle_{\rm geo}, \qquad (5.3.69)$$

where the left-hand and right-hand sides correspond to the arithmetic averaging in the Reuss and Voigt hypotheses, respectively. Instead, for the geometric mean (Matthies & Humbert, 1993) the inversion property is guaranteed,

$$\begin{aligned}\langle S\rangle_{\rm geo}^{-1} &= \exp\left[-\sum_{m=1}^{N} \nu_m \ln S_m\right] = \exp\left[\sum_{m=1}^{N} \nu_m \ln S_m^{-1}\right]\\ &= \langle S^{-1}\rangle_{\rm geo} = \langle C\rangle_{\rm geo}\\ &\text{or}\\ \langle S\rangle_{\rm geo}^{-1} &= \left[\prod_{m=1}^{N} S_m^{\nu_m}\right]^{-1} = \prod_{m=1}^{N} S_m^{-\nu_m} = \prod_{m=1}^{N} (S_m^{-1})^{\nu_m}\\ &= \langle S^{-1}\rangle_{\rm geo} = \langle C\rangle_{\rm geo}. \qquad (5.3.70)\end{aligned}$$

Replacing the subscript m with the rotation g to bring the crystal tensor into the sample frame, using the explicit notation with four indices for the rank-4 compliance tensor and replacing the summation with the integral over H space, we obtain

$$\begin{aligned}&\langle S_{ijkl}\rangle_a = \int\limits_{H} S_{ijkl}^{0}(g) f(g)\,\mathrm{d}g, \quad S_{ijkl}^{0}(g) = \sum_{m,n,p,q=1}^{3} g_{mi}g_{nj}g_{pk}g_{ql}S_{mnpq},\\ &\langle S_{ijkl}\rangle_{\rm geo} = \langle(\ln S)_{ijkl}\rangle_a. \qquad (5.3.71)\end{aligned}$$

This modelling gives good estimates of the macroscopic elastic properties (Matthies & Humbert, 1995) and does not result in large calculation times, *i.e.* it is suitable for implementation in the routine combined algorithm to calculate the strain tensor inside the crystallite from the macrostresses of the sample.

Using (5.3.68), we make the hypothesis that the strains are constant inside the sample (the Voigt hypothesis), the macro elastic tensor is computed using the arithmetic mean of the stiffness and everything reduces to the analogous $\sin^2\psi$ method. If we consider the stresses in the sample to be constant, the elastic tensor is computed through the Reuss hypothesis or the average of the compliance tensor.

We examine here the interesting case of the geometric mean, where neither the stresses nor the strains are constant throughout the sample but vary as a function of grain orientation. This is the inverse problem with respect to the homogenization technique [equations (5.3.70) and (5.3.71)]. This case has been solved by Matthies and co-workers (Matthies *et al.*, 2001; Matthies & Vinel, 1994) in a two-step process. Let us first obtain the solution by using the geometric mean (GEO) method to directly compute the so-called pathGEO approximation. Writing the stress factor using the Reuss hypothesis,

$$\begin{aligned}S_{33kl}^{L}(\mathbf{h}, \mathbf{y}) &= {}^{\rm Reuss}S_{33kl}^{L,p}\\ &= \frac{1}{4\pi\tilde{P}_{\mathbf{h}}(\mathbf{y})}\left[\int\limits_{\mathbf{h}\|\mathbf{y}} S_{33kl}^{0}(g) f(g)\,\mathrm{d}\tilde{\varphi} + \int\limits_{-\mathbf{h}\|\mathbf{y}} S_{33kl}^{0}(g) f(g)\,\mathrm{d}\tilde{\varphi}\right]; \qquad (5.3.72)\end{aligned}$$

in analogy, the pathGEO approximation gives

$$\begin{aligned}S_{33kl}^{L}(\mathbf{h}, \mathbf{y}) &= {}^{\rm pathGEO}S_{33kl}^{L,p}\\ &= \exp\left\{\frac{1}{4\pi\tilde{P}_{\mathbf{h}}(\mathbf{y})}\left[\int\limits_{\mathbf{h}\|\mathbf{y}} S_{33kl}^{0}(g) f(g)\,\mathrm{d}\tilde{\varphi} + \int\limits_{-\mathbf{h}\|\mathbf{y}} S_{33kl}^{0}(g) f(g)\,\mathrm{d}\tilde{\varphi}\right]\right\}. \qquad (5.3.73)\end{aligned}$$

In the latter equation, we neglect the interaction of the matrix surrounding the crystallites. Adding it to the formulation, we obtain the final Bulk-PathGEO (BPG) formulation (Matthies & Humbert, 1995; Matthies *et al.*, 2001),

$$S^{L,\rm BPG} = \left[\left(\langle S\rangle_{\rm geo}^{L}\,{}^{\rm pathGEO}S^{L}\right)^{1/2}\right]^{\rm sym}, \qquad (5.3.74)$$

and we are interested in the $S_{33kl}^{L,\rm BPG}$ components of (5.3.68).

Another approach has been developed which does not consider the nature of the residual stresses and may be more appropriate in the case of plastic deformation or when pure elastic strains/stresses are not present. The method aims to use the Rietveld method to extract the crystallographic stresses in order to obtain the so-called stress orientation distribution function (SODF). Details can be found in Wang *et al.* (2000, 2003).

In combined analysis, a variant of this method is used that is more suitable for implementation in a Rietveld code. This variant (Popa & Balzar, 2001) considers that texture and stresses are always coupled by (5.3.68), and instead of using the SODF it defines a so-called WSODF (weighted-strain ODF) that is the product of the crystallographic OD and the SODF. This simplifies the formalism greatly and avoids the propagation of the errors present in the OD to the SODF (which is one of the problems of the original method). The WSODF (and similarly the SODF) is then expanded using spherical harmonics, and the right-hand side of (5.3.68) can be written in terms of harmonic coefficients to be refined. We refer the reader to the original paper for details of the symmetrization and implementation.

Table 5.3.2
Results obtained from combined analysis on an AlN/Pt/TiO_x/Al_2O_3/Ni(Co–Cr–Al–Y) stack

Standard deviations are given in parentheses for the last digit.

	AlN	Pt	Al_2O_3	Ni(Co–Cr–Al–Y)
Unit-cell parameters (Å)	a = 3.11203 (1), c = 4.98252 (1)	a = 3.91198 (1)	a = 4.7562 (6), c = 12.875 (3)	a = 3.569377 (5)
Effective layer (nm)	14270 (3)	1204 (3)	7790 (31)	∞
Isotropic mean crystallite size (Å)	2404 (8)	2173 (10)	150 (2)	7600 (1900)
Isotropic mean microstrain (r.m.s.)	0.001853 (2)	0.002410 (3)	0.008 (3)	0.00236 (3)
Biaxial macrostresses (MPa)	$\sigma_{11} = -1019$ (2), $\sigma_{22} = -845$ (2)	$\sigma_{11} = -196.5$ (8), $\sigma_{22} = -99.6$ (6)	Not fitted	$\sigma_{11} = -328$ (8), $\sigma_{22} = -411$ (9)
F^2 (m.r.d.^{2})	9.30	5.36	—	1.04
OD R factors (%)	R_w = 4.09, R_b = 4.41	R_w = 33.25, R_b = 26.63	—	R_w = 49.15, R_b = 37.38

5.3.5.4.8. *Absorption and layers*

Computation of the absorption is another important part of the approach, especially considering some samples that do not meet the requirements of standard computation (Bragg–Brentano: specimen completely intercepts the beam, homogeneity inside the volume, infinite thickness; Debye–Scherrer: cylindrical or spherical shape, sample inside the beam, light absorber). In the simple case of a thin film or multilayers we already have a heterogeneous sample and special treatment of the absorption correction is needed. Another case is an irregular shape or a strong absorber in Debye–Scherrer geometry.

For multilayers, a first implementation to correctly approach the problem in a Bragg–Brentano geometry (Lutterotti *et al.*, 1993) is aimed at phase analysis in the layers. For a more comprehensive absorption correction for a multilayer sample that includes all possible geometries and cases, Simek *et al.* (2006) developed a correction that depends only on the incident angle θ_i of the beam (with respect to the plane parallel to the layering and surface of the sample) and the exit angle θ_o,

$$A_{i\Phi} = \frac{\nu_{i\Phi}\sin\theta_i\sin\theta_o}{\overline{\mu}_i(\sin\theta_i+\sin\theta_o)}[1-\exp(-\overline{\mu}_i\tau_i W)]\prod_{k<i}\exp(-\overline{\mu}_k\tau_k W),$$

$$W = \frac{1}{\sin\theta_i}+\frac{1}{\sin\theta_o}, \qquad (5.3.75)$$

where $\overline{\mu}_i = \sum_{\Phi=1}^{N_\Phi}\nu_{i\Phi}\mu_{i\Phi}$ is the average linear absorption coefficient for layer i, $\mu_{i\Phi}$ is the absorption coefficient of phase Φ in layer i and τ_i is the thickness of layer i.

In the Debye–Scherrer geometry with either a strong absorber or an irregular sample shape, special care should be taken with the absorption computation. A general procedure has been developed (Xie *et al.*, 2004; Volz *et al.*, 2006) that represents the sample shape using the same harmonic expansion formulae as for the anisotropic crystallites (Popa, 1998) and uses a discretized integration of the beam path through the sample volume or a simplified path through the centre only (for computational speed; however, the shape refined is no longer representative of the sample).

5.3.5.5. *Implementation*

The combined-analysis software should allow the possibility of using X-ray (classical, synchrotron, monochromatic or energy dispersive, all scanning strategies and geometries, zero-dimensional, one-dimensional, flat and curved two-dimensional detectors) as well as neutron (thermal and TOF) or even electron data. It should be able to incorporate all formalisms corresponding to residual stress analysis (RSA), X-ray specular reflectivity, qualitative microstructure analysis, structure, QPA *etc.* and index diagrams for phase identification in an automatic approach [such as using the Crystallography Open Database (Grazulis *et al.*, 2009) or the Powder Diffraction File (Fawcett *et al.*, 2017)]. If the RSA of textured materials is of interest it should also offer tensor homogenization, openly accessing single-crystal tensors (Pepponi *et al.*, 2012). All of these requirement are actually met in the *MAUD* software (Lutterotti, 2010).

5.3.5.6. *Examination of a solution*

Using single-pattern refinement, a simple examination of the modelled and measured diagrams can suffice to detect refinement problems or refinement quality. When several hundreds of patterns are refined, such a comparison is cumbersome or simply impossible. One possibility to rapidly check whether the chosen

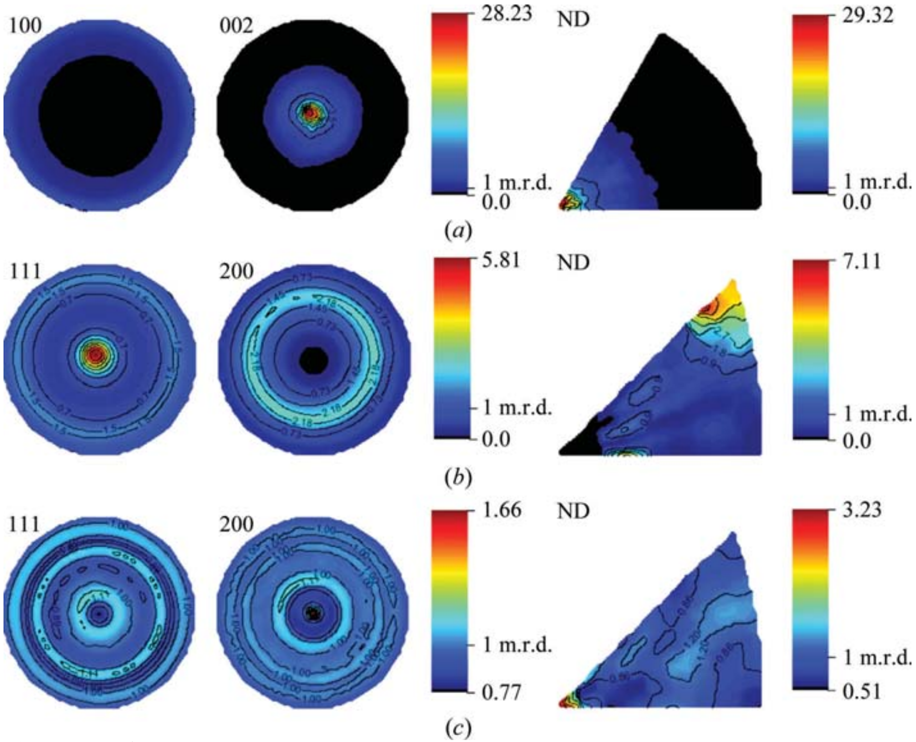

Figure 5.3.21
Low-index recalculated pole figures and Z_A inverse pole figures for the three textured phases of the stack. (*a*) AlN, (*b*) Pt, (*c*) Ni-based alloy. Equal-area density projections, linear density scale.

model is correct is to randomly select a small set of diffraction patterns to plot (Fig. 5.3.20*a*). However, such a method cannot prevent local strong discrepancies unless each diagram is examined in a laborious way. One can overcome this problem by plotting (for instance for an AlN/Pt/Al_2O_3/Ni alloy stack) all of the diagrams in a two-dimensional view (Fig. 5.3.20*b*), and completing the solution examination using two-dimensional residuals (Fig. 5.3.20*c*) in order to see where the main improvements to the model have to be carried out.

In such a case, combined analysis provides the characterization of the three ODs of Ni alloy, Pt and AlN, their respective biaxial residual stress states and structures. The layer thicknesses are also obtained with the crystallite isotropic sizes. The biaxial stress states are obtained using the geometric mean approach. All of the results are summarized in Table 5.3.2. These results were obtained within reliability factors of $R_{\rm w}$ = 24.12% and $R_{\rm exp}$ = 5.85% on 936 diagrams with a goodness of fit of 1.51.

The low-index pole figures of the three textured phases (Fig. 5.3.21) exhibit fibre textures with the fibre axis shifted slightly from the normal to the film plane Z_A. The substrate alloy shows the lowest texture strength; it is further increased in the Pt electrode and in the AlN film. This illustrates the electrical bias effect applied to the AlN orientation during sputtering, with a pronounced maximum of the {001} pole figure along Z_A of around 28 m.r.d. The Pt electrode exhibits a classical {111} orientation, with a slight tilt, while the Ni alloy is predominantly oriented with the {200} planes parallel to the sample plane. However, the corresponding inverse pole figures show that if AlN and Pt have a unique fibre orientation component, the Ni-alloy substrate also shows some minor fibre components.

The corresponding data for this example and many others can be found at http://www.ecole.ensicaen.fr/~chateign/formation/, together with some tutorials.

5.3.6. Conclusions

Classical quantitative texture analysis (and also residual stress, line broadening, phase composition *etc.*) becomes of questionable value for real samples that exhibit complex architectures with several phases and strong intra- and inter-phase peak overlapping. This is particularly true for poorly crystallized or nanocrystallized samples, for which line broadening is further enhanced. Proper deconvolution has to be carried out in such cases, which requires the use of full-pattern analysis in order to properly separate the various contributions to the diffraction diagrams (residual stresses, structure, phase content *etc.*). This can be elegantly achieved using the combined-analysis approach using X-rays, neutrons, electrons and *ad hoc* measurements.

5.4. Thin films and multilayers

M. Birkholz

5.4.1. Introduction

Thin films and multilayers represent an important class of materials for science and technology. Their first applications were in the fields of mirrors and decorative coatings, which subsequently extended to surface finishing as required for hard coatings and high-tech optics. Further applications were found with the advent of nanotechnology in the areas of microelectronics, photonics and sensors, which all had a large impact on the development of thin films and their deposition techniques (Ohring, 2002). Thin films typically exhibit thicknesses between about 1 and some 10^4 nm, while their lateral extensions may range from a few micrometres to hundreds of metres. Depending on the intended use, thin films are either made of metals, inorganic compounds or organic compounds, or from biological molecules. Since the characterization of their structural properties is a highly relevant issue in thin-film development, the two fields have concomitantly evolved with technological progress (Holy *et al.*, 1999; Tolan, 1999; Fewster, 2003; Birkholz, 2006; Guinebretière, 2007; Daillaut & Gibaud, 2009; Boscherini *et al.*, 2010; Chateigner, 2010).

X-ray scattering techniques for the investigation of thin films and multilayers have mostly been derived from $\theta/2\theta$ powder diffractometry. Generally, polycrystalline thin films might simply be considered as thin-slab powder samples, and various aspects of their X-ray patterns can be understood from the previous chapters of this volume. Modifications are required, however, when the film thickness t becomes comparable to the inverse linear attenuation coefficient of the sample: $t \simeq 1/\mu$. Conventional powder diffraction then turns out to be the limiting case, where the sample thickness is usually much larger and $\mu t \gg 1$ is valid. If this is not the case, a large fraction of the beam intensity might be wasted in a conventional $\theta/2\theta$ scan. Experimental geometries have been introduced that differ from the conventional powder setup in order to exploit this otherwise lost intensity. In these techniques, the incident beam impinges at low incidence angles in order to extend the X-ray path within the layer.

Thin-film structural features of interest are the microstructural organization relating to the density of voids, the distribution of grain sizes and possible amorphous fractions (Mittemeijer & Scardi, 2004). In addition, nonrandom orientation distributions of the constituent crystallites typically occur, and characterizing such distributions requires a texture analysis (Bunge, 1982; Kocks *et al.*, 1998; Wenk & Van Houtte, 2004; Chateigner, 2010). Closely related to microstructure, texture and grain size is the state of internal stress (Hauk, 1997; Genzel, 2004, 2005). Moreover, all of these structural properties typically vary with film thickness, leading to pronounced depth gradients. X-ray investigations for determining this structural information are often required for adjusting the properties of the sample and for understanding the growth process. The present chapter will give a short overview of these techniques along with examples of their applications. The focus will be on polycrystalline materials; the field of single-crystalline or epitaxial layers will not be considered here and the interested reader is referred to Holy *et al.* (1999) and Fewster (2003) for this topic. Neutrons will also not be considered here, since neutron-scattering cross sections are too small to yield sufficient structural information for thin films and multilayers.

5.4.2. Effects of absorption

In contrast to conventional powder diffractometry, absorption effects play an important role in X-ray diffraction by thin films.

5.4.2.1. *Absorption factor*

The intensities $I_{\mathbf{h}}$ of diffraction peaks from thin films and multilayers are subject to the usual dependence on scattering angle 2θ *via* the Lorentz–polarization factor Lp, the structure factor F, the multiplicity m, the texture factor $T_{\mathbf{h}}$ *etc.* as outlined in previous chapters of this volume. $I_{\mathbf{h}}$ may be given by

$$I_{\mathbf{h}} = SCF\, m_{\mathbf{h}}\, T_{\mathbf{h}}\, Lp\, |F_{\mathbf{h}}|^2\, A_{\theta 2\theta}(t), \qquad (5.4.1)$$

where $\mathbf{h}$ represents the specific Bragg reflection hkl under consideration and SCF is a scaling factor that is dependent on physical constants and instrumental conditions such as scanning velocity *etc.* Most particular for diffraction from layers, however, is the form of the absorption factor A, which (i) is different from the usual one in $\theta/2\theta$ geometry and (ii) has to be adapted to the different scattering geometries used in thin-film work.

As outlined in Creagh & Hubbell [*International Tables for Crystallography*, Volume C (1999), Section 4.2.4], the intensity I_0 that enters the sample will be exponentially damped to $I_0 \exp(-2\mu l)$ after a path of $2l$, where μ is the linear attenuation coefficient. The inverse of μ can be regarded as a penetration depth for normal incidence $\tau_{1/e} = 1/\mu$, after which path the intensity has dropped to $1/e$ of its initial value. For many substances, attenuation coefficients of the order of 10^5 to 10^7 m^{-1} are obtained for Cu $K\alpha$ radiation or comparable wavelengths, corresponding to penetration depths of between 0.1 and 10 µm. Since these values are in the range of typical layer thicknesses, it is evident that absorption effects might significantly affect the Bragg reflections from the sample.

The situation typically encountered in a $\theta/2\theta$ scan is visualized in Fig. 5.4.1. For any X-ray beam travelling through the sample and scattering into the detector, the primary intensity is reduced by $\exp(-2\mu l)$. The reduction in intensity of the total X-ray beam

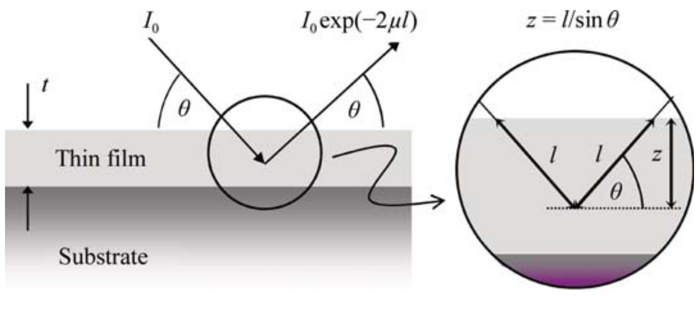

Figure 5.4.1

Copyright © 2019 International Union of Crystallography

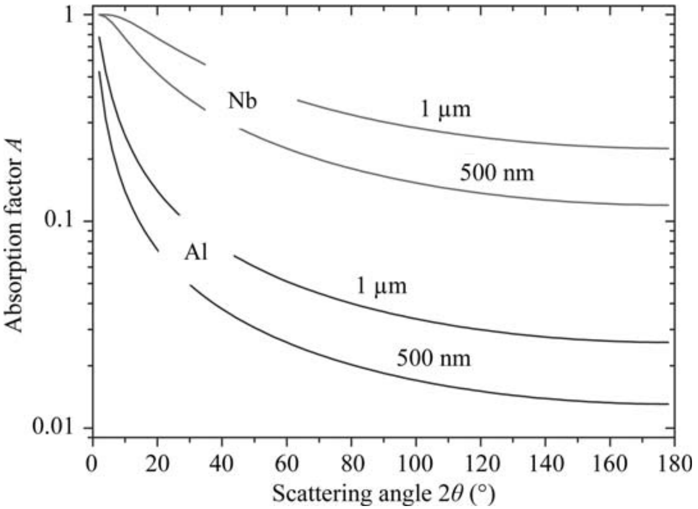

Figure 5.4.2
Absorption factor A for 500 nm and 1 µm Al and Nb films as function of 2θ.

derives from the sum over all beam paths within the limits 0 to $l_{\max}$,

$$\int_0^{l_{\max}} \exp(-2\mu l)\,\mathrm{d}l, \tag{5.4.2}$$

integration of which yields

$$\frac{1}{2\mu}\left[1-\exp\left(-\frac{2\mu t}{\sin\theta}\right)\right]. \tag{5.4.3}$$

The case of powder diffraction represents the limit of an infinitely thick sample, $t \to \infty$ or, equivalently, $t \gg 1/\mu$. In the latter case the well known result is $A = 1/(2\mu)$. In the following, the absorption factor A will be denoted by the ratio of the absorption for a sample of finite thickness to that for an infinitely thick sample:

$$A = \int_0^t \Big/ \int_0^\infty . \tag{5.4.4}$$

The application of this procedure yields the absorption factor of the $\theta/2\theta$ configuration:

$$A_{\theta 2\theta} = \left[1-\exp\left(-\frac{2\mu t}{\sin\theta}\right)\right]. \tag{5.4.5}$$

The subscript $\theta 2\theta$ has been added to indicate the measurement geometry. We will become acquainted with different A factors in the following for distinct instrumental configurations. The A factor is also denoted the thickness factor and it is seen to cause the measured intensity to decrease as a function of increasing scattering angle 2θ. In Fig. 5.4.2 the $A_{\theta 2\theta}$ factor is displayed for thin Al and Nb films of 500 nm and 1 µm thickness measured with Cu $K\alpha$ radiation, where use has been made of the material parameters $\mu = 1.31 \times 10^6$ m^{-1} for Al and 1.276×10^7 m^{-1} for Nb.

It can be realized from the plot that $A_{\theta 2\theta}$ is closer to unity the thicker the film or the larger μ is. Accordingly, the absorption factor depends on the product of these quantities and it will thus be denoted as the product μt in the following. This quantity derives from the two most important structural parameters of a thin film, which are its chemical composition and its thickness. The product μt is a dimensionless number and turns out to be the central parameter in X-ray investigations of thin films.

5.4.2.2. *Chemical phase identification*

As in powder diffraction in general, a typical task in thin-film analysis is the identification of chemical phases. The composition of the layers often has to be checked to ensure that the intended chemical phase has been successfully prepared. This may be done by measuring a diffraction pattern in a $\theta/2\theta$ powder-diffraction setup and comparing the Bragg-peak positions and intensities that are obtained with those of the phases that are expected, as listed in various crystallographic databases such as the Powder Diffraction File (PDF), the Inorganic Crystal Structure Database (ICSD), the Crystallography Open Database (COD) *etc.* (Chapter 3.7). Such comparison may be successful in identifying the chemical phase, but identification is often impeded by some of the specific phenomena observed in thin films. For instance, Bragg reflections may be:

(i) severely damped at higher scattering angles 2θ by the particular dependence of $A_{\theta 2\theta}$ on $\sin\theta$,
(ii) subject to strong broadening and subsequent overlap caused by small grain sizes,
(iii) modulated by a preferred crystallographic orientation (texture) such that one or a few reflections dominate the pattern, while others are missing, and/or
(iv) shifted from their usual $2\theta_0$ values because of residual stress.

Answering the question of what phases comprise the thin film may become very difficult in these cases. It may then become necessary to develop a thorough understanding of the microstructure of the sample and its underlying order parameters such as texture and strain. Again, the linear attenuation coefficient μ is of central importance for all of these tasks and should be determined at the beginning of any thorough X-ray study.

Most tables (such as those in Table 4.2.4.3 of Volume C of *International Tables for Crystallography*) specify the mass absorption coefficient μ_m, which is derived by dividing μ by the mass density,

$$\mu_m = \frac{\mu}{\rho}. \tag{5.4.6}$$

For a discussion of the physical causes of attenuation or absorption, the coefficient μ_m is advantageously further reduced to a cross section σ that is specified for a single atom. The normalization is achieved by multiplying by the atomic mass M and dividing by Avogadro's number N_A,

$$\sigma = \frac{\mu}{\rho}\frac{M}{N_A}, \tag{5.4.7}$$

leading to dimensions for σ of m^2 per atom.

If the linear absorption coefficient of a chemical compound is required, it must be derived from its density ρ and the sum over μ_m of the elements in the compound weighted by their mass fractions g_i/G. Here, g_i denotes the atomic mass of an element and $G = \sum g_i$ is the mass of the molecular unit. μ_m for a single element is then substituted by a sum over all elements in accordance with

$$\mu_m \to \sum_i \frac{g_i}{G}(\mu_m)_i, \tag{5.4.8}$$

Owing to the increase of μ_m with atomic number Z, the absorption coefficient of a compound or an alloy will in most cases be dominated by the heaviest elements in the sample.

It is a further feature of thin-film analysis that the calculated values $\mu_{\rm cal}$ are often found to be larger than those actually observed in the layer, $\mu_{\rm eff} < \mu_{\rm cal}$. This fact may sometimes be explained by porosity, which may affect $\mu_{\rm eff}$ through the inclusion of air or vacuum. In addition, the preparation of thin films in vacuum-based or wet-chemical processes may be accompanied by the inclusion of contaminants on inner surfaces, such as water, hydroxy groups, organic compounds *etc.*, that have a lower density than the main part of the film. However, the reverse situation $\mu_{\rm eff} > \mu_{\rm cal}$ can also occur. In plasma-assisted processes such as physical vapour deposition (PVD) or plasma-enhanced chemical vapour deposition (PECVD), for instance, sputter-gas atoms such as Ar may be included into the growing film. Depending on the processing parameters such as substrate bias *etc.*, the amount of Ar can rise to some at% so that μ may exceed the value calculated from the ideal film composition. The general statement can be made that for any calculation of μ according to (5.4.8) the real chemical composition of the layer has be checked carefully, as it may deviate from the intended one. Among other techniques, this may be performed by determining $A_{\theta 2\theta}$.

5.4.2.3. *Determination and interpretation of the product μt*

Because of its central role in X-ray analysis, the determination of the product μt should mark the start of every investigation of a thin film. This may be performed mathematically when μ and t are known from other sources. It may also be performed using X-ray techniques, and some approaches will now be presented.

A first technique relies on the appearance of a substrate Bragg reflection at scattering angle $2\theta_S$. If such a reflection is observed and can be measured in $\theta/2\theta$ scans, the integrated intensities for the uncoated and the coated sample $I_{S,{\rm unc}}$ and $I_{S,{\rm coa}}$ can be compared. The substrate peak of the coated sample will be damped by the absorption by the layer such that the intensities are related by

$$I_{S,{\rm coa}} = I_{S,{\rm unc}} \exp\left[-\frac{2(\mu t)_{\rm TF}}{\sin\theta_S}\right] \qquad (5.4.9)$$

since the X-ray beam has to traverse the thin film twice to appear as a diffraction peak of the substrate. The product $(\mu t)_{\rm TF}$ (where TF indicates thin film) of the film may then be calculated by rearranging (5.4.9) to obtain

$$(\mu t)_{\rm TF} = \frac{\sin\theta_S}{2}\ln\left(\frac{I_{S,{\rm unc}}}{I_{S,{\rm coa}}}\right). \qquad (5.4.10)$$

Use of this formula is straightforward: I_S is measured prior to and after the film deposition. It may also be applied to amorphous layers, since it makes use of a substrate reflection and does not rely on Bragg peaks from a polycrystalline layer.

These considerations can be extended to multilayer systems (see Fig. 5.4.3) that are built up from a stack of individual layers of different thicknesses and chemical compositions. In this case, the substrate is advantageously labelled by index J and assumed to be buried beneath $J-1$ layers, with the top layer being No. 1. It is evident that the intensity of a Bragg reflection from the jth layer is affected by the absorption of the layers above it. A modified absorption factor $A_{\theta 2\theta}^{\rm ML}$ (where ML indicates multilayer) then has to be introduced, which for the jth layer in a $\theta/2\theta$ scan becomes

$$A_{\theta 2\theta}^{{\rm ML},j}(2\theta) = \left\{1-\exp\left[-\frac{2(\mu t)_j}{\sin\theta}\right]\right\}\exp\left[-\sum_{p=1}^{j-1}\frac{2(\mu t)_p}{\sin\theta}\right]. \qquad (5.4.11)$$

Equation (5.4.11) can be compared with (5.4.5), with the second term describing the damping of beam intensities due to the upper layers.

Figure 5.4.3
Schematics of absorption in a multilayer system.

Another technique for determining $(\mu t)_{\rm TF}$ uses harmonic reflections, the Miller indices of which are related by $(h_2k_2l_2) = n(h_1k_1l_1)$, with n being an integer. When the two reflections arise at θ_1 and θ_2 and have integrated intensities I_1 and I_2, the following expression may be derived from their ratio:

$$\left\{1-\exp\left[-\frac{2(\mu t)_{\rm TF}}{\sin\theta_1}\right]\right\} = \frac{I_1}{I_2}\frac{(Lp)_2}{(Lp)_1}\frac{F_2F_2^*}{F_1F_1^*}\left\{1-\exp\left[-\frac{2(\mu t)_{\rm TF}}{\sin\theta_2}\right]\right\}. \qquad (5.4.12)$$

From this equation, $(\mu t)_{\rm TF}$ can be solved numerically by inserting the measured intensities and calculating the other factors. Factors such as multiplicity *etc.* are no longer accounted for, since they are equal for harmonic reflections. $T_{\bf h} = 1$ can be used for ideal powder samples, but not for polycrystalline thin films. It is therefore highly advantageous that the term $T_{\bf h}$ vanishes here.

The main difference between this and the first technique is that the intensities stem from the thin film, while those in the previous technique come from the substrate. On the other hand, the structure must be known to obtain the structure factors $F_{\bf h}$. Another disadvantage of the technique is its limitation to harmonic reflections.

As an alternative, thin films with a thickness of less than about 100 nm may also be studied by X-ray reflectivity (XRR; see Section 5.4.6), from which the electron density ρ_e and the thickness t may be derived. Combining the value obtained for ρ_e with reliable assumptions on the layer stoichiometry generally allows the attenuation coefficient μ to be estimated, and finally μt.

If none of the aforementioned procedures can be applied, a numerical regression of the full diffractogram can be carried out. This task is denoted Rietveld refinement or whole-pattern fitting: see Chapters 4.7 and 3.6 in this volume, and Ferrari & Lutterotti (1994), Ribárik *et al.* (2001), Scardi & Leoni (2002), Lutterotti *et al.* (2004) and Apel *et al.* (2011). Some Rietveld programs that were initially developed for powder samples also allow the analysis of thin films.

Interesting conclusions may be drawn from the experimentally determined value for the product μt [$(\mu t)_{\rm exp}$]. The first relates to the film thickness t that can be obtained by dividing $(\mu t)_{\rm exp}$ by a reliable value for the absorption coefficient μ of the layer. It is a decisive advantage of X-ray techniques that the thickness may be

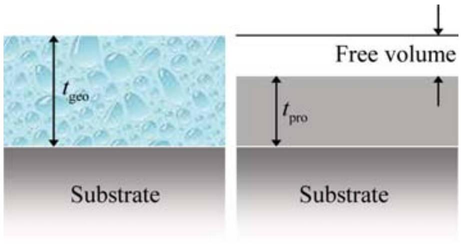

Figure 5.4.4
Visualization of geometrical thickness (left) and projected thickness (right). The difference between these accounts for the free volume of the layer.

determined without destroying the integrity of the sample, as is required for other methods such as profilometry or electron microscopy. To assess the obtainable accuracy and precision, one must be aware of any systematic variations in t caused by lateral inhomogeneity or surface roughness.

Other sources of systematic errors can be identified by decomposing the measured product μt into its constituent factors:

$$(\mu t)_{\mathrm{exp}} = \rho\mu_m t. \qquad (5.4.13)$$

Equation (5.4.13) clearly shows that systematic errors may stem from both ρ and μ_m. Possible errors in density (the term ρ_{bulk} is often used for macroscopic bulk material) may originate from voids and microcavities that are formed during growth. Inclusion of contaminants from the growth medium (mainly light elements) can also make the value of ρ_{bulk} larger than the density actually is.

On the other hand, (5.4.13) may be applied to quantitatively estimate the phenomena causing these systematic deviations. For example, the quantity $(\mu t)_{\mathrm{exp}}/(\rho\mu_m)$ can be denoted the projected thickness, t_{pro}, since it represents the thickness that a layer would have if it were free from voids and contaminants. The actual thickness, however, is the geometrical thickness t_{geo} that represents its geometrical height and may be determined by profilometry (see Fig. 5.4.4). A careful determination of both t_{pro} and t_{geo} may show a significant difference between these values, allowing conclusions to be drawn about the density of unintended phases within the layer.

5.4.2.4. *Phase inhomogeneities*

Deviations from a homogeneous chemical composition may arise in different variants in thin films. First, we consider a single-layer thin film containing P different crystalline phases, each having a weight fraction w_j/W. The sum over all phase weights w_j gives the total weight W of the film, $\sum_{j=1}^{P} w_j = W$.

The average mass attenuation coefficient $\overline{\mu}_m$ of phase mixtures is the sum over the μ_m coefficients of all phases weighted by their weight fraction,

$$\overline{\mu}_m = \sum_j \frac{w_j}{W}(\mu_m)_j. \qquad (5.4.14)$$

The average density, on the other hand, is the ratio of the sum over all phase weights and the total volume,

$$\overline{\rho} = \frac{1}{V}\sum_j w_j. \qquad (5.4.15)$$

The product of these quantities gives the average attenuation coefficient $\overline{\mu} = \overline{\rho\mu}_m$ of a mixed-phase sample, which replaces the term μ in the original formula for calculating the integral intensity of a diffraction pattern, resulting in

$$I_{\mathbf{h}j} = SCF\,Lp\,m_{\mathbf{h}j}\,T_{\mathbf{h}j}\,\frac{|F_{\mathbf{h}j}|^2}{V_{\mathrm{uc},j}^2}\,\frac{w_j}{\rho_j\overline{\mu}}\,A_{\theta2\theta}(t), \qquad (5.4.16)$$

where uc indicates unit cell, which describes the integral intensity of reflection **h** of phase j in a $\theta/2\theta$ diffractogram of a mixed-phase thin film.

Equation (5.4.16) shows that the reflection intensity depends on the weight fraction of the phase. This means that a $\theta/2\theta$ diffraction pattern of a polycrystalline phase mixture is strongly dominated by the compound containing elements with the highest Z values. The next important factor that may influence the application of (5.4.16) is the occurrence of a preferred orientation in the layer sample. This often occurs and may severely affect the integrated intensities gathered in a $\theta/2\theta$ scan, as shown by the $T_{\mathbf{h}}$ term in (5.4.16). In the case of strong sample texture, a quantitative determination of the chemical composition of the sample must be combined with an investigation of its texture. A whole-pattern fitting procedure should then be applied, such as that presented in Lutterotti *et al.* (2004).

In addition to phase mixtures, lateral phase inhomogeneities frequently occur in thin films. These may arise because of inhomogeneous deposition conditions during growth. Their effect often manifests itself as a radial inhomogeneity, where central areas of the sample are distinct from the areas at the substrate edges. However, this phenomenon can be exploited for the preparation of 'thin-film libraries', in which the composition and properties are systematically varied as a function of the sample position. Provided that lateral scanning techniques are available to probe the sample properties on appropriate length scales, the variation in properties can be correlated with the composition. This has recently been demonstrated by X-ray microdiffraction with a lateral resolution in the submillimetre range (Takeuchi *et al.*, 2002; Long *et al.*, 2009; Roncallo *et al.*, 2009). This allows the preparation of large thin-film libraries using a single sample and is an approach for high-throughput experimentation that is increasingly used in various fields of materials science.

5.4.3. Grazing-incidence configurations

As mentioned above, the inverse attenuation coefficient $1/\mu$ in many thin films is much larger than the film thickness, causing a large fraction of diffracted intensity in a symmetric $\theta/2\theta$ scan to stem from the substrate. Only a little structural information may then be gained from the sample, since the X-ray path is too short to deliver Bragg reflections with a sufficient peak-to-noise ratio.

X-ray diffraction techniques have thus been developed in which the primary beam enters the sample at very small angles of incidence. In its simplest variant this configuration is denoted grazing-incidence X-ray diffraction (GIXRD). The small incident angle causes the path travelled by the X-rays to significantly increase and the structural information contained in the diffractogram to stem primarily from the layer. The parafocusing geometry as applied in conventional powder diffractometry is not used in these experiments, and beam-shaping devices for parallel X-ray optics have to be used (see Chapter 2.1). Interestingly, the GIXRD technique allows depth-resolved structural information to be obtained by measuring diffraction patterns at different angles of incidence.

5.4.3.1. *Grazing-incidence X-ray diffraction (GIXRD)*

The experimental configuration in the GIXRD experiment is shown schematically in Fig. 5.4.5. The angle between the incoming beam and the sample surface is very small and amounts to only a few degrees or even less. It is generally denoted α. The incoming X-ray travels a maximum path of $l = t/\sin\alpha$ within the layer. A first criterion for a reliable choice of α is that the average path in the layer should be comparable to the inverse attenuation coefficient, *i.e.* $l \simeq 1/\mu$. This condition translates into the recommendation that $\alpha \simeq \arcsin(\mu t)$ should hold between the incidence angle and the product μt of the layer. Further restrictions have to be considered for α when α approaches the so-called critical angle. As in the symmetric $\theta/2\theta$ configuration, the wavevectors $\mathbf{K}_0$, $\mathbf{K}$ and the sample normal $\mathbf{s}_3$ all lie in the same plane in GIXRD and it is thus a coplanar configuration.

The measurement of the diffractogram is performed in such a way that the angle α is kept constant, while the detector is moved along the 2θ circle. However, the scattering angle 2θ again denotes the angle between the outgoing beam and the extension of the incoming beam. If the collected intensity is then plotted *versus* 2θ, Bragg reflections are found at comparable positions to those in a symmetrically measured pattern. In contrast to the latter, the angle between the outgoing beam and the sample surface is $2\theta - \alpha$ in a GIXRD experiment instead of θ as in a symmetrical scan.

The different measurement geometry has important consequences for the orientation of the scattering vector $\mathbf{Q}$ and the beam optics. In the symmetric $\theta/2\theta$ configuration the scattering vector $\mathbf{Q}$ is always parallel to the surface normal $\mathbf{s}_3$. The crystallographic lattice planes that give rise to an observed Bragg reflection are all oriented parallel to the substrate plane. In the grazing-incidence configuration, on the other hand, $\mathbf{Q}$ is neither parallel to $\mathbf{s}_3$ nor does its orientation remain constant. Rather, the orientation of $\mathbf{Q}$ changes over the course of the measurement, during which the scattering vector is tilted from the start position close to $\mathbf{s}_3$ towards an end position closer to the incoming beam $\mathbf{K}_0$. In the GIXRD configuration, reflections with distinct Bragg angles θ_{hkl} arise from lattice planes that are neither parallel to the substrate surface nor to each other. In the case of a random orientation of crystallites, as in a powder, a comparable pattern will be measured in both the symmetric and asymmetric configuration. For thin layers, however, where the structural parameters may sensitively depend on the film thickness and orientation, the different tilts of grain ensembles have to be considered in order to interpret the GIXRD patterns.

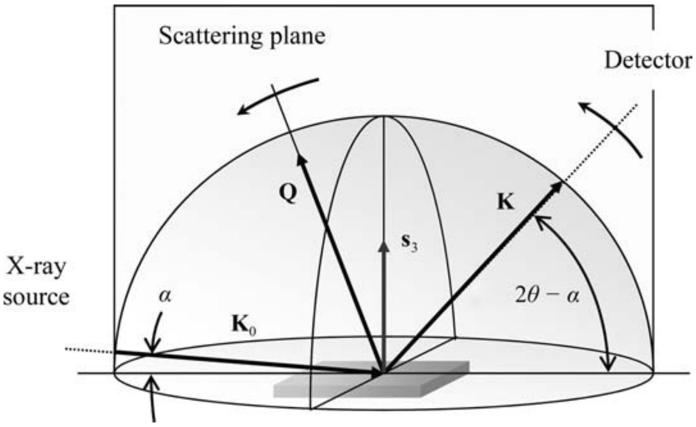

Figure 5.4.5
The geometry in grazing-incidence diffraction is characterized by a small incidence angle α that is kept constant during measurement.

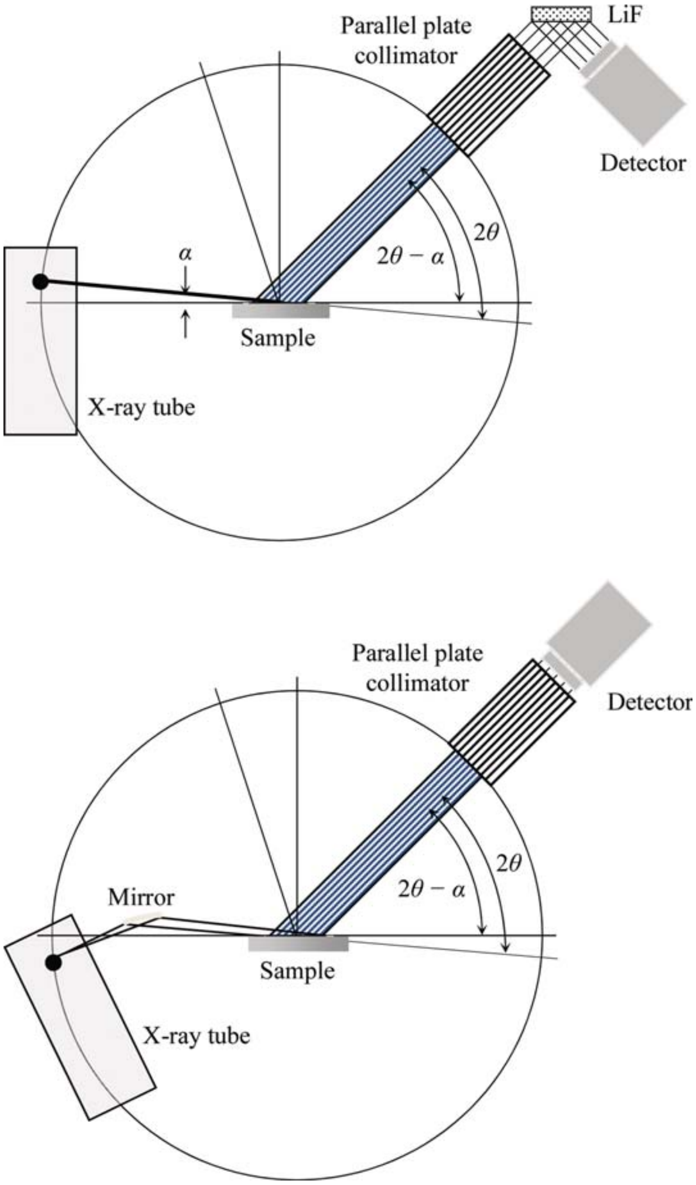

Figure 5.4.6
The two diffractometer configurations most frequently applied in GIXRD. The X-ray tube is operated in the line-focus mode. The drawing plane is the scattering plane.

The need for modified beam optics follows from the fact that the conditions of parafocusing geometry are not met in this asymmetric configuration. Because the incidence angle is fixed, the measuring circle and the focusing circle do not intersect throughout the whole scan, but only for a single point. Without taking special measures, the divergent beam leaving the X-ray tube and impinging on the sample would enter the detector unfocused. The solution to this problem is to run the diffractometer in parallel-beam mode. Fig. 5.4.6 displays the two different configurations that are in use when the tube operates in the line-focus mode. In the first setup (see Fig. 5.4.6*a*), the parallel fraction of the beam is collected on the secondary side by virtue of long collimator slits. Any remaining unparallel beam is subsequently cut off by a flat lithium fluoride crystal monochromator. The second (now widely used) parallel-beam setup, shown in Fig. 5.4.6(*b*), makes use of shaping the primary beam into a parallel bundle just after it has left the X-ray source. This can be achieved using laterally graded multilayer mirrors. A

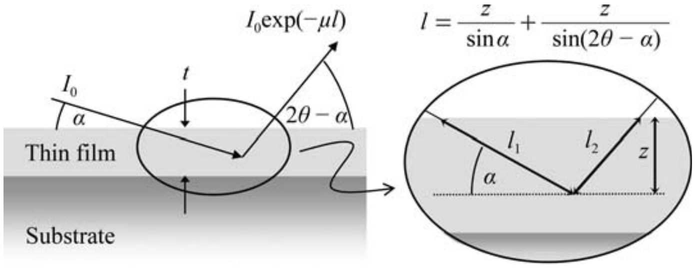

Figure 5.4.7
Schematics of the illuminated sample depth for the derivation of the absorption factor A_α in GIXRD.

sample rotation around the substrate normal or φ axis should be avoided in most GIXRD experiments, since this may cause extra broadening of reflections if the sample is not very precisely positioned. An average over many crystallites, which is the reason for φ spinning in symmetrical XRD, is already obtained in GIXRD through the illumination of many crystallites because of the flat entrance angle.

As a consequence of the particular beam course in GIXRD, the absorption factor A has a different form to that given in (5.4.4). The diffraction of the beam to a depth z is considered in Fig. 5.4.7 in order to derive the new absorption factor. A configuration factor k is now introduced to account for the beam path in the experiment. The factor k allows a general formulation of the absorption factor for any measurement configuration and, in general, it holds that

$$k = \frac{1}{\sin\alpha} + \frac{1}{\sin\beta}. \qquad (5.4.17)$$

It is easily seen for the symmetrical configuration that the factor becomes

$$k_{\theta 2\theta} = \frac{2}{\sin\theta}. \qquad (5.4.18)$$

For GIXRD, however, the more complex expression

$$k_\alpha = \frac{1}{\sin\alpha} + \frac{1}{\sin(2\theta - \alpha)} \qquad (5.4.19)$$

arises. The index α is used as subscript to k in order to characterize it as the appropriate GIXRD factor. The intensity scattered at depth z scales with $\exp(-\mu z/\sin\alpha)$ and $I_0/\sin\alpha$, since the incoming beam is attenuated and inclined. After being scattered, the intensity is attenuated in proportion to $\exp[-\mu z/\sin(2\theta - \alpha)]$,

$$\mathrm{d}P(z) = \frac{SCF \times I_0}{\sin\alpha}\exp\left\{-\mu z\left[\frac{1}{\sin\alpha} + \frac{1}{\sin(2\theta - \alpha)}\right]\right\}\mathrm{d}z. \quad (5.4.20)$$

Here, SCF is a constant that includes terms for the integrated intensity that are not considered in the following. The total scattered intensity follows from the integration over all depths,

$$P = \frac{SCF \times I_0}{\sin\alpha}\int\limits_0^t \exp(-\mu z k_\alpha)\,\mathrm{d}z = \frac{SCF \times I_0}{\mu}\frac{[1 - \exp(-\mu t k_\alpha)]}{k_\alpha \sin\alpha}. \qquad (5.4.21)$$

If P_∞ is used to represent the integrated intensity of a Bragg reflection of an infinitely thick sample, $P_\infty = SCF \times I_0/(\mu k_\alpha \sin\alpha)$ is obtained. As outlined at the beginning, the thin-film absorption factor A is obtained from (5.4.21) by division by P_∞. The GIXRD absorption factor A_α can accordingly be written as

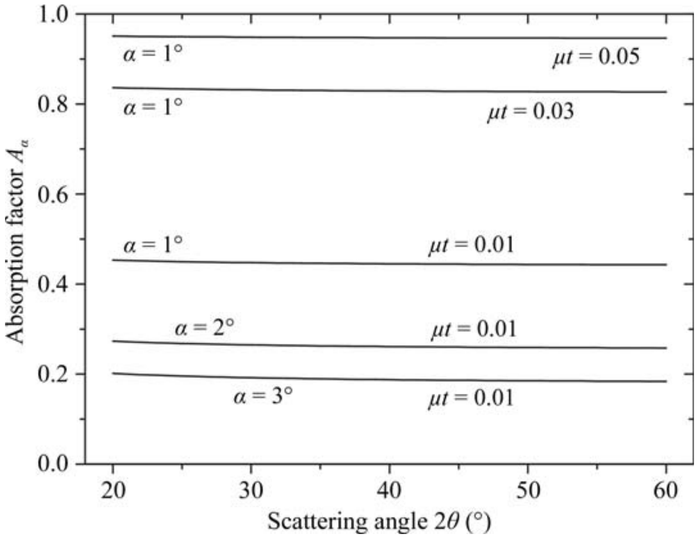

Figure 5.4.8
The absorption factor A_α in GIXRD geometry for various incidence angles α and values of the product μt.

$$A_\alpha = [1 - \exp(-\mu t k_\alpha)]. \qquad (5.4.22)$$

It is by this amount that a Bragg reflection from a thin-film sample is reduced in GIXRD geometry when compared with the intensity from an infinitely thick sample measured under the same conditions. The absorption factor A_α depends on the angles α and 2θ as well as on the product μt of the layer. Therefore, intensity corrections may only be performed when the latter is known and the same arguments as given in Section 5.4.2 hold with respect to the determination of μ, t or μt and the propagation of errors. In Fig. 5.4.8 some absorption factors A_α are displayed for various incidence angles α and values of μt. It can be seen that for all chosen combinations of α and μt the reduction of intensity is fairly constant over the 2θ range from 20 to 60°. This contrasts remarkably with the situation encountered in symmetric $\theta/2\theta$ diffractometry, for which the absorption coefficient $A_{\theta 2\theta}$ decreases significantly with increasing scattering angle 2θ. This different behaviour of A_α and $A_{\theta 2\theta}$ is caused by the different configuration factors k_α and $k_{\theta 2\theta}$ and demonstrates the versatility of GIXRD for the investigation of samples with low values of μt, such as thin films.

Fig. 5.4.9(*a*) displays the GIXRD pattern of a thin TiO_2 film prepared on a titanium-coated steel substrate measured with Cu $K\alpha$ radiation and an incidence angle of $\alpha = 1.8°$ for 2θ between 22 and 60° (Birkholz, Albers & Jung, 2004). Titanium dioxide occurs in a variety of phases, of which tetragonal rutile and anatase are the most common. In addition, thin TiO_2 films are often prepared as fully amorphous and are either transformed to crystalline phases *via* subsequent annealing steps or are used in the amorphous state when this is desired for the intended application. The optical index of refraction of different TiO_2 phases ranges from 2.2 to 2.8 and has the largest values for rutile films, the preparation of which either requires a minimum deposition temperature or high ion bombardment during film growth (Szczyrbowski *et al.*, 1999). Clearly, the peaks observed in Fig. 5.4.9(*a*) can be assigned to the rutile phase (PDF entry 00-021-1276), although the measured reflections are shifted to somewhat smaller 2θ angles. It turns out that the formation of the rutile phase at comparatively low temperatures is assisted by the high ion bombardment during the deposition process, which is also responsible for the intrinsic film stress indicated by the shift of the Bragg reflections. For comparison, the $\theta/2\theta$ pattern of the

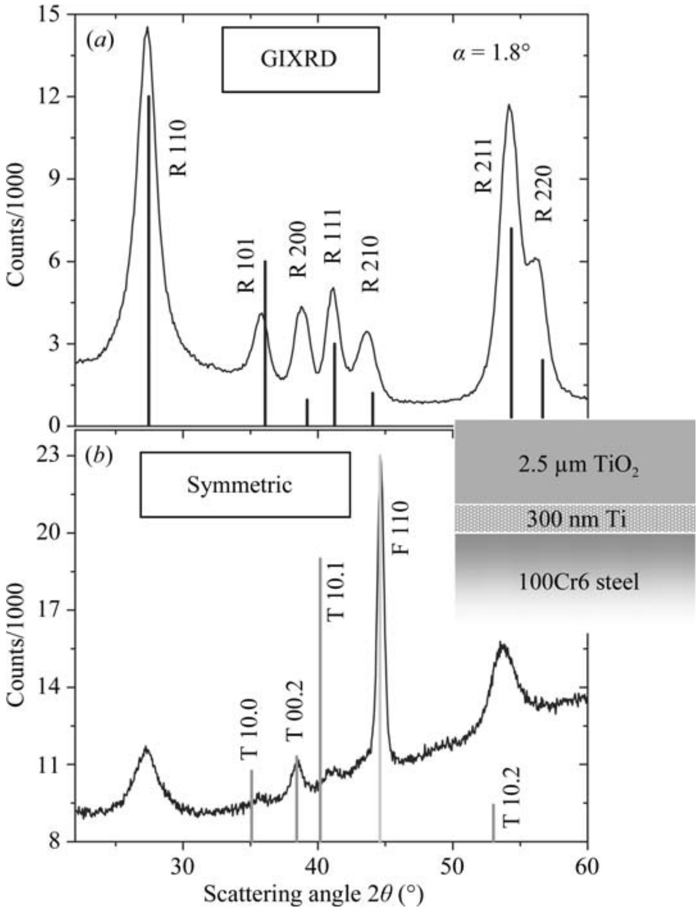

Figure 5.4.9
(*a*) GIXRD, $\alpha = 1.8°$, and (*b*) $\theta/2\theta$ diffraction pattern from the same TiO_2/Ti layer system on steel. Vertical lines indicate the positions of Bragg reflections *hkl* from rutile (R), titanium (T) and ferrite (F) according to the relevant entries in the Powder Diffraction File.

same film is also shown in Fig. 5.4.9(*b*). The symmetrically measured pattern is mainly characterized by the Bragg peaks of the steel substrate and the titanium interlayer, as is seen from the markers for the PDF entries 00-044-1294 for hexagonal-close-packed (h.c.p.) titanium and 0-006-0696 for body-centred cubic (b.c.c.) iron. Moreover, the $\theta/2\theta$ pattern of the same sample exhibits a pronounced background and a poorer signal-to-noise ratio owing to X-ray fluorescence from the iron substrate excited by the Cu $K\alpha$ radiation. For all but the lowest-angle peak, it is hard to decide whether the peaks stem from the substrate, the interlayer or the TiO_2 top layer. Many of the details of the rutile pattern obtained from the GIXRD measurement are completely buried under substrate and bottom-layer peaks in the symmetric $\theta/2\theta$ scan. This example convincingly illustrates the additional information that can be deduced from grazing-incidence diffraction for a thin-film sample.

The GIXRD technique that has just been outlined is also known under other names in the literature, such as grazing-incidence asymmetric Bragg diffraction (GIABD) and others.

5.4.3.2. *Penetration depth and information depth*

The growth of thin films is often associated with thickness-dependent evolutionary processes. For instance, the grain size may be observed to increase with increasing thickness, or the composition of distinct crystallographic phases may change either continuously or abruptly at a critical thickness. GIXRD studies may yield valuable experimental data on such property gradients by measuring a set of diffraction patterns $I(\alpha, 2\theta)$ under varying incidence angles α. However, transforming the measured structural information into a uniquely defined depth coordinate is not straightforward. The complexity of the problem is demonstrated by the existence of different concepts for the penetration depths τ of X-rays.

The first concept of intensity damping considers the depth $\tau_{1/e}$ as the characteristic quantity; this is the distance after which the X-ray beam is attenuated to $1/e$ of its initial value. In the case of GIXRD geometry this yields

$$\tau_{1/e} = \frac{\sin\alpha}{\mu}. \tag{5.4.23}$$

By virtue of the $1/e$ depth it is already possible to qualitatively understand distinct diffraction patterns obtained at different grazing angles α.

The disadvantage of the concept arises from the fact that $\tau_{1/e}$ may exceed the thickness t of the layer and should therefore be used with caution. Obviously, a useful depth definition for the ordering of structural information from different layer depths would have to include the film thickness t, or have the film thickness as a limiting value. These conditions are obeyed by the definition of the so-called average information depth $\overline{\tau}$. This quantity is calculated from the weighted sum of all beam paths that differ in the amount of damping that they suffer by diffraction at various depths. The exponential term, $\exp(-\mu z k)$, has the meaning of a weight function, while the integration is over all depths from the film surface to the interface with the substrate. The average information depth is of the general form

$$\overline{\tau} = \frac{\int_0^t z \exp(-\mu k z)\,\mathrm{d}z}{\int_0^t \exp(-\mu k z)\,\mathrm{d}z}. \tag{5.4.24}$$

Normalization is achieved by dividing the integral by the weight function. This expression is valid for all measuring configurations presented so far and may be adapted to the special configuration in use by inserting the appropriate configuration factor k. In the case of GIXRD, an information depth $\overline{\tau}_\alpha$ is calculated by inserting k_α from (5.4.19), obtaining

$$\overline{\tau}_\alpha = \frac{1}{\mu k_\alpha} + \frac{t}{1 - \exp(\mu t k_\alpha)}. \tag{5.4.25}$$

The appearance of the symbol τ in the context of a penetration depth is sometimes confusing in the literature. In some calculations it may be found as a term inserted for $1/\mu k$, where it has the meaning of an abbreviation. In addition to this, τ is frequently used when using $\overline{\tau}$ would be more appropriate.

In the limit of large incidence angles or small absorption, the average information depth approaches half the film thickness, $t/2$,

$$\lim_{\mu k \to 0} \overline{\tau} = \frac{t}{2}. \tag{5.4.26}$$

This limit corresponds to the situation in which the incident X-ray intensity is hardly damped at all over the whole thickness. In this situation, each partial layer of the film is almost equally illuminated and the measured diffraction information stems on average from the middle of the film. Bragg reflections measured at large α values would contain information from all depths.

5.4.3.3. *Depth-dependent properties*

The formalism discussed above can be developed for other depth-dependent properties such as the concentration of a chemical phase, the amorphous fraction, the crystallite size, microstrain or macrostress *etc*. If this depth-dependent property is denoted by $P(z)$, we realise that determining it by analysing a Bragg reflection yields a weighted average of this property $\overline{P} = \langle P(z)\rangle$, with the weight given by the attenuation of X-ray intensity. An attenuation length τ may be defined that allows $P(z)$ to be related to its average value by

$$\overline{P} = \frac{\int_0^t P(z)\exp(-z/\tau)\,\mathrm{d}z}{\int_0^t \exp(-z/\tau)\,\mathrm{d}z}. \tag{5.4.27}$$

A set of $\overline{P}_\alpha$ values under various incidence angles α can be determined by using the denominator (abbreviated by N_τ) and rewriting the equation using the Laplace transform $\mathcal{L}^t$, which for the GIXRD configuration results in

$$\overline{P}_\alpha = \frac{1}{N_\tau}\mathcal{L}^t[P(z), 1/\tau]. \tag{5.4.28}$$

$P(z)$ can be solved by inverting (5.4.28),

$$P(z) = (\mathcal{L}^t)^{-1}[N_\tau \overline{P}_\alpha(\tau), z], \tag{5.4.29}$$

but the result is highly dependent on the availability and reliability of $\overline{P}_\alpha$ data. Besides GIXRD, there are alternative techniques for collecting $\overline{P}_\alpha$ data. For instance, the scattering-vector technique was introduced by Genzel into the field of residual stress for elucidating stress gradients (Genzel, 1994, 2001). Another approach is to use synchrotron radiation, where the beam energy or wavelength can be varied. Birkholz proposed varying the information depth by using the strong variations of the product μt that occur at elemental absorption edges (Birkholz, 2007) and this has been applied to the determination of texture gradients (Birkholz *et al.*, 2008).

In a practical sense, inversion of the Laplace transformation is complicated by noisy and improperly spaced data in τ space. These cause instabilities in the numerical solution of (5.4.29) and may lead to physically meaningless results. A way to avoid this is to convert the equation into a polynomial equation and to use model parameters P_0, P_1, P_2, ... to compose the property function in real space:

$$P(z) = P_0 + P_1 z + P_2 z^2 + \ldots. \tag{5.4.30}$$

Equation (5.4.29) can be solved analytically by inserting the above expression, yielding

$$\overline{P}_\alpha = P_0 + P_1\left[\tau + \frac{t}{1+\exp(t/\tau)}\right] + P_2\left[2\tau^2 + \frac{t(t+2\tau)}{1+\exp(t/\tau)}\right] + \ldots. \tag{5.4.31}$$

This concept is mostly applied in the field of residual-stress analysis in thin films. However, a more appropriate expression for τ must be determined when very small incidence angles are approached, *i.e.* when α approaches the critical angle α_c, as will be seen in the following.

5.4.3.4. *Index of refraction for X-rays*

The energies of X-rays $h\nu$ by far exceed the resonance energies of intra-atomic excitations. Under this assumption, an expression may be derived for the refraction index of X-rays, showing that it deviates only little from unity, as indicated by

$$n = 1 - \rho_e \frac{\lambda^2 r_e}{2\pi}. \tag{5.4.32}$$

In this formula, ρ_e represents the density of electrons in the specimen and r_e is the classical radius of the electron: $r_e = 2.82 \times 10^{-6}$ nm. The rather small deviation is often denoted δ, leading to

$$n = 1 - \delta. \tag{5.4.33}$$

Table 5.4.1
Mass densities ρ, according to Weast (1986), electron densities ρ_e and critical angles α_c of some oxides used as optical coatings

Critical angles are given for Cu $K\alpha$ radiation.

Compound	ρ (g cm^{-3})	ρ_e (nm^{-3})	α_c (°)
Fused silica, SiO_2	2.20	662	0.216
Quartz, SiO_2	2.64–2.66	794–800	0.237–0.238
Anatase, TiO_2	3.84	1100	0.279
Rutile, TiO_2	4.26	1220	0.294
Nb_2O_5	4.47	1236	0.294
ZnO	5.61	1576	0.326
Amorphous Pr_2O_3	7.07	2040	0.352
SnO_2	6.95	1833	0.359
HfO_2	9.68	2437	0.399

The material constant δ is of the order of only 10^{-6} for wavelengths in the range $0.1 < \lambda < 0.2$ nm. The combination of these equations results in an expression for a monoatomic solid having ρ_a atoms per volume and a nuclear charge Z,

$$\delta = \rho_a (Z + f')\frac{\lambda^2 r_e}{2\pi}. \tag{5.4.34}$$

The scattering power of the Z electrons per atom has to be modified by adding the dispersion correction f'. Often, the real part of the susceptibility δ is expressed by the mass density ρ instead of the electron density ρ_e or atomic density ρ_a. For the general case of a solid composed of different component atoms having nuclear charges Z_i and atomic weights M_i, one obtains

$$\delta = \rho N_A \frac{\sum_i (Z_i + f_i')}{\sum_i M_i}\frac{\lambda^2 r_e}{2\pi}, \tag{5.4.35}$$

where the sums extend over all atoms in the unit cell.

In addition to the real part of the X-ray index of refraction, an imaginary part of the dielectric susceptibility β is needed to fully describe the deviation of n from unity. β is related to the attenuation coefficient μ *via*

$$\beta = \frac{\lambda}{4\pi}\mu. \tag{5.4.36}$$

This equation may be written in a comparable fashion to (5.4.35),

$$\beta = \rho N_A \frac{\sum_i f_i''}{\sum_i M_i}\frac{\lambda^2 r_e}{2\pi}, \tag{5.4.37}$$

where f'' is the imaginary anomalous dispersion factor.

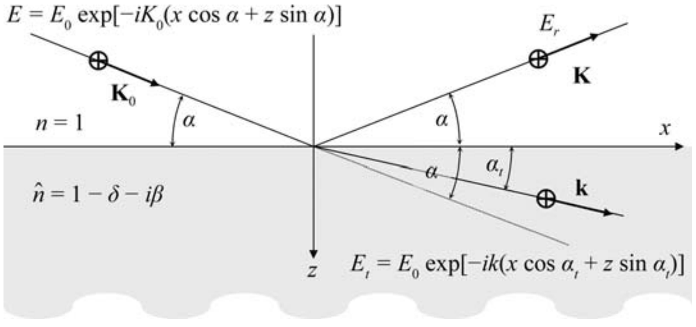
Summarizing, the complex index of refraction for X-rays is given by

$$\hat{n} = 1 - \delta - i\beta. \tag{5.4.38}$$

Mass and electron densities ρ_e are given in Table 5.4.1 for a number of optical coatings, along with critical angles for Cu $K\alpha$ radiation, which is typically used for these studies.

5.4.3.5. *Total external reflection and critical angle*

The fact that $n < 1$ holds for X-rays has important consequences for the phenomenon of total reflection. This effect is generally encountered when electromagnetic radiation traverses a phase border. For optical wavelengths, total internal reflection can be observed in a medium surrounded by vacuum, where



$E = E_0 \exp[-iK_0(x\cos\alpha + z\sin\alpha)]$
E_r

x
$\hat{n} = 1 - \delta - i\beta$
α
α_t
$\mathbf{k}$
z
$E_t = E_0 \exp[-ik(x\cos\alpha_t + z\sin\alpha_t)]$

Figure 5.4.10
Electric field vectors **E** and wavevectors **K** and **k** of an electromagnetic plane wave at the surface of an illuminated sample (π polarization).

$n_{\rm med} > n_{\rm vac}$ holds. In X-ray optics, however, a beam impinging on the sample surface may become totally externally reflected, since $n_{\rm vac} > n_{\rm med}$ is valid. The critical angle α_c denotes the incidence angle below which the effect of total reflection will occur. It is described as a function of δ and β with the help of Fig. 5.4.10.

According to Snell's law of refraction, the sines of the incoming and outgoing angles are proportional to the indices of refraction of the two media at the interface at which the transition occurs. Since in X-ray terminology the beam angles are measured with respect to the sample surface and relative to the substrate normal in geometrical optics, the sine functions in Snell's law have to be substituted by cosines, and one arrives at

$$\frac{1}{\hat{n}} = \frac{\cos\alpha_t}{\cos\alpha}, \qquad (5.4.39)$$

where $\hat{n}$ is the index of refraction of the thin film or the substrate, and α_t and α are the angles of transmitted and incident beam, respectively. Both angles may be assumed to be very small such that the cosine functions may be approximated by $\cos x \simeq (1 - x^2/2)$ for $x \simeq 0$.

The transmission angle α_t in a case where absorption is fully neglected can be expressed as

$$\alpha_t = (\alpha^2 - 2\delta)^{1/2} \text{ for } \beta \simeq 0. \qquad (5.4.40)$$

Total reflection, *i.e.* $\alpha_t = 0$, will be observed for all angles of incidence for which the condition $\alpha^2 \leq 2\delta$ is fulfilled. The critical angle α_c is thus defined from this condition and it holds that

$$\alpha_c = (2\delta)^{1/2}. \qquad (5.4.41)$$

It may be estimated from the electron densities given in Table 5.4.1 that α_c takes values between 0.1 and 0.4° for Cu $K\alpha$ radiation.

When absorption is taken into consideration, α_t is described instead,

$$\alpha_t = (\alpha^2 - \alpha_c^2 - 2i\beta)^{1/2} \text{ for } \beta > 0, \qquad (5.4.42)$$

where the same approximations are made as above and α_c^2 has been inserted instead of 2δ. This angle can be developed into the sum of a real and an imaginary part,

$$\alpha_t = \mathrm{Re}(\alpha_t) + \mathrm{Im}(\alpha_t) = B_+ + iB_-, \qquad (5.4.43)$$

where the B_+ and B_- terms may be represented by the real and imaginary deviation of n from unity:

$$B_\pm^2 = \tfrac{1}{2}\Big\{\big[(\alpha^2 - \alpha_c^2)^2 + 4\beta^2\big]^{1/2} \pm (\alpha^2 - \alpha_c^2)\Big\}. \qquad (5.4.44)$$

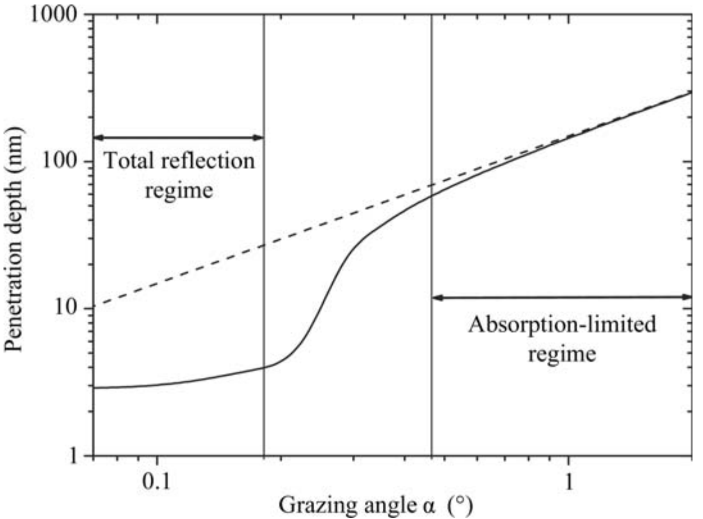

Figure 5.4.11
Penetration depth $\tau_{1/e}$ as function of incident angle α for TiO$_2$ and Cu $K\alpha$ radiation according to (5.4.45) (straight line) and (5.4.23) (dashed line).

For small incidence angles close to the critical angle, (5.4.45) describes the penetration depth $\tau_{1/e}$ better than (5.4.23):

$$\tau_{1/e} = \frac{\lambda}{4\pi B_-} = \frac{2^{1/2}\lambda}{4\pi}\Big\{\big[(\alpha^2 - \alpha_c^2)^2 + 4\beta^2\big]^{1/2} - (\alpha^2 - \alpha_c^2)\Big\}^{-1/2}. \qquad (5.4.45)$$

The penetration depths calculated using both equations [dashed line for equation (5.4.23) and straight line for equation (5.4.45)] are shown in Fig. 5.4.11.

The penetration depth $\tau_{1/e}$ can be divided into three ranges: the first has a grazing angle below the critical angle α_c with a nearly constant value of $\tau_{1/e}$, where $\tau_{1/e} \simeq \lambda/4\pi\alpha_c$ approximately holds. The second range lies above the critical angle α_c, where the penetration depth $\tau_{1/e}$ approaches the limit of $\mu/\sin\theta$, as given in (5.4.23) and as represented by the dashed line. The third (middle) range shows a transition in the vicinity of the critical angle between the two limiting cases. It is obvious that the sample may be monitored with respect to depths that differ by orders of magnitude by varying the incidence angle around α_c. For measurement settings of $\alpha < \alpha_c$, however, only structural information from the uppermost layer is collected.

The transition from (5.4.23) to (5.4.45) describes the effect of total reflection and absorption at very low incidence angles. The penetration depth given in (5.4.45) thus represents the required generalization given at the end of Section 5.4.3.3. By inserting (5.4.45) into equations (5.4.27) and (5.4.28), formulae to determine depth-dependent properties at incidence angles close to the critical angle α_c can be obtained.

Another aspect to be taken into account when using small incidence angles is the shift of reflections from their Bragg peak position θ_B, which increases as the angle of incidence α approaches the critical angle α_c (see Fig. 5.4.12). The shift $\Delta(2\theta)$ is written as

$$\begin{aligned}\tfrac{1}{2}\Delta(2\theta) &= \tfrac{1}{2}(2\theta - 2\theta_B) = \alpha - \mathrm{Re}(\alpha_t)\\ &= \alpha - B_+ \xrightarrow{\beta=0} \alpha - (\alpha^2 - \alpha_c^2)^{1/2}. \qquad (5.4.46)\end{aligned}$$

In the small-incidence-angle approximation and for negligible absorption, (5.4.46) becomes α for $\alpha < \alpha_c$ and $\alpha_c^2/2\alpha$ for $\alpha \gg \alpha_c$.

This effect has been studied in GIXRD experiments carried out on what was intended to be a thin film of γ-phase Fe$_2$O$_3$ for data-storage applications. By controlling the scattering depth through the variation of the incidence angle, the investigation

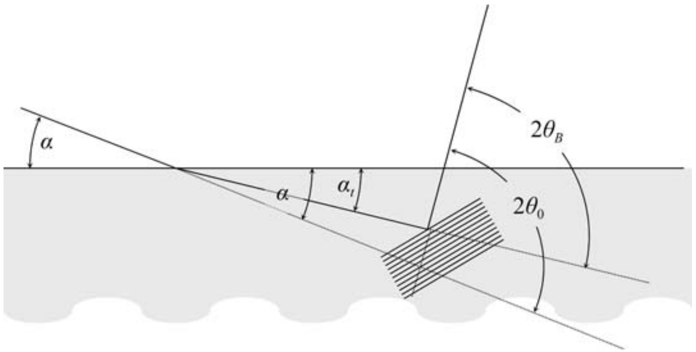

Figure 5.4.12
Schematic drawing for deriving the Bragg peak position shift in GIXRD due to the refraction of the incoming beam.

revealed a less-magnetizable layer of antiferromagnetic α-phase Fe_2O_3 on the film surface. The regression of the data to an appropriate fit function of the type in (5.4.27) allowed quantification of the thickness of the surface layer as 9 nm (Huang, 1990). Appropriate equations for the peak shift in a non-coplanar setup of asymmetric grazing-incidence diffraction have also been derived (Genzel, 2005).

5.4.3.6. *Use of synchrotron radiation*

The preference for a zero-divergent X-ray beam for grazing-incidence experiments is an important argument for using synchrotron radiation. Another reason, which holds in particular for thin films, where only a small scattering volume is active, is the high photon flux, which allows much faster recording of diffraction patterns than with conventional laboratory systems. Accordingly, thin-film studies are increasingly performed at synchrotron beamlines. Synchrotron radiation offers the additional advantage of delivering high-intensity radiation over a large spectral range that may be used in energy-dispersive or white-beam experiments. Based on these qualities, *in situ* investigations of thin-film growth have become possible, for which deposition chambers have been directly installed at synchrotron beamlines; one of the various examples is an energy-dispersive magnetron sputtering system, with which transparent conductive oxides have been investigated (Ellmer *et al.*, 2003).

The high intensity of synchrotron radiation may be a disadvantage when radiation-sensitive samples are under investigation. Organic layers are more prone to destruction by the beam (Beetz & Jacobsen, 2003) than inorganic layers. This effect should thus be considered in every synchrotron experiment; a basic understanding has been developed for protein crystals (Garman, 2010).

5.4.4. Thin-film textures and their depth dependence

The occurrence of texture is a ubiquitous phenomenon in polycrystalline thin films. It seems, in fact, that the preparation of an untextured layer is the exception rather than the rule. It is thus prudent to perform a texture analysis prior to any advanced structure investigation. To give only two reasons: the microstructure may be severely affected by the orientation distribution of crystallites, and also the texture state has to be considered for choosing appropriate grain-interaction models in residual-stress analysis.

Two kinds of texture typically occur in thin films. The first type is the fibre texture that has been identified in a large number of studies, where the fibre axis was typically found to coincide with the substrate normal $\mathbf{s}_3$. In this case, the crystallites have only one orientational degree of freedom: the angle of rotation around the fibre axis. Because of its widespread occurrence in thin films, it is also denoted as layer texture. The second type is biaxial texture, where the orientation of the crystallites is fixed along two directions in the sample reference frame (Chapter 5.3). This state can be regarded as a prelude to an epitaxial film into which the polycrystal would merge for perfectly aligned crystallites.

Thin-film textures may thus be investigated without using the full three-dimensional orientation distribution function (ODF) (a description of which is given in Chapter 5.3). For many cases, the investigation may be restricted to simplified methods such as the determination of texture factors $T_{\mathbf{h}}$, the measurement of pole figures of selected Bragg peaks, ω scans (rocking curves) or φ scans. A typical thin-film phenomenon that deserves consideration is the occurrence of texture gradients, *i.e.* the variation of texture strength with layer depth (Bonarski, 2006; Birkholz, 2007).

5.4.4.1. *Texture factors*

Texture factors $T_{\mathbf{H}}$ represent a straightforward approach to quantifying the degree of preferred orientation in a fibre-textured sample with fibre axis $\mathbf{H}$. The starting point of the calculation is the integrated intensity $I^m_{\mathbf{H}}$ of the measured reflection in a $\theta/2\theta$ pattern,

$$I^m_{\mathbf{H}} = SCF\, m_{\mathbf{H}}\, T_{\mathbf{H}}\, Lp\, |F_{\mathbf{H}}|^2 A_{\theta 2\theta}, \qquad (5.4.47)$$

where $A_{\theta 2\theta}$ is the absorption factor from the symmetric $\theta/2\theta$ setup [see equation (5.4.4)]. The meaning of $T_{\mathbf{H}}$ is that of a weight or concentration factor accounting for the enhancement of the *H*th reflection when compared with a powder sample. The latter is accounted for by $T_{\mathbf{H}} = 1$,

$$I^{\rm rand}_{\mathbf{H}} = SCF\, m_{\mathbf{H}}\, Lp\, |F_{\mathbf{H}}|^2, \qquad (5.4.48)$$

(where rand indicates ‘random’), which differs from (5.4.47) by the missing absorption factor $A_{\theta 2\theta}$, since this expression is valid for powder samples of infinite thickness ($\mu t \gg 1$).

In a second step, the sum of intensities $\sum_{\mathbf{h}} I_{\mathbf{h}}$ is calculated from all Bragg peaks observed in the 2θ range that is investigated. In order to remove the scaling factor, the sum is normalized to a fixed value such as 100, for instance, for both the thin-film pattern and the pattern of that would result from an ideally random orientation. The ratio $I_{\mathbf{H}}/\sum_{\mathbf{h}} I_{\mathbf{h}}$ is subsequently calculated for both patterns, and the texture factor $T_{\mathbf{H}}$ may be derived from

$$T_{\mathbf{H}} = \frac{I^m_{\mathbf{H}}/A_{\theta 2\theta}(\theta_{\mathbf{h}})}{\sum_{\mathbf{h}} I^m_{\mathbf{h}}/A_{\theta 2\theta}(\theta_{\mathbf{h}'})} \frac{\sum_{\mathbf{h}} I^{\rm rand}_{\mathbf{h}}}{I^{\rm rand}_{\mathbf{H}}}. \qquad (5.4.49)$$

The determination of $T_{\mathbf{H}}$ factors by measuring the integrated intensities and relating them to a model pattern offers a simple approach to obtaining a rough estimate of the degree of texture. It is for this purpose that texture factors are found widely in the literature. It has to be emphasized that the correct approach relies on the knowledge of the product μt for the layer, which enters *via* the absorption factor $A_{\theta 2\theta}$ of individual reflections into (5.4.49). Moreover, the method should be applied with caution, since misleading conclusions are easily drawn. For example, the preferred orientation has to be safely verified as a fibre texture with coinciding fibre axis $\mathbf{H}$ and substrate normal $\mathbf{s}_3$ and, moreover, the quantitative result may differ severely from that derived from a thorough harmonic analysis (Chapter 5.3).

5.4.4.2. *Pole-figure scans and analysis*

Measurements of pole figures $I_{\mathbf{h}}(\varphi, \psi)$ of single Bragg reflections, as is usual in ODF analysis, offer a more thorough approach to texture determination. The reader is thus referred to Chapter 5.3, in which the recording of pole figures and their analysis in the framework of harmonic analysis and appropriate methods is presented.

The texture strength is quantified in the harmonic method by the texture index J,

$$J = \frac{1}{4\pi} \sum_{l,\mu} (C_l^{\mu})^2, \tag{5.4.50}$$

which is the sum over the squared coefficients of the expansion coefficients of the ODF. This index might be the relevant condensate of a full harmonic analysis for the thin-film grower, since it gives a quantitative measure for texture optimization (Birkholz *et al.*, 2003).

In contrast to 'thick-sample' diffractometry ($\mu t \gg 1$), however, one has to consider the variation of information depth during the pole-figure measurement for thin films. The effect can be estimated by calculating the information depth τ according to equations (5.4.24) and (5.4.25) adapted to the actual configuration used by inserting the appropriate configuration factor k_ψ,

$$k_\psi = \frac{2}{\sin\theta\cos\psi}. \tag{5.4.51}$$

This can then be used to calculate the average information depth for ψ-tilted configurations:

$$\overline{\tau}_\psi = \frac{1}{\mu k_\psi} + \frac{t}{1 - \exp(\mu t k_\psi)}. \tag{5.4.52}$$

The influence of the tilt angle on the average information depth is shown in Fig. 5.4.13 for a set of thin $BaTiO_3$ films of various thickness and Cu $K\alpha$ radiation (μ = 0.10631 μm^{-1}). Layer thicknesses t of 0.5, 1 and 2 µm were chosen for the simulation and a reflection at $2\theta = 32°$ was investigated. The plot displays the general tendency that the average information depth $\overline{\tau}_\psi$ increases with increasing film thickness. It should be remembered that the limiting value is half the thickness, $t/2$, which would be attained for $\theta = 90°$. The value of $\overline{\tau}_\psi$ stays nearly constant close to zero tilt, but diminishes the closer the tilt angle approaches 90°. This is easily understood, since diffraction in the vicinity of $\psi = 90°$ is mainly due to layers from the utmost surface of the sample.

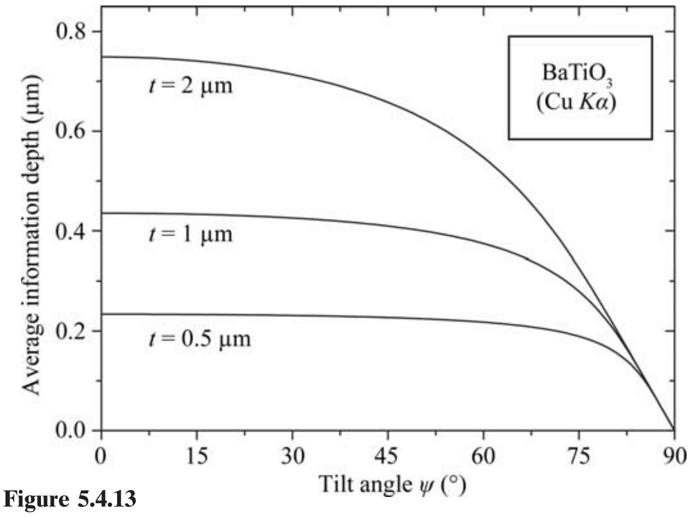

Figure 5.4.13
Average information depth $\overline{\tau}_\psi$ as a function of tilt angle ψ for a $2\theta = 32°$ reflection from thin $BaTiO_3$ films. Layer thicknesses were assumed as indicated in the figure.

It can be concluded from this example that a possible texture gradient would mainly affect the measurement for large tilt angles ψ. It is thus recommended that the variation of the information depth is estimated prior to the measurements. Depending on the result, it might be preferable to measure more pole figures with small $\psi_{\max}$ instead of a few pole figures with high $\psi_{\max}$. Otherwise, the measured pole-figure set would represent a mixture from various information depths (Bonarski *et al.*, 1998).

Pole figures are particularly clear for fibre-textured thin films, when the fibre axis $\mathbf{H}$ is oriented along the substrate normal $\mathbf{s}_3$. The measured intensity distribution $I_{\mathbf{H}}(\varphi, \psi)$ then becomes independent of the azimuth φ such that an intensity measurement for varying tilt angles $I_{\mathbf{H}}(\psi)$ contains the full orientation information. Two kinds of tilt-angle measurements may be performed: tilting in the scattering plane, which is denoted a ω scan, or tilting out of the scattering plane, which is denoted a ψ scan. The term 'rocking curve' is also frequently used for ω scans, since neither the X-ray source nor the detector are moved, but only the orientation of the sample is varied ('rocking the crystal'). The determination of FWHM values $\Delta\omega$ or $\Delta\psi$ may then serve as a quantitative measure for the degree of texture; this is a technique that is widely in use. However, defocusing corrections have to be applied to derive the crystallite orientation distribution from the intensity data (Vaudin, 1999).

Various model functions may describe the dependence of the intensity distribution $I_{\mathbf{H}}(\psi)$ on the tilt angle ψ (Bunge, 1982; Dollase, 1986). The analytical modelling may simply be performed by writing the texture factor as a function of ψ: $T_{\mathbf{H}} \rightarrow T_{\mathbf{H}}(\psi)$. It turns out that model functions of type $\cos^n \psi$ appear to be particularly suited for thin films (Birkholz, 2007; Birkholz *et al.*, 2008). They still have to be multiplied by the normalization factor N to include all crystal orientations in the irradiated volume. This results in an intensity distribution for a ψ-dependent texture factor,

$$T_{\mathbf{H}}(\psi) = \frac{n+1}{2\pi} \cos^n \psi, \tag{5.4.53}$$

in which n describes an order parameter which increases in value the more pronounced the fibre texture is. It may take any positive number, while a value of $n = 0$ accounts for a random orientation distribution. The strength of a fibre texture in the fibre pole is specified in intensity units of m.r.d. (multiples of the random distribution; Bunge, 1982; Chateigner, 2005). Applying a distribution function of the type given in equation (5.4.53) has the advantage that the parameter n directly corresponds to the m.r.d. value.

The intensity distribution for the fibre reflection then becomes

$$I_{\mathbf{H}}(\psi) = SCF\,\lambda^3\,Lp\,m_{\mathbf{H}}\,|F_{\mathbf{H}}|^2\,\frac{n+1}{2\pi}\cos^n\psi\,\frac{1}{2\mu}A_{\theta 2\theta}. \tag{5.4.54}$$

A fibre texture may be regarded as limiting the freedom of orientation of the crystallites in the out-of-plane direction, where the crystal orientation is given by the distribution function $I_{\mathbf{H}}(\psi)$. The orientation distribution in thin films may furthermore be limited to a quite small range of variation within the film plane, which is referred to as a twist and is denoted $\Delta\varphi$.

A quantitative determination of tilt may be performed in such cases by a ω scan of the fibre reflection $\mathbf{H}$ and deriving the tilt $\Delta\psi$ from the full-width at half-maximum (FWHM). This method,

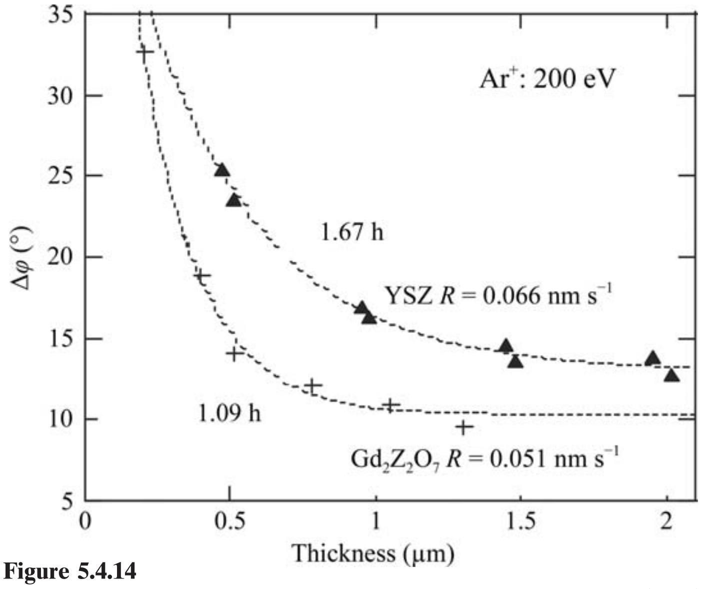

Figure 5.4.14
Thickness dependence of twist $\Delta\varphi$ for yttria-stabilized zirconia (YSZ) and $Gd_2Zr_2O_7$ films. Growth rates are indicated by R (see Iijima *et al.*, 2004).

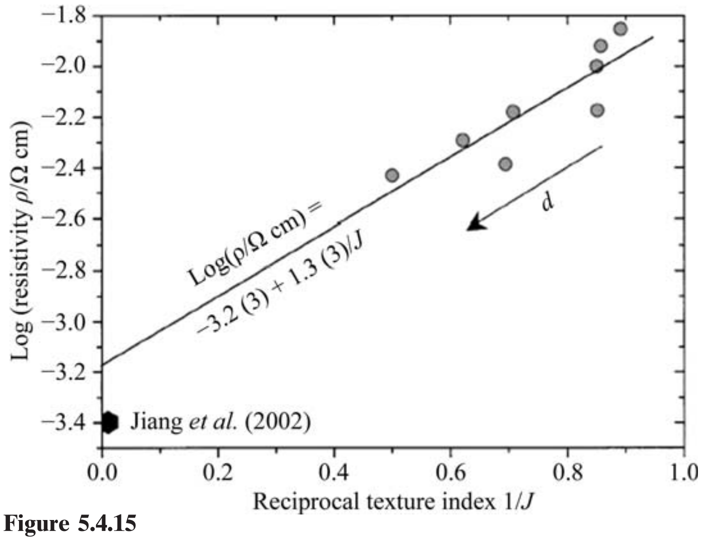

Figure 5.4.15
Resistivity of thin ZnO:Al films *versus* reciprocal texture index $1/J$ (Birkholz *et al.*, 2003).

however, will yield no information on $\Delta\varphi$. In most cases, another reflection $\mathbf{h}$ that exhibits a defined inclination with respect to the fibre reflection is measured for this purpose. The angle between the two crystallographic directions is then chosen as a constant tilt angle $\psi_t = \angle(\mathbf{h}, \mathbf{H})$ at which a rotational scan is performed within $0 \leq \varphi < 2\pi$. An intensity function $I_{\mathbf{h}}(\varphi)$ is obtained from this so-called φ scan, showing as many reflections $\mathbf{h}$ as the multiplicity $m_{\mathbf{h}}$ allows (for an example, see Fig. 5.4.14). A quantitative measure for the twist $\Delta\varphi$ is then derived from the FWHM of the reflections appearing in $I_{\mathbf{h}}(\varphi)$.

Important examples are found in thin-film technologies where a biaxial texture is required for suitable functioning of the device. One recent example is that of high-temperature superconductors (HTSCs), for which small twists and tilts can be achieved *via* clever choices of substrate and deposition process. These structural parameters directly control the superconducting currents through the scattering of Cooper pairs at grain boundaries. In yttrium barium copper oxide (YBCO) layers, for instance, quantification of the degree of texture has mainly been performed by determining $\Delta\omega$ and $\Delta\varphi$ for 103 reflections. The buffer layers for HTSC ribbon substrates are made from oxides such as MgO, CeO_2, yttria-stabilized Zr_2O_3 and $Gd_2Zr_2O_7$. The evolution of a biaxial texture in these buffer layers is supported by oblique deposition or ion-beam irradiation techniques (Iijima *et al.*, 2004; Arendt & Foltyn, 2004). In addition, the introduction of a $\{211\}\langle111\rangle$ copper-type texture into an amorphous precursor film has been demonstrated for yttria-stabilized zirconia in a combined process of oblique ion bombardment, oxidation and thermally induced crystallization (Berdahl *et al.*, 2003). The possibility of influencing the texture by ion-beam irradiation has long been recognized (Rauschenbach & Helming, 1989; Dong & Srolovitz, 1999; Birkholz, Genzel & Jung, 2004; Ellmer *et al.*, 2004), although the explanation of the effect is still controversial and under discussion.

5.4.4.3. *Texture gradients*

Thin-film textures have often been shown to exhibit pronounced depth dependence. It appears to be no exaggeration to state that whenever the effect is looked for, a gradient in preferred orientation is practically always found to occur in thin films. This phenomenon simply represents the fact that the thin-film deposition conditions change with increasing thickness. These changes are mainly related to the surface state and morphology upon which the growth processes occur, even when the thermodynamic conditions within the deposition chamber remain constant. Texture inhomogeneities may severely complicate the analysis, since pole figures become inconsistent owing to the variation of information depth during measurement [Bonarski *et al.*, 1998; Bonarski, 2006; see equation (5.4.52)].

Various techniques have been introduced for the experimental determination of texture gradients. The simplest one consists of preparing a set of samples under identical deposition conditions but of various thicknesses and measuring each sample separately (Birkholz *et al.*, 2000, 2001, 2003; Fenske *et al.*, 2005). The use of synchrotron-radiation sources allows *in situ* monitoring of selected Bragg peaks or even whole diffraction patterns during the deposition process, and valuable studies become possible with this tool (Tagliente *et al.*, 2001). However, this technique requires that the deposition system is connected to a synchrotron beamline and thus is only of limited use for most thin-film technologists. The most appealing approach for determining a texture gradient within a sample makes use of the procedures of depth monitoring by grazing-incidence techniques. By varying the incidence angle of the incoming beam, various depths of the sample are exposed to different X-ray intensities, and so is the diffracted beam.

An intensively investigated example of fibre-texture evolution is that of ZnO layers. ZnO and its derivatives may be used for various optoelectronic thin-film applications, among them the use of Al-doped ZnO for transparent electrodes in solar cells and liquid-crystal displays. Wurtzite-structured ZnO has been shown to exhibit an almost universal tendency to develop a *c*-axis layer texture during many different deposition processes (Kajikawa *et al.*, 2003; Kajikawa, 2006). In one of the few texture studies where the C_l^{μ} coefficients of the harmonic analysis were determined for thin-film samples, the texture index was found to be directly related to the resistivity of the ZnO:Al layers (Birkholz *et al.*, 2003). Fig. 5.4.15 shows the resistivity ρ of a set of eight ZnO:Al samples from a thickness series *versus* the inverse of the texture index, $1/J$, derived from the C_l^{μ} coefficients. A structure–function relationship could be established for the two parameters, relating the resistivity to the inverse texture index *via* $\rho = A\exp(B/J)$. According to a grain-boundary scattering model developed in this work, a value of $\rho = 6.9 \times 10^{-4}\,\Omega\,\mathrm{cm}$ was predicted for perfectly aligned ZnO:Al crystallites having $1/J = 0$. This value corresponds within the experimental margins of errors to one of the lowest resistivity values measured in a highly textured thin ZnO:Al film (Jiang *et al.*, 2002), shown as a black hexagon in the figure.

Preferred orientation has also been extensively investigated in semiconductor layers. Thin polycrystalline silicon films (poly-Si), as used for contacting the transistor-gate oxide in a metal–oxide–semiconductor field-effect transistor (a MOSFET), were shown to exhibit a pronounced layer texture, changing from an ($hh0$) preferred orientation observed at medium temperatures to ($h00$) at higher temperatures (Bisaro *et al.*, 1986; Wenk *et al.*, 1990). This effect was also observed for microcrystalline thin Si films intended for solar-cell applications, for which the depth dependence was accounted for by a power law, showing that the layer texture increased with $t^{1/6}$ (Birkholz *et al.*, 2000).

The concept of texture factors $T_{\mathbf{H}}$ offers a route to describing the depth dependence of a fibre texture by introducing a z dependence into $T_{\mathbf{H}}$, *i.e.*

$$T_{\mathbf{H}}(\psi) \rightarrow T_{\mathbf{H}}(\psi, z). \qquad (5.4.55)$$

In accordance with the arguments given in Section 5.4.3.3, it was shown in Birkholz (2007) that the tilt-angle-dependent intensity distribution given in (5.4.47) may then be expressed as

$$I_{\mathbf{h}}(\psi) = SCF\,\lambda^3\,Lp\,|F_{\mathbf{h}}|^2\,m_{\mathbf{h}}\,\frac{k}{2}\,\mathcal{L}^t(T_{\mathbf{h}}), \qquad (5.4.56)$$

where $\mathcal{L}^t(T_{\mathbf{h}})$ represents the finite Laplace transformation of the depth-dependent texture distribution function:

$$\mathcal{L}^t[T_{\mathbf{h}}(\psi, z)] = \int\limits_0^t T_{\mathbf{h}}(\psi, z)\exp(-\mu z k)\,\mathrm{d}z. \qquad (5.4.57)$$

This is the fundamental equation for describing the intensity distribution of a depth-dependent fibre texture. It directly represents the experimental result that is obtained by the thin-film diffractionist when measuring the intensity as a function of tilt ψ. The solution of the equation is not trivial and attempting it requires some assumptions to be made about the analytical form of $T_{\mathbf{h}}(\psi, z)$.

It is particularly useful to express the texture depth dependence through the order parameter n that was introduced in equation (5.4.53) for the $\cos^n \psi$ distribution of crystallite orientations. The increase in the texture strength may rather naturally be represented by a z-dependent index $n(z)$ increasing with thickness. In the simplest case, n is regarded as a first-order polynomial with the film growth starting at n_0 and continuously increasing by $n_1 z$ with sample thickness:

$$n \rightarrow n_0 + n_1 z. \qquad (5.4.58)$$

A solution to (5.4.57) was developed with this approach in Birkholz (2007). It makes use of a modified attenuation coefficient

$$M = \mu k - n_1 \ln(\cos\psi), \qquad (5.4.59)$$

by which the tilt-angle-dependent intensity distribution can be given in an analogous form to (5.4.54),

$$I_{\mathbf{H}}(\psi) = SCF\,\lambda^3\,Lp\,m_{\mathbf{H}}\,|F_{\mathbf{H}}|^2\,\tilde{N}\cos^{n_0}\psi\,\frac{k}{2M}\tilde{A}(t). \qquad (5.4.60)$$

Here, $\tilde{A}$ and $\tilde{N}$ represent the modified absorption and normalization factor, respectively:

$$\tilde{A}(t) = 1 - \exp(-Mt) = 1 - (\cos^{n_1 t}\psi)\exp(-\mu t k), \qquad (5.4.61)$$

$$\tilde{N} = \frac{1}{2\pi}\left[n_0 + n_1 t\left(\frac{1}{Mt} + \frac{1}{1-\exp(Mt)}\right) + 1\right]. \qquad (5.4.62)$$

These terms take the correct limiting values, *i.e.* $\tilde{A} \rightarrow A$ and $\tilde{N} \rightarrow (n_0 + 1)/(2\pi)$ for $n_1 \rightarrow 0$.

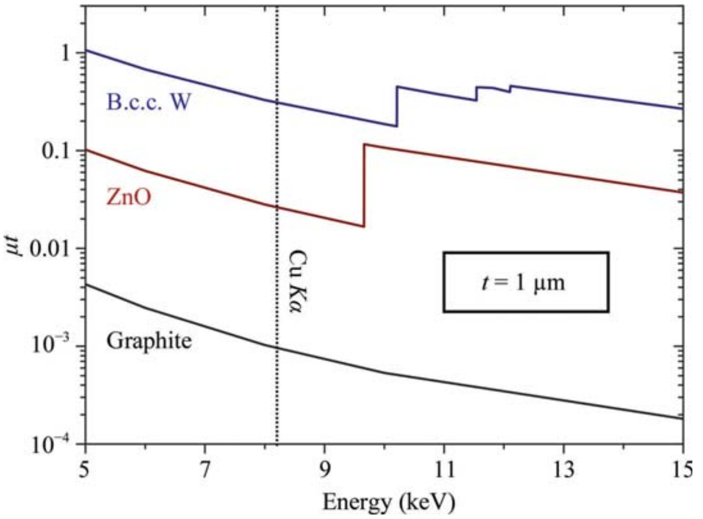

Figure 5.4.16

Variation of the products μt of representative thin-film materials having high, average and low electron densities in the X-ray energy range between 5 and 15 keV. The thickness of the films is assumed to be 1 μm (Birkholz, 2007).

A technique was presented in Birkholz *et al.* (2008) that allows the determination of texture gradients in a single sample by the use of 'coloured' X-ray probes. Instead of preparing a set of samples of different thickness, the information depth is varied by exploiting the dependence of the product μt on the X-ray wavelength. The procedure is particularly effective at the absorption edges of one of the elements forming the layer, where diffraction patterns can be recorded above and below the absorption edge. In general, the technique requires access to a synchrotron beamline, where, favourably, both powder diffraction and EXAFS experiments are routinely performed (Erko *et al.*, 2004). Fig. 5.4.16 shows the variation of the product μt of 1 μm-thin layers from examples of b.c.c. W, ZnO and graphite between 5 and 15 keV. A drastic change in μt by an order of magnitude is seen to occur at the Zn K edge at 9.67 keV. Measurements of ZnO 002 reflections in Birkholz *et al.* (2008) were thus performed at 8 and 10 keV, and texture gradients n_1 were found by this procedure to range from 0.03 to 0.3 m.r.d. nm^{-1}. These high values indicate a strong reconstruction of microstructure during growth, showing the significance of effective control of the texture during thin-film growth for engineering its properties. Collection of more data, such as n_1 values from other layer systems, would be of great interest in order to obtain a better understanding of the physical phenomena governing the evolution of texture, and the formalism presented in equations (5.4.54) to (5.4.62) offers a route to this approach.

5.4.5. Stress and strain analysis

The field of stress analysis by X-ray scattering techniques is outlined in Noyan *et al.* (1995), Hauk (1997), Welzel *et al.* (2005) and Birkholz & Genzel (2006), and in Chapter 5.2 of this volume. Here, only some remarks and references will be given with respect to the investigation of thin films and multilayers.

Remarkably high residual stresses $\sigma_{\rm RS}$ up to the GPa range may arise in thin films, stresses that are mainly caused by either (i) the difference in thermal-expansion coefficients of the substrate and layer or (ii) ion bombardment during plasma-assisted deposition processes. Residual stresses in thin films are anisotropic *par excellence*, *i.e.* a compressive (tensile) strain $\sigma_{\|}$ in the layer plane corresponds to a tensile (compressive) strain $\sigma_{\perp}$ along the substrate normal. The difference in interplanar spacing $\Delta d = (d - d_0)/d_0$ as measured in a symmetric $\theta/2\theta$ scan accounts for the strain $\varepsilon_{\perp}$ in the direction of the substrate normal and the experimentalist is asked to derive $\sigma_{\|}$ from it, since the state of residual stress, which is either compressive or tensile, is always indicated with respect to the in-plane stress $\sigma_{\|}$. The integral stress state may be determined without X-ray diffraction by measuring the bending of the sample and analysing it using the Stoney formula (Ohring, 2002), which works better the thinner the substrate.

A thorough investigation of residual stresses in thin films, however, requires the recording of a set of components of the strain tensor $\boldsymbol{\varepsilon}_{ij}$ by X-ray diffraction procedures, which may become a challenging task because of the occurrence of stress gradients and the interaction of stress and microstructure (texture and grain interaction). The presence of stress gradients and texture mean that the classical $\sin^2\psi$ method for stress analysis seldom yields reliable results for thin films. The scattering-vector method as used in single-crystal diffractometry was therefore introduced into the field by Genzel and combined with GIXRD in such a way that the variation of information depth may encompass the full thickness of a layer (Genzel, 1994, 2001). It was found that residual-stress gradients could be determined with a previously unattained precision by applying the technique to different hard coatings (Genzel & Reimers, 2003; Klaus *et al.*, 2006, 2008). A dedicated beamline has been commissioned at BESSY II, where residual stresses in thin films and near-surface layers in other materials may be investigated by virtue of energy-dispersive diffraction (Genzel *et al.*, 2007; Klaus *et al.*, 2009). In addition, a whole-pattern fitting program for Rietveld refinement against energy-dispersive synchrotron data has been developed for analysis (Apel *et al.*, 2011). This setup thus allows the experimenter to perform depth-resolved measurements with varying probe energies, as outlined above for determining texture gradients, and which has also been applied to the investigation of stress gradients (Wohlschlögel *et al.*, 2008).

In addition to the occurrence of stress gradients, the morphology may also have a pronounced effect on the residual-stress state. The underlying physical cause is easily understood, since the compliance C_{ij} or stiffness S_{ij} values with the elastic constants will not govern the stress alone, but the stress state will depend on the precise mechanical interactions of the crystallites, *i.e.* a grain-interaction model has to be included (Faurie *et al.*, 2009; Ortolani *et al.*, 2009). The best-established models are those of Voigt (1910) and Reuss (1929), which assume a constant strain or stress, respectively, to act between the crystallites. Both models seem to describe outlier cases, and reliable results for thin films have been obtained with the combined model of Hill (1952). In the case of polycrystalline layers, however, the effects of texture (Genzel, 2001, 2004; Birkholz, Genzel & Jung, 2004; Martinschitz *et al.*, 2009; Faurie *et al.*, 2011), anisotropic crystallite growth (Welzel *et al.*, 2003) and the occurrence of nanometre-sized crystallites (Birkholz, Albers & Jung, 2004; Kuru *et al.*, 2008), for which the mechanical properties may differ from macroscopic and mesoscopic materials, represent further challenges.

5.4.6. X-ray reflectivity (XRR)

It was shown in Section 5.4.3.4 that the X-ray index of refraction $\hat{n} = 1 - \delta - i\beta$ contains information on the density and chemical composition of the sample. In fact, the constants δ and β do not depend on the mass density, but on the electron density ρ_e. However, combining the knowledge of ρ_e with reliable assumptions allows interesting conclusions to be drawn about the sample composition.

Both the parameters δ and β may be determined from the measurement of the X-ray reflectivitiy (XRR), and this method has become an important characterization technique for thin films and multilayers (Daillaut & Gibaud, 2009). XRR does not rely on the diffraction of X-rays; rather it makes use of reflection and refraction like in optical ellipsometry, where the complex index of refraction is determined. The decisive distinction between the two methods is the radiation wavelength, which differs by about three orders of magnitude. Because of this, the associated phenomena may be observed only under very small incidence angles in the X-ray case. A further characteristic derives from the fact that the index of refraction n is smaller than unity for X-rays. Therefore, on passing from air into the film, the beam enters the less-dense optical medium, which is the opposite situation to that encountered in ellipsometry.

The use of XRR for the investigation of thin films has steadily increased in recent years. This development is rooted in the fact that the technique yields important information on structural quantities such as the depth-resolved electron density $\rho_e(z)$, the layer thickness t and the surface roughness. In addition, the sample may be amorphous and does not need to consist of crystalline matter, since the technique does not rely on diffraction.

5.4.6.1. *Reflectivity from a substrate*

XRR measurements are performed in a $\theta/2\theta$ mode, but in contrast to the conventional powder-diffraction setup the divergence of the incoming beam should be as low as possible. Experiments are thus preferably performed with a parallel-beam geometry as in GIXRD. In the following, the incidence and critical angles will be referred to as θ and θ_c instead of α and α_c as used in Section 5.4.3.

Firstly, the reflectivity from an uncovered substrate will be considered. For this purpose, the ratio of the reflected to incoming beam intensities I_R/I_0 should be calculated. The quotient is derived from the appropriate Fresnel coefficient by making use of the continuity of the tangential electric field component of the incident and reflected beam, giving

$$\frac{I_R}{I_0} = \left| \frac{\theta - (\theta^2 - \theta_c^2 - 2i\beta)^{1/2}}{\theta + (\theta^2 - \theta_c^2 - 2i\beta)^{1/2}} \right|^2. \qquad (5.4.63)$$

This expression is derived by equating $\sin\theta \simeq \theta$ *etc.*, as is allowed for small θ.

Equation (5.4.63) has two remarkable properties. Firstly, it yields a constant value of unity for $\theta < \theta_c$ and, on the other hand, it describes a very steep decrease for $\theta > \theta_c$. The latter effect becomes obvious when numerical values are inserted, such as a typical critical angle $\theta_c = 0.23^\circ$ (4×10^{-3} rad, $2\delta = 1.6 \times 10^{-5}$) and a vanishing absorption $\beta = 0$ is assumed. While $I_R/I_0 = 1$ then holds for all $\theta \leq 0.23^\circ$ because of total reflection, the intensity ratio declines by 3.5 orders of magnitude at $\theta = 2.3^\circ$ and, even more drastically, to a few 10^{-7} at $\theta = 4.6^\circ$. This means that a

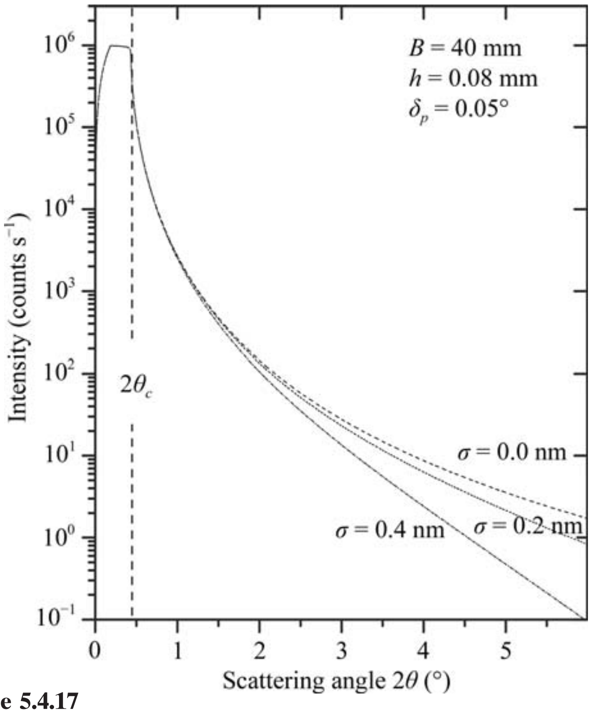

Figure 5.4.17
Simulation of an X-ray reflectivity scan from a quartz glass substrate of varying surface roughness σ probed by Cu $K\alpha$ radiation. δ_p and h represent the in-plane divergence and height of the beam, respectively, and B accounts for the in-plane extent of the sample.

dramatic intensity drop of almost seven orders of magnitude is observed in the range of scattering angles 2θ from 0.46 to 9.2°.

As an example, Fig. 5.4.17 displays the X-ray reflectivity of a fused silica substrate that was calculated using equation (5.4.63) for Cu $K\alpha$ radiation (using δ and β as given in Table 5.4.1). The region of total reflection up to θ_c and the steep decrease beyond can clearly be recognized. In an XRR experiment, the course of $I(2\theta)$ is measured in the vicinity of θ_c and the intensity curve is subjected to a numerical regression, from which the material constants δ, β and ρ_e are obtained.

So far, only an ideally smooth sample surface has been considered. It is evident, however, that any surface roughness will cause an even steeper decrease due to a loss of intensity scattered into the detector. The effect may be modelled by multiplying (5.4.63) by a factor $\exp(-\sigma^2 Q^2)$, which resembles a Debye–Waller factor. Here, σ accounts for the r.m.s. (root-mean-square) roughness of the surface and is given by

$$\sigma = \textstyle\int [z(x,y)^2 - \overline{z}^2]^{1/2}\,\mathrm{d}x\,\mathrm{d}y \Big/ \textstyle\int \mathrm{d}x\,\mathrm{d}y, \qquad (5.4.64)$$

where $\overline{z}$ represents the average height. Fig. 5.4.17 demonstrates the effect of surface roughness on the measured pattern by displaying the reflectivity curves of perfectly smooth fused silica and those with small r.m.s. roughnesses of 0.2 and 0.4 nm. Apart from the steeper decrease in intensity, rough surfaces also give rise to a diffuse component to the observed intensity. The reflectivity can thus be considered to be composed of a specular component and a diffuse component,

$$I(2\theta) = I_{\rm specular} + I_{\rm diffuse}. \qquad (5.4.65)$$

For high levels of surface roughness and at high scattering angles the diffuse component is similar in magnitude to the specular component and must be included. In many thin-film applications, however, it is sufficient to evaluate the XRR curve as being purely specular and to include the effects of surface roughness by modelling the Fresnel coefficient in combination with modified Debye–Waller factors.

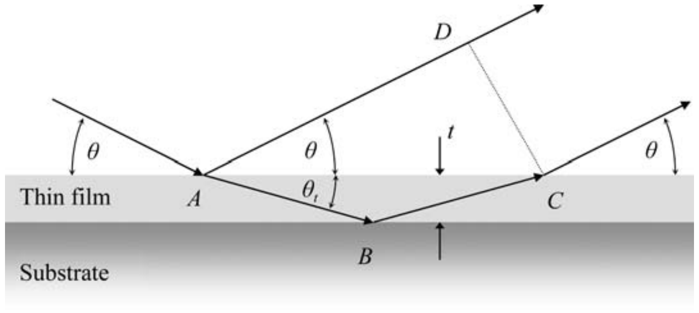

Figure 5.4.18
Scheme of reflected and refracted beams for deriving the phase difference Δ.

5.4.6.2. *Reflectivity of a single layer*

In addition to the steep intensity decline for $\theta > \theta_c$, the XRR pattern of a single-layer sample shows additional features caused by the interference of X-rays reflected at the layer surface and the film–substrate interface. This phenomenon is well known from optical ellipsometry, where it leads to characteristic intensity oscillations from which the layer thickness t may be deduced. Comparable intensity oscillations were first observed for X-rays by Kiessig in 1930 during his investigation of thin Ni films on glass. By using monochromatic X-rays, he observed intensity oscillations in the reflected pattern upon tilting the X-ray mirror in a static source–detector configuration (Kiessig, 1931*a*,*b*). These intensity oscillations were subsequently named Kiessig fringes.

A schematic drawing of the interfering beams is shown in Fig. 5.4.18. It can be seen that their phase difference is given by

$$\Delta = (AB + BC)n - AD, \qquad (5.4.66)$$

where n is the real part of the index of refraction, $n = 1 - \delta$. Since the incidence angle of the transmitted beam θ_t depends on both the critical angle θ_c and the incidence angle of the primary beam, it follows from $AB = BC = t/\sin\theta_t$ and Snell's law, $n = \cos\theta/\cos\theta_t$, that Δ is given by

$$\Delta = 2t\sin\theta_t \text{ or } \Delta \simeq 2t\theta_t = 2t(\theta^2 - \theta_c^2)^{1/2}. \qquad (5.4.67)$$

The phase difference has to be an integral multiple of the wavelength for constructive interference to occur, *i.e.* $\Delta = m\lambda$ should hold. This results in positions of the intensity maxima given by

$$\theta_m^2 = \theta_c^2 + \left(\frac{\lambda}{2t}\right)^2 m^2. \qquad (5.4.68)$$

This is the basic equation from which the thickness of a thin film may be determined by X-ray reflectivity. Its value is usually derived by fitting the reflectivity curve with the thickness t as a refinable parameter. The method is limited to a maximum value of about 100–200 nm, the precise value of which depends on the instrumental and sample properties such as beam divergence, possible bowing of the substrate, surface and interface roughness, and other factors that cause the smearing out of the sharp fringes that are required for the numerical regression. Fig. 5.4.19 displays an X-ray reflectivity curve of a 25 nm-thin Ta_2O_5 film on a glass substrate that was calculated using the XRR simulation program *RCRefSim* (Zaumseil, 2005).

The small 2θ spacing between fringe maxima is the main reason for requiring a preferably zero-divergent beam for XRR

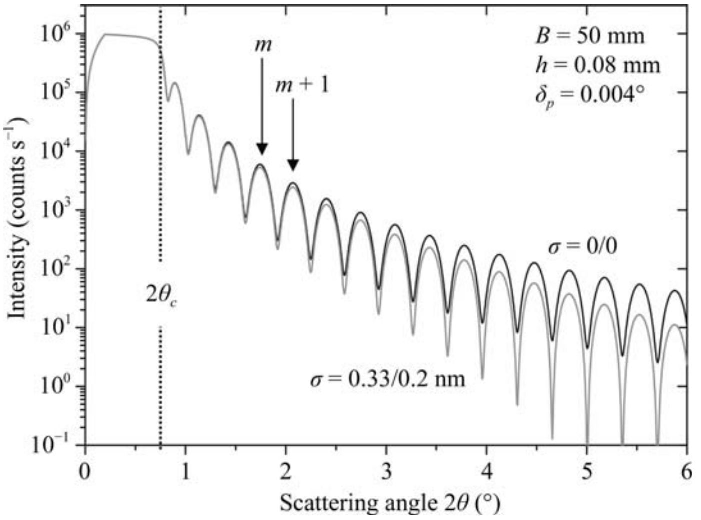

Figure 5.4.19
Simulated X-ray reflectivity of a Ta_2O_5 thin film, t = 25 nm, on a fused silica substrate recorded with Cu $K\alpha$ radiation. The upper curve is for a smooth surface and interface (black), while the lower curve is for 0.2 nm interface roughness and 0.33 nm surface roughness (grey).

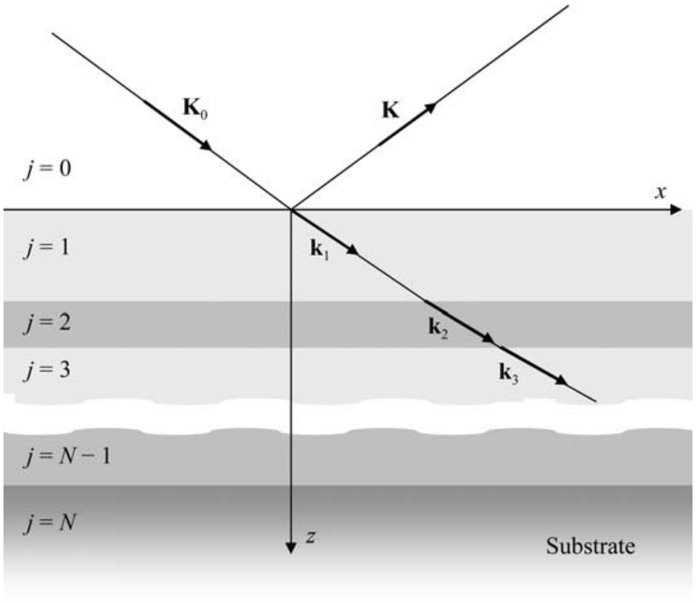

Figure 5.4.20
Notion of participating wavevectors of XRR of a multilayer system.

experiments. It is evident that fringing would not be observed if the divergence is comparable to the fringe separation. On the contrary: the smaller the beam divergence is, the thicker the layer may be for Kiessig fringes to be resolved. Like the high dynamic range in intensity that has to be dealt with in XRR, this constraint favours the use of synchrotron radiation. Dedicated XRR beamlines are thus available at synchrotron-radiation facilities that offer the possibility of recording XRR patterns within very short times. On the other hand, modern powder diffractometers can also be equipped with beam-shaping devices for parallel-beam experimentation, such as laterally graded multilayer mirrors (Chapter 2.1). Together, these developments made XRR a routine thin-film characterization technique that is widely in use, in particular for low-electron-density organic and biological materials (see, for example, Miller *et al.*, 2005; Birkholz *et al.*, 2006; Chen *et al.*, 2011). Detailed investigations of thin-film growth have also been carried out using this technique, revealing a wealth of structural information on density, roughness, molecular orientation *etc.* and their evolution during growth (Kowarik *et al.*, 2006; Hosokai *et al.*, 2010).

5.4.6.3. *Reflectivity of multilayers and superlattices*

In XRR measurements of multilayer systems, the incident-beam intensity will be reduced by the effects of reflection at interfaces and absorption in individual layers. The calculation of the reflected-beam intensity is based on the continuity condition of the tangential components of the electric fields and the conservation of tangential components of the wavevectors at the different interfaces. Parrat solved this task in 1954 during the investigation of surface-oxidation effects of metallic layers (Parratt, 1954).

A schematic of a multilayer system is depicted in Fig. 5.4.20. The layers are numbered in increasing order from the top to the bottom. In the matrix-technique approach (Gibaud & Hazra, 2000), the reflectivity of the multilayer system is described using reflection coefficients $r_{j,j+1}$,

$$r_{j,j+1} = \frac{k_{z,j} - k_{z,j+1}}{k_{z,j} + k_{z,j+1}}, \tag{5.4.69}$$

that contain the z wavevector components $k_{z,j}$ and $k_{z,j+1}$ in the two neighbouring media and account for the reflection of the incoming and the exiting beam at the j, $j + 1$ interface. A set of 2 × 2 matrices is introduced for each interface j, $j + 1$ and for each layer j, which are the refraction and transfer matrices $\boldsymbol{R}_{j,j+1}$ and $\boldsymbol{T}_j$, respectively. The product of all of these establishes the transfer matrix $\boldsymbol{M}$, with the ratio of the M_{12} and M_{22} components giving the amplitude of the multilayer reflectivity. Applying the procedure to a single-layer system results in an expression for the intensity of the reflected beam,

$$\frac{I_R}{I_0} = \frac{r_{0,1}^2 + r_{1,2}^2 + 2r_{0,1}r_{1,2}\cos 2k_{z,1}t}{1 + r_{0,1}^2 r_{1,2}^2 + 2r_{0,1}r_{1,2}\cos 2k_{z,1}t}, \tag{5.4.70}$$

that depends on the reflection coefficients of the air–film interface, $r_{0,1}$, and the film–substrate interface, $r_{1,2}$, according to (5.4.70). The ratio also accounts for the oscillation phenomena observed in Fig. 5.4.19 *via* the cosine term, which depends on the layer thickness t. The recursion scheme of the matrix technique allows it to be effectively integrated into computer code. Moreover, surface-roughness effects may also be included by multiplying the reflection coefficients by Debye–Waller-factor-like damping terms that contain the r.m.s. roughness of all individual j, $j + 1$ interfaces.

Analytical expressions for the reflectivity of multilayers with two and more layers become rather complicated, making it difficult to recognize the underlying physics. Instead of presenting the generalization of (5.4.70) to two-layer, three-layer systems and so on here, an example for a complex multilayer architecture is given. Fig. 5.4.21 displays a set of simulations from a thermal-barrier multilayer that comprises a stacking of oxide and metal layers, and small differences in the assumed architecture can be seen to cause substantial changes in the XRR pattern.

XRR may also uncover the inner architecture of periodic multilayers, which are also denoted as superlattices. These layer structures essentially comprise a stack of N pairs of layers of type A and B, where the thicknesses of individual layers t_A and t_B add up to the superlattice period $t_{\rm per}$,

$$t_{\text{per}} = t_A + t_B. \tag{5.4.71}$$

Such superlattices are fabricated for applications as so-called Bragg mirrors in light-emitting devices or as X-ray mirrors. The X-ray reflectivity curves of such multilayers have various characteristic features that are illustrated for the example of an X-ray mirror system in Fig. 5.4.22. The figure also displays the reflectograms of a 10 × (6 nm TiO_2/6 nm C) superlattice on an Si substrate that was again calculated using *RCRefSim* (Zaumseil, 2005). As for the single-layer system, a modified Bragg equation (5.4.53) may be derived describing the occurrence of the superlattice peaks by inserting t_{per} instead of t,

$$\theta_m^2 = \langle\theta_c\rangle^2 + m^2\left(\frac{\lambda}{2t_{\text{per}}}\right)^2, \tag{5.4.72}$$

where $\langle\theta_c\rangle$ is the average critical angle of the total superlattice. The thickness values for each individual layer A and B and the interface roughness σ_{AB} and σ_{BA} can be determined by fitting with the matrix formalism. The figure displays three different simulations with varying interface roughnesses. The difference between the large fringes is accounted for by (5.4.72), while the small fringing scales with the total thickness of the layer system, *i.e.* $1/(Nt_{\text{per}})$. Ideally, there are $N - 2$ small fringes between two adjacent superlattice peaks. It can be realized from the figure that for certain combinations of σ_{AB} and σ_{BA} every second maximum may vanish. This effect may be observed in superlattices having $t_A = t_B$ and is due to the destructive interference from X-ray beams reflected at the AB and BA interfaces.

Superlattices with large differences in electron density between individual layers can be used as X-ray mirrors. Typical material combinations are Mo/Si, V/C or La/B_4C and other systems with substantial ρ_e contrast. XRR also provides a sensitive tool for studying the surface oxidation of metals and other materials that are sensitive to surface oxidation. In fact, in his seminal study Parrat investigated a thin copper film on glass, where reliable agreement between the measured and simulated reflectivity could only be achieved by introducing a 15 nm-thin surface-oxide layer into the model (Parratt, 1954). The possibility that there may be an oxide layer on the top of a thin-film or multilayer system should routinely be considered when fitting measured reflectivity curves. Surface chemical reactions may also be studied by XRR.

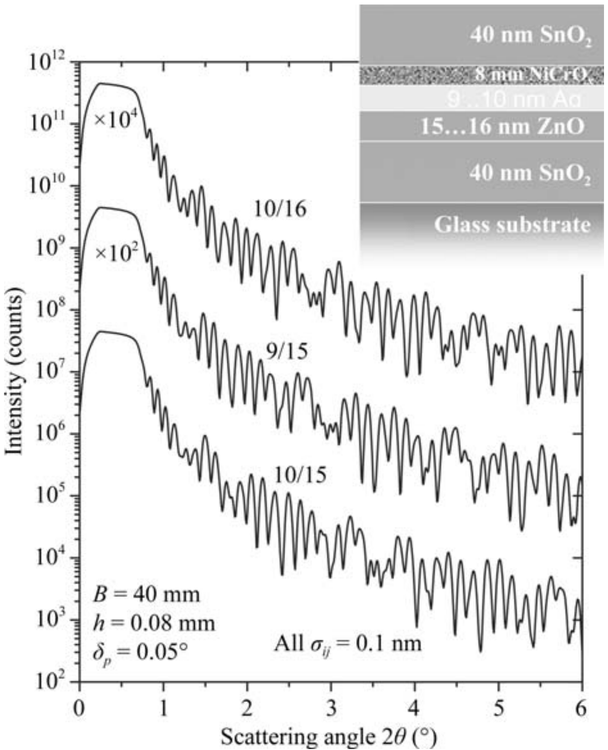

Figure 5.4.21

Simulated X-ray reflectivity patterns of barrier coating SnO/NiCrO$_x$/Ag/ZnO/SnO on glass recorded with Cu $K\alpha$ radiation. The numbers above each pattern indicate the thicknesses of the Ag and ZnO layers, respectively, in nanometres. Other thicknesses were kept constant.

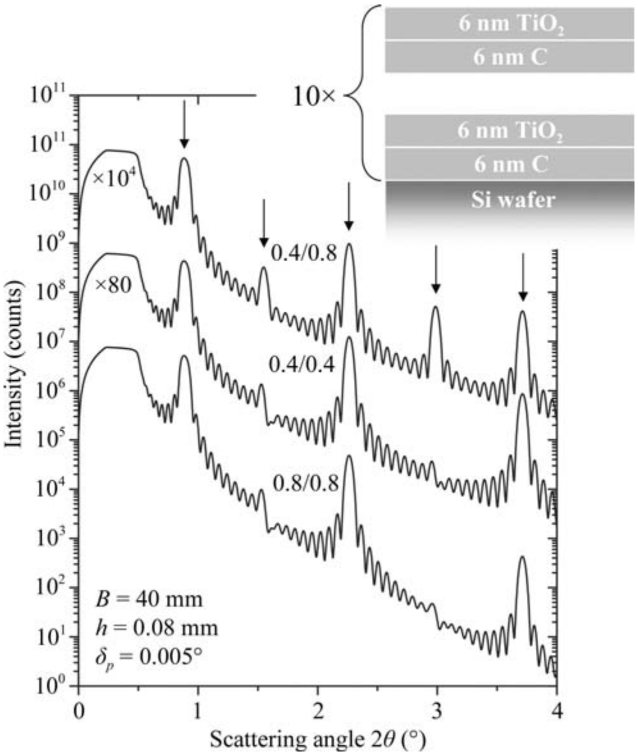

Figure 5.4.22

Simulation of X-ray reflectivity of a (TiO_2/C) superlattice on an Si wafer. The numbers above the pattern give the roughnesses of the TiO_2 and C layers, respectively, in nanometres. The substrate roughness was set to a constant 0.4 nm. Superlattice peaks are indicated by arrows.

5.4.7. Grazing-incidence X-ray scattering (GIXS)

In a GIXS experiment, a primary beam with momentum $\mathbf{K}_0$ impinges on the sample at a very small incidence angle, as in XRR. Again, the elastically scattered intensity with momentum vector $\mathbf{K}$, $|\mathbf{K}| = |\mathbf{K}_0| = 2\pi/\lambda$, is measured in a reflective configuration, but it is not the specular reflection alone that is measured by a point detector. Instead, the intensity in GIXS is collected by a two-dimensional detector screen, allowing scattering events for which the scattering vector $\mathbf{Q} = \mathbf{K} - \mathbf{K}_0$ deviates from the substrate normal to also be recorded. The incidence angle between the primary (scattered) beam and the substrate surface is generally denoted by α_i (α_f), while the azimuth of the scattered beam is indicated by $2\theta_f$. The two-dimensional intensity map is then given as a function of momentum-transfer coordinates Q_y and Q_z according to

$$\begin{aligned} Q_y &= \frac{2\pi}{\lambda}\sin\theta\cos\alpha_f\sin 2\theta_f, \\ Q_z &= \frac{2\pi}{\lambda}\sin\theta(\sin\alpha_i + \sin\alpha_f), \end{aligned} \tag{5.4.73}$$

where the projection of $\mathbf{K}_0$ to the sample surface is assumed to define the x axis. The method is often used with small scattering angles, and in this case is denoted as GISAXS. The analysis of the intensity patterns obtained is then performed within the conceptual framework developed for small-angle X-ray scattering (SAXS) (Chapter 5.8). The parameters to be derived are characterized by low momentum transfer and real-space extents that are much larger than the probing wavelength (Müller-Buschbaum, 2009). For thin films, for instance, the shape and size of the scattering entities in nanogranular films or nucleation layers have been investigated (d'Acapito & Zontone, 1999; Stangl *et al.*, 1999; Leroy *et al.*, 2003). This approach has also been extended to a grazing-exit configuration (GESAXS), where the scattering pattern in the $\alpha_f < \alpha_c$ range is monitored and the coherence of the radiation is employed (Pfeiffer *et al.*, 2004). Interesting results on the evolution of the microstructure of thin metal films during annealing have been obtained (Zhang & Robinson, 2007).

Experiments in a GIXS configuration meanwhile extend beyond the classical SAXS investigation, since diffraction peaks are often also observed and combined-analysis techniques have been developed to derive complete structural information from the measured intensity map. An important role in the development of the method has been played by diblock copolymers, owing to their pronounced tendency for forming self-assembled nanostructures such as, for instance, hexagonally perforated layers (Heo *et al.*, 2008). In general, GIXS is well suited for the investigation of organic thin layers (Jiang *et al.*, 2012).

5.4.8. Conclusions and perspective

To summarize, it is recommended that powder diffractionists start investigating a thin-film or multilayer by determining the product μt (or the set of products μt). Combining this result with knowledge of sample preparation will allow a critical estimation of the chemical composition and possible inhomogeneities. Subsequently, the texture and possible texture gradients should be investigated and, on the basis of these results, further microstructural properties such as the effective electron density, the extension of coherently scattering domains (the 'X-ray grain size') and residual stresses and their gradients can be examined. The results that are obtained will enable a basic understanding of the structure–function relationships operating within the sample and suggest possible ways to improve its properties. Most of the methods presented here will be helpful in this respect; it should be remembered, however, that a truly comprehensive picture becomes visible when different probing techniques are combined: either X-ray scattering methods only or in combination with other probes such as optical probes, ion beams, magnetic resonance *etc.*

It might be expected that the high rate of development of this field will continue and probably even increase in the next few years. A search for the combination of the terms 'X-ray diffraction' and 'thin film' in Google Scholar yielded an increase from about 6000 records in 2001 to more than 26 000 in 2017. It has thus become impossible to provide a complete overview of all the relevant developments in the field. In spite of this, I hope to have presented the most important aspects for the newcomer to the field as well as for the expert, and apologize if any of my colleagues feel that their work has been under-represented.

It seems that the unspoken programmatic goal of thin-film technology and analysis is to become capable of indicating the chemical nature and spatial position $r_i = (x_i, y_i, z_i)$, $i = 1, \ldots, N$, of every atom forming the layer *and* to describe how this set of data depends on the deposition conditions. Coming ever closer to this holy grail will pave the way to predicting the layer properties *in silico* with ever more accuracy. Although this goal has not been declared by any national or international agency or association, it represents an inherently crystallographic programme, since crystallography seeks the development of methods that allow the prediction of the properties of crystalline matter from the relative arrangement of their atomic constituents. It is obvious that the field of thin films and multilayers will develop in this direction, and perhaps will reach this target earlier than we expect today. The various X-ray powder-diffraction techniques that are in use and under development will continue to deliver indispensable contributions during this fascinating journey.

5.5. Multigrain crystallography and three-dimensional grain mapping

H. F. Poulsen and G. B. M. Vaughan

5.5.1. List of symbols

2θ: Bragg diffraction angle.

$(\mathbf{x}_l, \mathbf{y}_l, \mathbf{z}_l)$: laboratory frame; $\mathbf{x}_l$ lies along the incident beam, $\mathbf{y}_l$ and $\mathbf{z}_l$ are perpendicular to the incident beam, laterally and vertically.

(x_l, y_l, z_l): position of the origin of a scattering event in the laboratory frame; the centre of mass of a diffracting crystal.

ω: rotation around $\mathbf{z}_l$

η: rotation around $\mathbf{x}_l$

$(x_\omega, y_\omega, z_\omega)$: rotated sample frame.

$\mathbf{\Omega}$, $\mathbf{X}$, $\mathbf{\Theta}$: rotation matrices of a generalized goniometer.

$\mathbf{\Gamma}$: total rotation matrix, $\mathbf{\Gamma} = \mathbf{\Omega X \Theta}$.

$(y_{\rm raw}, z_{\rm raw})$: detector coordinates on the face of the detector.

SC: spatial-distortion operator on the face of the detector.

$(y_{\rm det}, z_{\rm det})$: spatially corrected detector coordinates in the detector frame.

$(\varphi_x, \varphi_y, \varphi_z)$: right-handed detector tilts around $(\mathbf{x}_l, \mathbf{y}_l, \mathbf{z}_l)$.

$\boldsymbol{R}^X$, $\boldsymbol{R}^Y$ and $\boldsymbol{R}^Z$: detector rotation matrices corresponding to rotations of φ_x, φ_y and φ_z, respectively.

$\boldsymbol{R}$: total detector rotation matrix, $\boldsymbol{R}^X\boldsymbol{R}^Y\boldsymbol{R}^Z$.

$[y_{\rm det}(0), z_{\rm det}(0)]$: pixel coordinates for the incident ray passing through $(x_l, y_l, z_l) = (0, 0, 0)$.

P_y, P_z: pixel sizes on the detector face along $\mathbf{y}$ and $\mathbf{z}$.

$\mathbf{G}$: scattering vector (G vector)

$\mathbf{G}_l$, $\mathbf{G}_\omega$, $\mathbf{G}_\gamma$, $\mathbf{G}_s$, $\mathbf{G}_c$, $\mathbf{G}_{hkl}$: G vectors in the laboratory frame, ω frame, rotated frame, sample frame, Cartesian grain frame and reciprocal-lattice frame, respectively.

$\boldsymbol{S}$: rotation of the sample with respect to the goniometer rotation axes.

$\boldsymbol{U}$: rotation of a grain with respect to the sample.

$\boldsymbol{B}$: rotation between the Cartesian grain and reciprocal-lattice frames.

$(\mathbf{x}_c, \mathbf{y}_c, \mathbf{z}_c)$: Cartesian grain frame.

$(\mathbf{a}^*, \mathbf{b}^*, \mathbf{c}^*)$: reciprocal-lattice frame.

(hkl): Miller indices.

$(a, b, c, \alpha, \beta, \gamma)$; $(a^*, b^*, c^*, \alpha^*, \beta^*, \gamma^*)$: lattice parameters in direct and reciprocal space.

$\mathbf{y}$, $\mathbf{h}$, $\mathbf{v}$: unit G vectors in the sample, reciprocal-lattice and laboratory frames.

$\mathbf{u}$: scattering vector in the laboratory frame.

λ: wavelength of the incident radiation.

L: sample-to-detector distance.

$d_{\rm width}$, $d_{\rm height}$: detector width and height in pixels.

t: distance from the point of diffraction to the point of detection.

$\boldsymbol{g}$, $\boldsymbol{g}^*$: metric tensors expressing crystal-lattice size and orientation in direct and reciprocal space.

$(\varphi_1, \phi, \varphi_2)$: Euler angles.

$\mathbf{r}$, $\mathbf{n}$, φ: Rodrigues vector, its rotation axis and angle.

$\mathbf{q}$, $\mathbf{n}$, φ: quaternion, its rotation axis and angle.

$\boldsymbol{\varepsilon}$: strain tensor in direct space.

$(\mathbf{x}_d, \mathbf{y}_d, \mathbf{z}_d)$: basis in crystal coordinates for $\boldsymbol{\varepsilon}$.

$\boldsymbol{A}_0$, $\boldsymbol{A}$: matrices transforming the undeformed and deformed crystal coordinates to the laboratory frame.

$\boldsymbol{T}$: matrix characterizing the crystal deformation with respect to its initial state.

$\boldsymbol{\sigma}$: stress tensor.

$\beta_{\mathbf{k}}$: misorientation of a symmetry-equivalent direction with respect to the fundamental zone.

$\boldsymbol{g}$: $\boldsymbol{U}^{-1}$; sample rotation in Euler space.

5.5.2. Introduction

Conventionally, crystallography is based on either single-crystal or powder diffraction measurements. Such methods apply to two extremes of sample morphology: a homogeneous, mono-domain specimen, or an (ideally) mono-disperse and homogeneous powder comprising a huge number of isotropically oriented crystals. Unfortunately, the morphology of a sample is often a heterogeneous assembly of a finite number of poor crystals, perhaps even including several phases. While perturbative methods allow samples departing significantly from the ideal to be treated, many samples are still inappropriate for crystallographic characterization by these methods, leading to significant effort in sample preparation (see Chapter 2.10). In numerous cases, preparation of suitable single crystals is not possible, *e.g.* in relation to studies in extreme environments, studies involving first-order transitions or more generally cases where suitable crystallization conditions have not been found. In other cases, samples are extremely unstable, making it impossible to collect complete data sets. Structures are now routinely solved and refined from powder-diffraction data, but these structures are intrinsically less well determined than those from single crystals owing to the poorer data-to-parameter ratio and lack of redundancy, making them more prone to statistical and systematic errors. In particular, *ab initio* structure solution based on powder-diffraction data can be highly problematic for structures with more than about 40 atoms in the asymmetric part of the unit cell.

In the last decade, however, methods have been developed for treating polycrystalline specimens as ensembles of individual crystals, creating the possibility of rigorously characterizing such samples in terms of not just average properties, but of the distributions of those properties. In this way, crystallographic techniques developed for analysis of single-crystal data have been generalized to simultaneously characterize each of the crystals in the polycrystalline specimen. In particular, structure solution and refinement on multigrain data have been shown to be on a par with single-crystal work and superior to results from state-of-the-art powder diffraction (Vaughan *et al.*, 2004; Sørensen, Schmidt *et al.*, 2012). Other applications include reciprocal-space mapping (Jakobsen *et al.*, 2006), and characterization of size, strain and defect populations (Ungár *et al.*, 2010). In the following we shall refer collectively to these methods by the term *multigrain crystallography*.

Furthermore, methods such as three-dimensional X-ray diffraction (3DXRD) microscopy (Lauridsen *et al.*, 2001; Poulsen, 2004; Hefferan *et al.*, 2009; Bernier *et al.*, 2011) and diffraction contrast tomography (DCT) (Ludwig *et al.*, 2008, 2009) have emerged which enable 3D mapping of the morphology of the individual embedded crystals – known as grains – as well as 3D mapping of local crystallographic properties such as phase, crystallographic orientation and strain.

Copyright © 2019 International Union of Crystallography

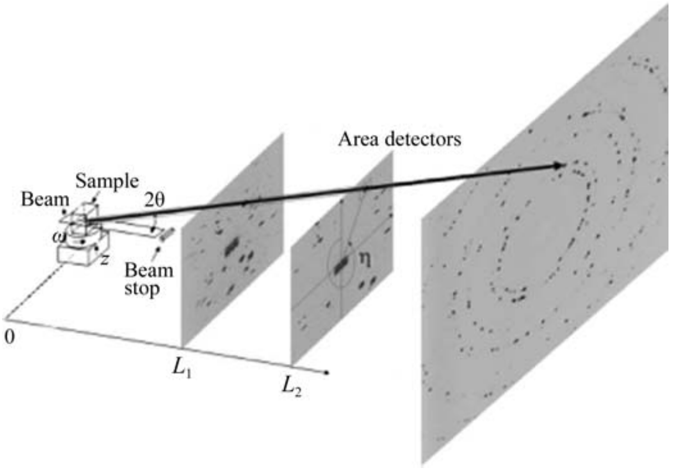

Figure 5.5.1
Sketch of the 3DXRD principle. The Bragg angle 2θ, the rotation angle ω and the azimuthal angle η are indicated for the diffracted beam arising from one grain of a coarse-grained specimen. The axes for the laboratory coordinate system are also shown.

Samples with up to 20 000 grains have been characterized in this way. Currently, the spatial resolution is at best 500 nm (Poulsen *et al.*, 2010). In the following we shall refer collectively to these methods by the term *3D grain mapping*.

Note that when using synchrotron radiation, data-acquisition rates are sufficiently rapid that all of the multigrain methods can be applied recursively during *in situ* studies. This implies a unique opportunity for materials scientists and geoscientists to directly visualize the structural dynamics at the grain level during processing. As examples of such work, studies have been made of nucleation (Offerman *et al.*, 2002; Iqbal *et al.*, 2005; West *et al.*, 2009), recrystallization (Schmidt *et al.*, 2004; Hefferan *et al.*, 2012), grain growth (Schmidt *et al.*, 2008; Hefferan *et al.*, 2009), stress evolution in grains at crack tips (Oddershede *et al.*, 2012) and the interaction of cracks with the 3D microstructure (King *et al.*, 2008). Such work has motivated the construction of dedicated 3D mapping instruments at a number of synchrotrons.

In the following sections, we report on the methodology behind these methods. Initially the experimental setup is presented and a rigorous formalism for the diffraction geometry is introduced. We then discuss methods for polycrystalline indexing and the work on multigrain crystallography is summarized. Next, the work on grain mapping is divided into two sections: centre-of-mass and stress mapping, and 3D grain and orientation mapping. The former type of mapping requires a simpler setup and the data acquisition can be faster, but for each grain only the centre-of-mass position (and the size, orientation and stress state) is determined. The latter types of routines provide a full volumetric mapping of the sample. These sections are followed by three sections of reference material on the representation of orientation space, the representation of strain and stress and on the topic of crystal symmetry for multigrain samples. Finally a short outlook is provided.

A comment on typography: vectors and quaternions are shown as bold, and matrices and tensors are shown as bold italic. (They are distinguishable by their subscripts.)

For a general introduction to the field of multigrain crystallography see also Sørensen, Schmidt *et al.* (2012). For grain mapping we also refer to Poulsen (2004) and Poulsen (2009). A comprehensive mathematical treatment of the geometry of 3DXRD is provided in Alpers *et al.* (2007).

5.5.3. Experimental setup

The setup for multigrain crystallography is identical to that typically used in modern single-crystal or powder crystallography, with a parallel incoming monochromatic beam, a fully illuminated sample in transmission geometry on an ω-rotary table and a 'far-field' 2D detector. Exposures are made during rotation in a manner identical to that used for single-crystal diffraction for equi-angular settings of ω with a step of $\Delta\omega$. As an option, x, y and z translations may be added, as well as additional rotations.

As sketched in Fig. 5.5.1, in a 3DXRD setup additional 2D detectors are added at different distances L from the centre of rotation. These are exposed either simultaneously (many detectors are semi-transparent to hard X-rays) or subsequently, thereby comprising a 3D detector. The added near-field detectors typically have a spatial resolution of 1 to 10 μm and are placed at distances of 2 to 20 mm from the sample. In comparison, the far-field detector typically has a resolution of 50 to 200 μm, with an L value in the range 20 to 50 cm. The high-resolution near-field detectors provide information on positional and orientational degrees of freedom, as well as detailed information about the grain morphology *via* the projections of the grain shape in the diffraction spots, while the latter probes the crystallography, including the potential strain degrees of freedom. Probing direct and reciprocal space simultaneously has several mathematical benefits; for example, it enables ray tracing of the diffracted beam, as illustrated in Fig. 5.5.1.

An example of a set of exposures obtained with this setup is provided in Fig. 5.5.2. Note that in the near-field images the spots are extended (comprising information on grain shape) and form no clear pattern on the detector, as their position is determined by Bragg's law as well as by the positions of the associated grains within the sample. In contrast, in the far-field image the spot sizes are instrumentally limited. Owing to L being much larger than

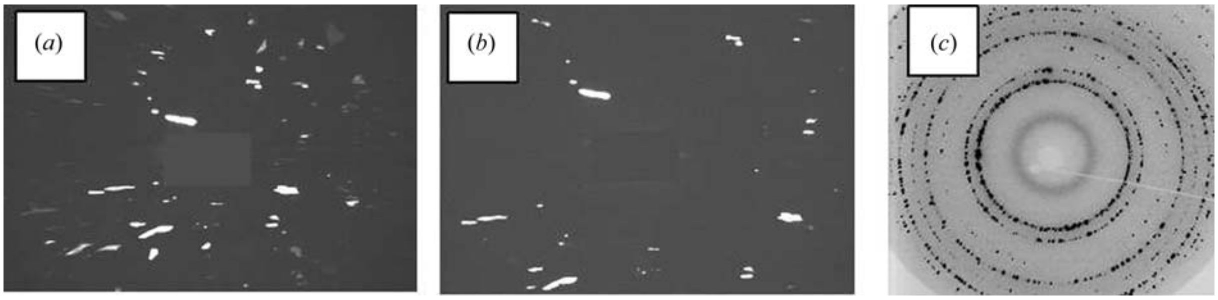

Figure 5.5.2
Typical 3DXRD data from a coarse-grained undeformed polycrystal. (*a*), (*b*) 'Near-field' exposures with high-spatial-resolution detectors (see Fig. 5.5.1) at distances of L = 4 and 8 mm, respectively. (*c*) A corresponding 'far-field' image made with the low-resolution detector at L = 400 mm and shown with inverted grey scale to improve visibility.

the displacement of the grains with respect to the centre of rotation, the positions of grains within the sample now make a small or even vanishing contribution to the positions of the spots, as is the case in conventional crystallography.

In a DCT setup only one near-field detector is used: this serves both to map grains and simultaneously to perform absorption or phase contrast tomography (Ludwig *et al.*, 2008, 2009).

5.5.4. Diffraction geometry

The algebra for associating diffraction observations with reciprocal space is well described for single crystals. The polycrystal case differs by the need for one extra coordinate system, since the sample and the grains are separate objects. In the following, equations describing a single scattering event are derived, first for the case of no detector tilt, then generalized to include such tilts.

The formalism below has served as a standard for the *FABLE* suite of programs (Schmidt *et al.*, 2009). [A closely related treatment can be found in Bernier *et al.* (2011)]. It is subject to the following basic assumptions:

(1) kinematical scattering;

(2) the beam divergence and the energy band width are neglected; and

(3) the relevant part of the sample is assumed to be fully illuminated at all ω settings.

When relevant, the single-crystal formalism of Busing & Levy (1967) is followed closely. However, the sign convention for ω used here is opposite to the one used there.

5.5.4.1. *The laboratory and rotated coordinate systems*

We first consider the basic setup shown in Fig. 5.5.1 with only one rotation axis, which is directed perpendicular to the incoming beam. In this case we define the laboratory system ($\mathbf{x}_l$, $\mathbf{y}_l$, $\mathbf{z}_l$) as having $\mathbf{x}_l$ pointing along the incoming beam, $\mathbf{y}_l$ transverse to it in the horizontal plane and $\mathbf{z}_l$ positive upwards, parallel to the ω rotation axis. Furthermore, ($\mathbf{x}_l$, $\mathbf{y}_l$) = (0, 0) along the ω rotation axis. The definition of $\mathbf{z}_l = 0$ is made by means of a reference beam of infinitesimal size.

In this system the direction of the diffracted ray can be parameterized by the Bragg angle 2θ and the azimuthal angle η, both defined in Fig. 5.5.1. Note that η is defined as positive in the clockwise (cw) direction when viewed along the beam direction from the sample towards the detector and η = 0 when pointing upwards (in the positive direction of $\mathbf{z}_l$). (For historical reasons, this is a left-handed system.)

Next, we define ω positive counterclockwise (ccw) when viewed along the z axis from the top of the instrument. Then

$$\begin{pmatrix} x_l \\ y_l \\ z_l \end{pmatrix} = \boldsymbol{\Omega} \begin{pmatrix} x_\omega \\ y_\omega \\ z_l \end{pmatrix} = \begin{pmatrix} \cos\omega & -\sin\omega & 0 \\ \sin\omega & \cos\omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x_\omega \\ y_\omega \\ z_l \end{pmatrix}. \qquad (5.5.1)$$

The coordinates (x_ω, y_ω, z_l) refer to the rotated system, which is rigidly attached to the ω turntable. This coordinate system is identical to the sample system, unless the user wants to redefine the latter using a matrix $\boldsymbol{S}$ (see below).

We next consider a more generalized goniometer. Following Busing & Levy, we shall operate with three rotations, namely an outer ω-rotation stage (rotating around the z axis), a χ rotation and an innermost φ stage. The combined rotation is given by

$$\begin{pmatrix} x_l \\ y_l \\ z_l \end{pmatrix} = \boldsymbol{\Gamma} \begin{pmatrix} x_\omega \\ y_\omega \\ z_l \end{pmatrix} = \boldsymbol{\Omega}\mathbf{X}\boldsymbol{\Theta} \begin{pmatrix} x_\omega \\ y_\omega \\ z_l \end{pmatrix}. \qquad (5.5.2)$$

This definition can be used to handle, for example, a Eulerian cradle, a kappa goniometer or a double tilt above the ω axis. We shall leave the exact definition of $\mathbf{X}$ and $\boldsymbol{\Theta}$ to the user. We will assume that the ω rotation is used for scanning/oscillating during actual data acquisition and that this axis is perpendicular to the incident beam.

5.5.4.2. *Detector coordinate systems*

The detector read-out is in a pixel coordinate system. Different detector systems use different conventions for how to flip the image and where to put the origin. Here we define our own standard convention ($y_{\rm raw}$, $z_{\rm raw}$), which is used in equations below. This is a regular grid defined in pixels, as shown in Fig. 5.5.3. Other detector orientations (there are eight in total, considering the origin at any corner, and the detector viewed from the front or the back) may be treated by applying the appropriate unitary transformation matrix to the detector coordinates.

Hence, for the detector-plane normal parallel to the beam, $y_{\rm raw}$ is parallel to $\mathbf{y}_l$ and $z_{\rm raw}$ is parallel to $\mathbf{z}_l$. We define (0, 0) as corresponding to the centre of the pixel in the lower-right corner of the image. This implies that the border of the detection area will have half-integer values.

A spatial distortion, given by the operator SC, may be associated with the detector. We define ($y_{\rm det}$, $z_{\rm det}$) to represent the corrected system:

$$(y_{\rm det}, z_{\rm det}) = {\rm SC}[(y_{\rm raw}, z_{\rm raw})]. \qquad (5.5.3)$$

The detector-plane normal may be tilted with respect to the incoming beam. We define:

φ_x: tilt of detector around x (positive ccw around x: right-handed system);

φ_y: tilt of detector around y (positive ccw around y: right-handed system;

φ_z: tilt of detector around z (positive ccw around z: right-handed system).

Determining SC is typically performed by means of inserting a calibration grid in front of the detector.

Correspondingly we have the associated rotation matrices $\boldsymbol{R}^X$, $\boldsymbol{R}^Y$ and $\boldsymbol{R}^Z$:

$$\boldsymbol{R}^X = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\varphi_X & -\sin\varphi_X \\ 0 & \sin\varphi_X & \cos\varphi_X \end{pmatrix},$$

$$\boldsymbol{R}^Y = \begin{pmatrix} \cos\varphi_Y & 0 & \sin\varphi_Y \\ 0 & 1 & 0 \\ -\sin\varphi_Y & 0 & \cos\varphi_Y \end{pmatrix},$$

$$\boldsymbol{R}^Z = \begin{pmatrix} \cos\varphi_Z & -\sin\varphi_Z & 0 \\ \sin\varphi_Z & \cos\varphi_Z & 0 \\ 0 & 0 & 1 \end{pmatrix}. \qquad (5.5.4)$$

Furthermore, we use the convention that the detector system is rotated with respect to the laboratory system by[1]

$$\boldsymbol{R} = \boldsymbol{R}^X \boldsymbol{R}^Y \boldsymbol{R}^Z. \qquad (5.5.5)$$

We can now express the connection between a point on the detector as defined by pixel coordinates ($y_{\rm det}$, $z_{\rm det}$) and the corresponding point (x', y', z') in the laboratory system:

---

[1] Note that the order in which $\boldsymbol{R}^X$, $\boldsymbol{R}^Y$ and $\boldsymbol{R}^Z$ appear is important, even for relatively small tilts.

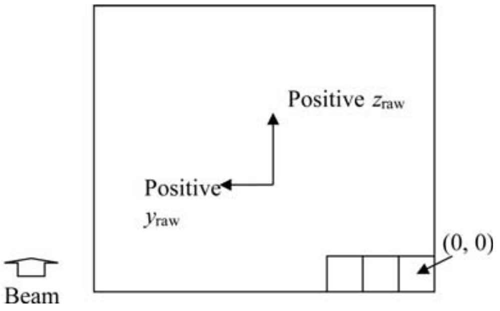

Figure 5.5.3
Definition of the detector pixel coordinate system (see text).

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} L \\ 0 \\ 0 \end{pmatrix} + \boldsymbol{R} \begin{pmatrix} 0 \\ P_y[y_{\text{det}} - y_{\text{det}}(0)] \\ P_z[z_{\text{det}} - z_{\text{det}}(0)] \end{pmatrix}. \qquad (5.5.6)$$

Here $[y_{\text{det}}(0), z_{\text{det}}(0)]$ are the pixel coordinates of the reference beam [the incident ray passing through $(x_1, y_1, z_1) = (0, 0, 0)$], P_y and P_z are the pixel size in the two directions, and L is the distance from the centre of rotation to the point where the incident ray hits the detector.

5.5.4.3. *Diffraction*

The scattering vector associated with the diffraction event is denoted $\mathbf{G}$. To describe its relationship with reciprocal space we need five Cartesian coordinate systems: the laboratory system, the omega system, the rotated system, the sample system and the Cartesian grain system. These are identified by subscripts l, ω, γ, s and c, respectively. The first three have already been defined. Hence, the scattering vector transforms as $\mathbf{G}_l = \boldsymbol{\Omega}\mathbf{G}_\omega = \boldsymbol{\Gamma}\mathbf{G}_\gamma$. (If there is only one rotation axis $\boldsymbol{\Gamma} = \boldsymbol{\Omega}$.)

The sample system is fixed with respect to the sample, as defined *a priori* by the experimentalist. As an example, in metallurgy the sample coordinates are typically defined by the rolling, transverse and normal directions of a rolled sheet (RD, TD and ND, respectively). The orientation of the sample on the ω turntable is given by the $\boldsymbol{S}$ matrix: $\mathbf{G}_\gamma = \boldsymbol{S}\mathbf{G}_s$. By default $\boldsymbol{S} = \boldsymbol{I}$, the identity matrix.

The crystallographic orientation of a grain with respect to the sample is represented by the matrix[2] $\boldsymbol{U}$, $\mathbf{G}_s = \boldsymbol{U}\mathbf{G}_c$, where index c refers to a Cartesian grain system. This system is fixed with respect to the reciprocal lattice $(\mathbf{a}^*, \mathbf{b}^*, \mathbf{c}^*)$ in the grain. We use the convention that $\mathbf{x}_c$ is parallel to $\mathbf{a}^*$, $\mathbf{y}_c$ is in the plane of $\mathbf{a}^*$ and $\mathbf{b}^*$, and $\mathbf{z}_c$ is perpendicular to that plane. Let $\mathbf{G}$ be represented in the reciprocal-lattice system by the integer Miller indices $\mathbf{G}_{hkl} = (h, k, l)^T$. The correspondence between the Cartesian grain system and reciprocal space is then given by the $\boldsymbol{B}$ matrix: $\mathbf{G}_c = \boldsymbol{B}\mathbf{G}_{hkl}$, with

$$\boldsymbol{B} = \begin{pmatrix} a^* & b^*\cos\gamma^* & c^*\cos\beta \\ 0 & b^*\sin\gamma^* & -c^*\sin\beta^*\cos\alpha \\ 0 & 0 & c^*\sin\beta^*\sin\alpha \end{pmatrix} \qquad (5.5.7)$$

and

$$\cos\alpha = \frac{\cos\beta^*\cos\gamma^* - \cos\alpha^*}{\sin\beta^*\sin\gamma^*}, \qquad (5.5.8)$$

Here $(a, b, c, \alpha, \beta, \gamma)$ and $(a^*, b^*, c^*, \alpha^*, \beta^*, \gamma^*)$ symbolize the lattice parameters in direct and reciprocal space, respectively.

With these definitions we have

$$\mathbf{G}_l = \boldsymbol{\Gamma}\boldsymbol{SUB}\mathbf{G}_{hkl}. \qquad (5.5.9)$$

At times it is relevant to operate with normalized scattering vectors instead. Let $\mathbf{u} = \mathbf{G}_l/||\mathbf{G}_l||$, $\mathbf{y} = \mathbf{G}_s/||\mathbf{G}_s||$ and $\mathbf{h} = \boldsymbol{B}\mathbf{G}_{hkl}/||\boldsymbol{B}\mathbf{G}_{hkl}||$. Then

$$\mathbf{u} = \boldsymbol{\Gamma}\boldsymbol{S}\mathbf{y} = \boldsymbol{\Gamma}\boldsymbol{SU}\mathbf{h} = \begin{pmatrix} -\sin\theta \\ -\cos\theta\sin\eta \\ \cos\theta\cos\eta \end{pmatrix}. \qquad (5.5.10)$$

For completeness, we mention that Bragg's law provides an alternative way to determine the norm of the G vectors. Using a formalism that includes 2π in the reciprocal-space definition, the corresponding equation for $\mathbf{h}$ is

$$\begin{pmatrix} h_1 \\ h_2 \\ h_3 \end{pmatrix} = ||\mathbf{G}||^{-1}\boldsymbol{B}\begin{pmatrix} h \\ k \\ l \end{pmatrix} = \frac{\lambda}{4\pi\sin\theta}\boldsymbol{B}\begin{pmatrix} h \\ k \\ l \end{pmatrix}. \qquad (5.5.11)$$

5.5.4.4. *Forward projection, no detector tilt*

Let the diffraction event take place at position (x_l, y_l, z_l) in the laboratory system and be associated with a certain orientation $\boldsymbol{U}$. Assume further we know $\mathbf{X}$ and $\boldsymbol{\Theta}$, the Bravais lattice, the lattice parameters (and therefore $\boldsymbol{B}$) and the X-ray wavelength. The task at hand is then to find the detector coordinates for the diffraction spot associated with a set of Miller indices $\mathbf{G}_{hkl}$.

We may proceed as follows. For each $\mathbf{G}_{hkl}$ first we find $\mathbf{G}_\omega$. The ω position at which the diffraction condition is fulfilled is then given by

$$\sin\theta = -\mathbf{u}_l = -[\boldsymbol{\Omega}\mathbf{G}_\omega]_l \qquad (5.5.12)$$

with $\sin\theta$ defined by Bragg's law. This is a quadratic equation for determination of ω given $\mathbf{G}_\omega$ and $\mathbf{h}$. The two possible solutions are

$$\cos\omega = \frac{ac \pm b(D)^{1/2}}{a^2 + b^2} \text{ and } \sin\omega = \frac{bc \mp a(D)^{1/2}}{a^2 + b^2}, \qquad (5.5.13)$$

where

$$a = \frac{G_{\omega,1}}{|G_\omega|}, \quad b = \frac{-G_{\omega,2}}{|G_\omega|}, \quad c = \frac{(\cos 2\theta) - 1}{[2 - 2\cos 2\theta]^{1/2}}$$
$$\text{and } D^{1/2} = a^2 + b^2 - c^2. \qquad (5.5.14)$$

Evidently the expression for c can be transformed in various ways.

Depending on ω range, none, one or two of these solutions may be real. Also note that (5.5.13) has to be interpreted carefully to obtain ω, because taking only the arccos or arcsin will not do. The proper value of ω has to be chosen to fulfil both equations.

Knowing $\boldsymbol{\Omega}$ we can compute $\mathbf{G}_l$ and $\mathbf{u}$. In the case of an *untilted* detector we have

---

[2] In the texture community it is customary to operate with $\boldsymbol{g} = \boldsymbol{U}^{-1}$. Note that this $\boldsymbol{g}$ is not related to the metric d$\boldsymbol{g}$ as defined in Section 5.5.9.

$$\begin{aligned}P_Y[y_{\rm det} - y_{\rm det}(0)] &= y_l - (L - x_l)\tan 2\theta \sin \eta \\ &= y_l + \frac{(L - x_l)\tan 2\theta}{\cos \theta} u_2 \\ &= y_l + \frac{(L - x_l)\lambda}{2\pi \cos 2\theta} G_{1,2}, \\ P_Z[z_{\rm det} - z_{\rm det}(0)] &= z_l - (L - x_l)\tan 2\theta \cos \eta \\ &= z_l + \frac{(L - x_l)\tan 2\theta}{\cos \theta} u_3 \\ &= z_l + \frac{(L - x_l)\lambda}{2\pi \cos 2\theta} G_{1,3}, \qquad (5.5.15)\end{aligned}$$

where L is the distance from the rotation axis to the detector.

5.5.4.5. *Forward projection with detector tilt and non-centred sample*

A number of different specifications for detector tilts exist. For reference, we introduce two of these below. The origins of the detector coordinate systems are defined in two different reference systems. In one case the origin has to be interpreted as the origin after tilting, while in the other case it is interpreted as the origin before tilting. In both cases we derive the equivalent of (5.5.15): an equation for determining the detector coordinates given a diffraction event in (x_l, y_l, z_l) and the G vector.

First, let us introduce some notation. The detector width and height in pixels are given by $d_{\rm width}$ and $d_{\rm height}$; the corresponding pixel sizes are denoted by P_y and P_z. The detector tilt angles are specified by the matrix $\boldsymbol{R}$ in (5.5.5). We want to compute the actual detector pixels $y_{\rm det}$ and $z_{\rm det}$ recording the diffraction, which takes place at $(x_l, y_l, 0)$ in the laboratory system. The unit directional vector $\mathbf{v}$, along which diffraction occurs, is given by

$$\mathbf{v} = \begin{pmatrix} \cos 2\theta \\ -\sin 2\theta \sin \eta \\ \sin 2\theta \cos \eta \end{pmatrix}. \qquad (5.5.16)$$

5.5.4.5.1. *Detector tilt specification I*

In this specification, the detector origin $[y_{\rm det}(0), z_{\rm det}(0)]$ is defined as the pixel in the tilted detector coordinate system that corresponds to the $(L, 0, 0)^T$ beam centre.

In the laboratory system, the diffracted beam thus hits the detector as expressed by

$$\begin{pmatrix} L \\ 0 \\ 0 \end{pmatrix} + \boldsymbol{R} \begin{pmatrix} 0 \\ P_Y[y_{\rm det} - y_{\rm det}(0)] \\ P_Z[z_{\rm det} - z_{\rm det}(0)] \end{pmatrix} = \begin{pmatrix} x_l \\ y_l \\ 0 \end{pmatrix} + t\mathbf{v}. \qquad (5.5.17)$$

We want to solve the three row equations in (5.5.17) for $y_{\rm det}$, $z_{\rm det}$ and t, the distance from the point of diffraction to the point of detection. The solution for t is

$$t = \frac{R_{11}(L - x_l) - R_{21} y_l - R_{31} z_l}{R_{11} v_1 + R_{21} v_2 + R_{31} v_3}, \qquad (5.5.18)$$

from which we find

$$\begin{aligned}&P_Y[y_{\rm det} - y_{\rm det}(0)] \\ &\quad = R_{12}[(x_l - L) + t v_1] + R_{22}(y_l + t v_2) + R_{32}(z_l + t v_3), \\ &P_Z[z_{\rm det} - z_{\rm det}(0)] \\ &\quad = R_{13}[(x_l - L) + t v_1] + R_{23}(y_l + t v_2) + R_{33}(z_l + t v_3).\end{aligned} \qquad (5.5.19)$$

5.5.4.5.2. *Detector tilt specification II*

In this case, the origin of the detector coordinate system $[y_{\rm det}(0), z_{\rm det}(0)]$ is specified within the laboratory system.

In the laboratory system, the diffracted beam thus hits the detector as expressed by

$$\boldsymbol{R} \begin{pmatrix} 0 \\ P_Y(y_{\rm det} - d_{\rm width}/2 + 1) \\ P_Z(z_{\rm det} - d_{\rm height}/2 + 1) \end{pmatrix} + \begin{pmatrix} L \\ y_{\rm det}(0) \\ z_{\rm det}(0) \end{pmatrix} = \begin{pmatrix} x_l \\ y_l \\ 0 \end{pmatrix} + t\mathbf{v}. \qquad (5.5.20)$$

From this equation we compute t by left-multiplication with the transpose of the first column vector of $\boldsymbol{R}$:

$$t = \frac{R_{11}(L - x_l) - R_{21}[y_{\rm det}(0) - y_l] - R_{31} z_{\rm det}(0)}{R_{11} v_1 + R_{21} v_2 + R_{31} v_3}. \qquad (5.5.21)$$

Left-multiplication with the transpose of the second and third column vectors of $\boldsymbol{R}$, respectively, yields

$$P_Y(y_{\rm det} - d_{\rm width}/2 + 1) = (R_{12}, R_{22}, R_{32}) \left(t\mathbf{v} + \begin{pmatrix} x_l - L \\ y_l - y_{\rm det}(0) \\ -z_{\rm det}(0) \end{pmatrix} \right) \qquad (5.5.22)$$

and

$$P_Z(z_{\rm det} - d_{\rm height}/2 + 1) = (R_{13}, R_{23}, R_{33}) \left(t\mathbf{v} + \begin{pmatrix} x_l - L \\ y_l - y_{\rm det}(0) \\ -z_{\rm det}(0) \end{pmatrix} \right), \qquad (5.5.23)$$

from which we obtain $(y_{\rm det}, z_{\rm det})$.

5.5.5. Indexing

An important simplification arises in the case where the diffraction pattern is composed of a set of primarily non-overlapping diffraction spots. Three examples of such data sets are shown in Fig. 5.5.2. In this case, polycrystalline indexing schemes can be applied readily (Lauridsen *et al.*, 2001).

The starting point for such schemes is peak-search routines, which identify the diffraction spots and determine their centre-of-mass positions in $(y_{\rm det}, z_{\rm det}, \omega)$ space, where $y_{\rm det}$ and $z_{\rm det}$ are the detector coordinates. Next, the directions of the corresponding diffracted X-rays are determined. In the case of the setup illustrated in Fig. 5.5.1, with several near-field detectors, ray tracing may be used. Alternatively or additionally, if acquiring data for a full 360° rotation in ω, Friedel pairs can be used (*e.g.* Ludwig *et al.*, 2009). In the case of far-field data, one may simply assume as a first approximation that all grains are positioned at the centre of rotation.

Assuming that the Bravais lattice of the material is known *a priori*, *e.g.* as the result of a traditional powder-diffraction analysis applied to the polycrystalline data (Vaughan *et al.*, 2004) or because the structure is known, we can associate each diffraction spot with a G vector. Indexing in this case means finding the orientation matrices of the grains in the sample and sorting the G vectors according to grain of origin. Following the presentation of the original polycrystalline indexing program *GRAINDEX* by Lauridsen *et al.* (2001), several alternative approaches have been proposed (Schmidt, 2014; Wright, 2011; Ludwig *et al.*, 2009; Bernier *et al.*, 2011; Sharma *et al.*, 2012). Some of these rely on the use of direct-space information on grain position, which is relevant for materials-science studies of coarse grain specimens but less so for crystallographic studies, where the size of the entire polycrystalline sample may be a few micrometres or less. For reasons of brevity, in the following we shall restrict ourselves to indexing based on orientation relationships between G vectors only.

In a triclinic system each G vector corresponds to one line in 3D orientation space. This line is known in different communities as the projection line, the fibre or the geodesic. Depending on the choice of representation of orientation space, the projection line may be straight or curved (see Section 5.5.11). Any point on this line is consistent with diffraction on the lattice planes defined by the G vector. The projection lines for all the G vectors belonging to a given grain will intersect in one point in orientation space. Hence, one indexing route is to project data into orientation space and search for intersections of lines. For other symmetry groups this route is complicated by the fact that orientation space maps onto itself under crystal symmetry operations. This implies that orientation space becomes tessellated into N regions of different sizes, with N being the number of symmetry operations (*e.g.* 24 for cubic). Furthermore, there will be N projection lines for each measurement (this is further explored in Section 5.5.11),

This approach of finding intersections is implemented in the *GrainSpotter* program (Schmidt, 2014) and has been shown to be very rapid. The complexity of the algorithm increases linearly with N, where N is the number of grains.

Alternatively, forward-simulation programs such as *GRAINDEX* calculate for each trial orientation the corresponding theoretical G vectors. These algorithms loop over orientation space and attempt at any given orientation to match the theoretical G vectors with experimental G vectors in the vicinity. Grains are defined mainly by a completeness criterion on the ratio between observed and expected G vectors. The program *ImageD11* (Wright, 2011), on the other hand, searches pairwise the list of G vectors, looking for those vectors with appropriate angular relationships for the structure under study. Candidate orientations thus generated are then tested against the remaining vectors, and orientations with many matches are retained.

In any case, once grains have been identified, subsequent filtering and optimization algorithms can be applied to fit the centre-of-mass grain positions, grain orientations and stress tensors using, for example, error estimation and outlier rejection (Oddershede *et al.*, 2010; Bernier *et al.*, 2011, Wright, 2011; Sharma *et al.*, 2012). The resulting combined algorithms are able to index as many as 3000 grains simultaneously. Furthermore, for each grain, the lattice orientations, lattice strain tensors and centre-of-mass coordinates may be determined to a precision that is better than 0.05°, 1×10^{-4} and 0.1 pixels, respectively.

The main limitation to the indexing techniques described above is spot overlap. The probability of spot overlap on the detector is determined by the number of grains illuminated, the texture of the sample, the size of the unit cell and – most critically – by the orientation spread of each grain. Experience shows that an overlap fraction of the order of 10% is acceptable for indexing, in the sense that overlapping spots are weeded out by the algorithms because of their erroneous positions and/or intensities. It follows that for typical samples of relevance to hard-materials science, one can aim to index up to a few thousand grains simultaneously, while for small molecules indexing of up to 100 grains is feasible (Sørensen, Schmidt *et al.*, 2012).

For generalizations towards indexing with larger degrees of spot overlap and for indexing of unknown Bravais lattices, see Sørensen, Schmidt *et al.* (2012).

5.5.6. Multigrain crystallography

The basic principle of multigrain crystallography is to extract quality data sets for each grain in the sample and then use existing single-crystal approaches for crystal solution and refinement. In the following we first assume that the sample is monophasic. In this case, as an alternative approach, data from different grains may be scaled and merged in order to create one single data set with increased redundancy. Next, we discuss generalizations to multigrain indexing of unknown multiphase materials.

5.5.6.1. *Monophase materials*

As for other crystallographic applications, the principal problem is to obtain the very accurate intensities necessary for precise structure refinement. Structure solution itself, whether by direct or real-space methods, is rather tolerant of noisy or even systematically faulty data. Structure refinement, however, is very sensitive to outliers, and for accurate structures to be refined they must be eliminated or appropriately down-weighted. In the following we discuss procedures for this filtering step, as described originally in Vaughan *et al.* (2004) and implemented in a series of programs (Vaughan, 2011).

The peaks are first filtered: peaks having too few or too many pixels, those near the rotation axis, those having peak intensities near the dynamic range of the detector and those not allowed by space-group symmetry are eliminated. Intensities are corrected for Lorentz and polarization factors. Additionally, it is possible to correct for lost intensity below the intensity threshold applied in the program by estimation of a peak-shape function from the measured data, either based on the extrapolation of an analytical fit, or *via* a learned empirical function. Correction for absorption is done grain-by-grain based on position within the sample.

If the data for each crystal in the sample are sufficiently redundant, it is possible to perform robust intra-crystal filtering based on equivalent statistics. The data can then be scaled by comparing the relative intensities of equivalent families, and a single data set can be produced by merging the data from all of the crystals, if appropriate. At each step outlier elimination must be carried out. As the outlier distributions are generally highly asymmetric, care must be taken regarding the central tendency indicator chosen for outlier elimination, with either the weighted mean, median or most-likely value (the mode of the histogrammed distribution) being the most appropriate depending on the data set.

The origins of the asymmetry in the intensity distribution are twofold. In particular, if a sample contains many crystals, peaks from other crystals will occur coincidentally near lattice points in reciprocal space occupied by reflections from the crystal in question. Those coming from unindexed crystals create a tail on the high side of the distribution. The tail on the low side of the distribution is due to imperfect treatment of the background. At present, backgrounds are estimated by using either the pixel-by-pixel through the image series median or minimum value. Neither is totally satisfactory, the first tending to overestimate, and the second to underestimate, the true value. In either case, the weakest peaks are the most affected.

By filtering and down-weighting outliers, it is possible to obtain symmetric distributions of equivalent intensities. The widths of these intensity distributions can then be used to more accurately determine the gain of the system, thereby making it possible to convert the measured intensities into counts, and produce proper weights.

Having carried out these steps, it is generally advantageous to use the set of filtered, weighted peaks to re-determine orientation matrices and global parameters, and to iterate through the procedure a second time in order to produce a final data set.

In the first iteration, it is preferable to filter with strict equivalence and statistical criteria in order to produce a data set for structure solution. If solution is successful, Fourier recycling and structure refinement can be carried out, with previously rejected peaks reconsidered at each step as merging parameters are improved. This is done by considering the *expected* value of structure factors, based on estimates of the crystal scale factors and the structure factors calculated by the current structure. Scale factors are thus refined iteratively along with the structure, with outlier rejection or down-weighting also carried out, until a satisfactory structure is obtained.

In order to illustrate the method and test its validity, Vaughan *et al.* (2004) performed an analysis and comparison of the structural results on cupric acetate monohydrate obtained by state-of-the-art high-resolution powder diffraction with the new multigrain crystallography approach. The quality of the two structures was compared with the high-quality structure determined from a single crystal. The final model refined from the polycrystal data gave R_1 of 0.057, and included positions and anisotropic mean-square displacement parameters of all non-H atoms. Furthermore, the H-atom positions of the water molecule could be located in the Fourier map and refined without geometric restraints.

It was not possible to refine the model to anywhere near the same level of detail from the powder data: no meaningful anisotropic displacement parameters for the carbon atoms could be obtained and H-atom positions could not be refined. Comparison of the multigrain structure and powder-diffraction structure with the single-crystal structure showed that the root-mean-square deviations of all positions were 0.0178 Å and 0.0350 Å, respectively. The comparison of the displacement parameters shows that the parameters obtained from multigrain refinement were about 10 times more accurate than the ones obtained from the powder-diffraction experiment. Furthermore, the deviations in bond distances are 2–3 times smaller for the multigrain crystallography structure compared with the powder-diffraction structure.

For an overview of multi-crystal crystallography, see Sørensen, Schmidt *et al.* (2012).

5.5.6.2. *Multiphase materials containing unknown phases*

A multigrain indexing algorithm for use with samples comprising an arbitrary number of known or unknown phases has been presented by Wejdemann & Poulsen (2016). No *a priori* crystallographic knowledge is required. The algorithm is for use with data acquired with a monochromatic beam and a conventional two-dimensional detector. Initially, candidate grains are found by searching for crystallographic planes, using a Dirac comb convoluted with a box function as a filter. Next, candidate grains are validated and the unit cell is optimized. The algorithm is validated by simulations. Simulations of 500 cementite grains and 100 reflections per grain resulted in 99.2% of all grains being indexed correctly and 99.5% of the reflections becoming associated with the right grain. Simulations with 200 grains associated with four mineral phases and 50–700 reflections per grain resulted in 99.9% of all grains being indexed correctly and 99.9% of the reflections becoming associated with the right grain. The main limitations are in terms of overlap of diffraction spots and computing time.

5.5.7. Centre-of-mass and stress mapping

The grain centres of mass (x_l, y_l, z_l) are obtained as fit parameters in the refinement of the orientation matrices, *via* the equations developed in Section 5.5.4. This suggests that these values may be used to make an approximate grain map with no additional input being necessary. In such maps, the grain boundaries are reconstructed *via* indirect methods. As a first approximation, boundaries can be inferred by Voronoi tessellation whereby the distances between grains are simply bisected. This procedure is demonstrated in Fig. 5.5.4, in which the grain boundaries reconstructed by Voronoi tessellation in one layer of a sample are shown. If the grain volumes can also be estimated from the intensities with 10% accuracy or better, this information can be included to improve the tessellation – the so-called modified Laguerre tessellation (Lyckegaard *et al.*, 2011). Laguerre maps have been shown to be more than 85% accurate in terms of voxel assignment to grains, and although the details of the grain boundaries are not characterized, the assignment of neighbouring grains is quite accurate (Lyckegaard *et al.*, 2011).

The generation of centre-of-mass grain maps has been implemented in programs such as *FitAllb* (Oddershede *et al.*, 2010), *ImageD11* (Wright, 2011) and the work by Bernier *et al.* (2011). The maps may be used as the starting point for more detailed reconstructions based on grain projections as described in Section 5.5.8, or used alone to give an approximate indication of the grain distribution.

The centre-of-mass algorithms typically involve fitting 12 parameters per grain: in addition to position and the lattice orientation, the six independent components in the average strain tensor for the grain are also determined. The combined indexing and centre-of-mass algorithms can be highly accurate, allowing the determination of crystallographic strain at the level of $\Delta d/d$

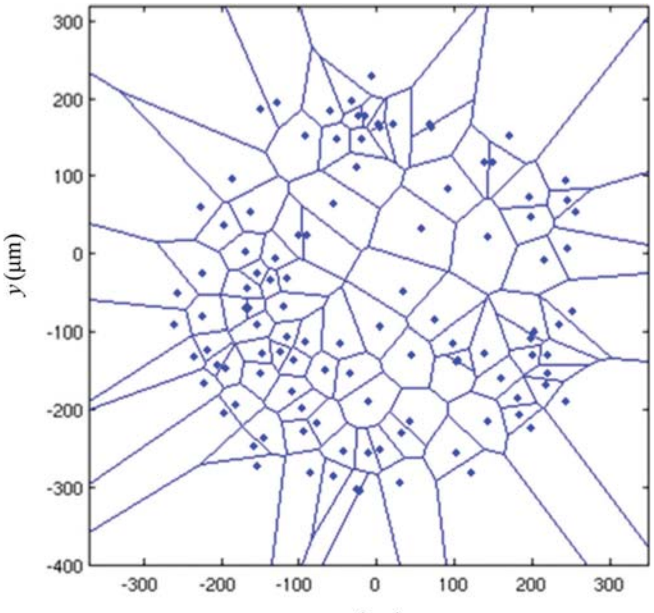

Figure 5.5.4
Grain areas reconstructed by Voronoi tessellation based on experimentally measured centres of mass (the points). In some cases two neighbouring grains have nearly identical centres of mass – an indication in this case of twinning. In an accurately reconstructed map, the measured grain centres will correspond to the centres of the reconstructed grains.

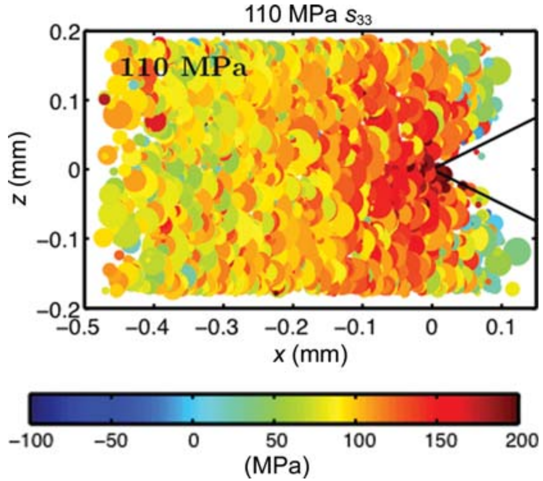

Figure 5.5.5
Stress map of 1750 grains around a notch in an Mg AZ321 sample during tensile deformation. Shown is the axial stress in each grain at an external load of 110 MPa colour coded according to the colour bar at the bottom. The figure represents a 2D projection of the 3D map. The diameters of the spheres represent the grain sizes. Reprinted from Oddershede *et al.* (2012), with permission from Elsevier.

$\simeq 10^{-4}$ and grain orientations to 0.5° precision (Margulies *et al.*, 2002; Martins *et al.*, 2004; Oddershede *et al.*, 2012; Bernier *et al.*, 2011). These properties imply that the method is well adapted to studies of grain rotations (*e.g.* Poulsen *et al.*, 2003). Furthermore, having determined the entire strain tensor for each grain, the corresponding stress tensor can be derived, using Hooke's law; see Section 5.5.10. Fig. 5.5.5 is an example of the application of such stress mapping. In practice this formalism is applicable up to 5–10% plastic deformation; at higher external loads the centre-of-mass algorithms tend to break down because of spot overlap.

5.5.8. 3D grain and orientation mapping

3DXRD microscopy and diffraction contrast tomography (DCT) enable relatively fast generation of large 3D grain maps and 3D orientation maps by use of tomographic reconstruction algorithms. The development of such algorithms is non-trivial, as the complexity in terms of the dimensionality and sheer size of the reconstruction space is much larger than for classical tomography. Another difference is that in 3DXRD and DCT the number of useful projections is given by the number of observable reflections and as such is intrinsically limited (Poulsen, 2004).

In the most general case, some or all of the grains may be smaller than the voxel size and as such the relevant representation is in terms of associating an orientation distribution function, ODF, with each voxel. This implies operating in a numerically very large six-dimensional solution space. Reconstruction algorithms for this case are not routinely available. In practice, focus has been on vector-field reconstructions, where each voxel is associated with one and only one orientation. However, even with this constraint, further simplifications may be required for computational reasons.

An important simplification is the case where the grains are both large in comparison to the voxel size and 'undeformed'; that is, the orientation spread within each grain is negligible. In this case the spatial and angular degrees of freedom are separate, and one may effectively reconstruct *grain maps* rather than orientation maps. Mathematically speaking, the task at hand in this case is to determine the 3D boundary network with as high a precision as possible.

Furthermore, if the diffraction spots do not overlap, one may initially index the various grains, and then reconstruct the 3D morphology of individual grains independently. Powerful methods from the field of discrete tomography can then be applied, allowing for reconstructions even in the case of very few projections (Alpers *et al.*, 2006; Batenburg *et al.*, 2010). The first 3D grain maps were of this kind (Fu *et al.*, 2003).

Another simplification for reconstructing both grains and orientations is the use of a line beam, *cf.* Fig. 5.5.1. In this case, 3D maps are generated by stacking independent reconstructions from a set of layers.

At the time of writing, orientation maps comprising up to 20 000 grains have been obtained. The spatial resolution is of the order 1–5 µm. Using synchrotron sources, the data-acquisition time for a full 3D map is typically of the order of a few hours.

Below we outline two popular approaches for reconstruction.

5.5.8.1. *Approach 1: Grain-by-grain volumetric mapping*

In this approach it is assumed that the grains have negligible orientation gradients. First, the orientations and centres-of-mass of the grains are found, *cf.* Section 5.5.7. Then the 3D shape of each grain is reconstructed. Owing to experimental uncertainties the shapes of the grains will not form a perfect 3D space-filling map, so the last step in the procedure is typically an optimization of the grain-boundary position based on standard image-analysis techniques such as smoothing or erosion/dilation. In practice, the presence of voids can be a concern when the aim is to reach a detailed description of boundary curvatures and triple-junction geometry.

Diffraction contrast tomography (*e.g.* Johnson *et al.*, 2008; Ludwig *et al.*, 2008; King *et al.*, 2008) is performed in this way, as are standard 3DXRD microscopy experiments. As an example of such work, Fig. 5.5.6 shows a grain map of a β-Ti sample reconstructed by the DCT algorithm.

5.5.8.2. *Approach 2: Orientation mapping by Monte Carlo optimization*

Classical transform algorithms are not well suited to handling vector-field reconstructions. Focus has therefore been on Monte Carlo based optimization routines. An example is the forward-

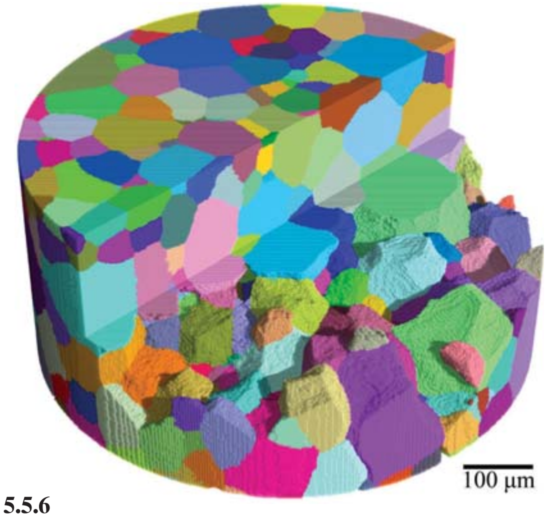

Figure 5.5.6
Rendition of the 3D grain structure in a cylindrical β-Ti specimen containing 1008 grains, as obtained by the DCT algorithm. From Ludwig *et al.* (2008).

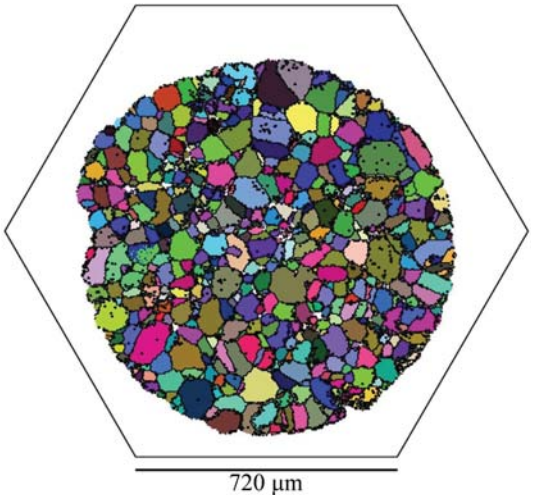

Figure 5.5.7
Map of one layer from a cylinder of high-purity nickel. The orientation (symbolized by colour) of each voxel element was fitted independently. Black lines in the map show edges separating voxels with more than a 2° misorientation. Reprinted from Hefferan *et al.* (2009), with permission from Elsevier.

projection software developed by Suter and collaborators (Hefferan *et al.*, 2009). This is a Monte Carlo Potts model layer-by-layer reconstruction method, where all voxels within the illuminated layer in the sample are free to take all orientations. Experimental work on high purity, well annealed nickel (Hefferan *et al.*, 2009) is reproduced here in Fig. 5.5.7. In this case, statistics on grain orientations, intra-granular misorientations, and nearest-neighbour grain misorientations were compared with statistics obtained from electron-microscopy data. The correspondence was excellent, and it was furthermore demonstrated that the orientation resolution with the setup at 1-ID at the Advanced Photon Source is of order 0.05°. Extensive 3D maps of this kind have been generated with a spatial resolution of 1–2 μm.

This algorithm can also be applied to deformed specimens, but is ultimately limited by the fact that the cross-talk between voxels is not considered. In order to provide a global optimization, it is of interest to reduce the size of configuration space by using known properties of the microstructure. More specifically, assume that prior information – arising for example from an indexing procedure based on far-field information – makes it possible to identify the number of grains, and for each grain determine an approximate average orientation and one voxel in the layer that belongs to this grain. Given these assumptions, Rodek *et al.* (2007) presented a forward-projection Monte Carlo algorithm, where the grains are 'grown' by allowing the following three basic operations:

(1) A voxel not yet assigned to a grain may be assigned to the grain and orientation of a neighbouring voxel.
(2) A labelled voxel may retain its association with a grain while its orientation is changed to an adjacent one in orientation space.
(3) A labelled voxel at a grain boundary may be associated with the grain and the orientation of a neighbouring voxel currently associated with another grain.

This approach was tested on a set of simulated microstructures typical of various degrees of deformation. As an example, in Fig. 5.5.8 the reconstruction of a microstructure with 22 grains and with an internal orientation spread within grains of up to 22° is shown. (In this reproduction it is difficult to see the orientation gradient within the grains.) It can be seen that the reconstruction is nearly perfect.

Finally we mention the *Grainsweeper* program (Schmidt *et al.*, 2008), which has generated a number of 3D grain maps of deformed specimens, for example in connection with 3D mapping of nucleation centres in Al (West *et al.*, 2009) and orientation gradients in 17% NaCl (Borthwick *et al.*, 2012).

5.5.9. Representation of crystallographic orientation

Crystallographic orientations can be expressed in numerous ways, as described in detail in the literature on texture (Kocks *et al.*, 1998; Randl & Engler, 2000). Traditionally four representations are used. The choice between these is non-trivial for numerical reasons. For algebra the natural choice is the 3 × 3 orthogonal matrix $\boldsymbol{U}$ or its inverse (transpose) $\boldsymbol{g}$, as defined above. For visualization and sampling, a representation by three parameters is preferable. The three alternatives are: Euler angles, Rodrigues vectors and unit quaternions. In the following we provide definitions and summarize the most important transforms and geometric properties for each of these representations.

Furthermore, we introduce a novel (fifth) representation based on bounding cubes, with superior numerical properties for some tasks.

5.5.9.1. *Euler angles (Bunge definition)*

Traditionally, orientations are parameterized by a set of Euler angles (φ_1, ϕ, φ_2), expressing sequential rotations around three axes, *cf.* Fig. 5.5.9. With the definitions of the angles as provided by Bunge (1969),

Difference map

Figure 5.5.8
Monte Carlo based reconstruction of a test case representing 20% deformed aluminium. From left to right: the reference map, with colours representing orientations; an example of the simulated data; the seeds used for the Monte Carlo reconstruction algorithm; and the difference between the reference and the reconstructed grain maps. Black voxels denote voxels correctly identified, white voxels represent mismatching ones. Adapted from Rodek *et al.* (2007).

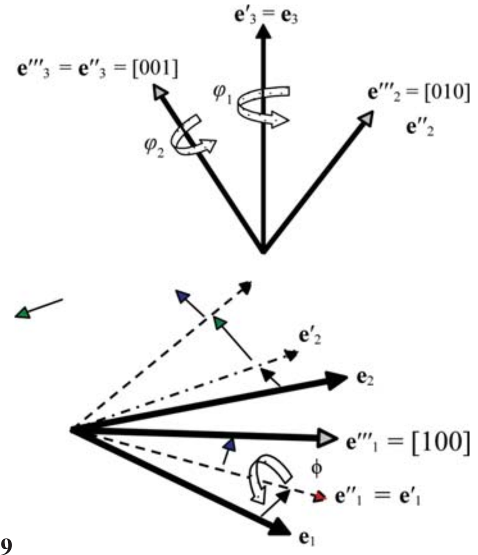

Figure 5.5.9
Definition of the Euler angles (φ_1, ϕ, φ_2) according to Bunge (1969). The sample system ($\mathbf{e}_1$, $\mathbf{e}_2$, $\mathbf{e}_3$) is rotated first around the third axis by φ_1, then around the new first axis $\mathbf{e}'_1$ by ϕ and finally around the new third axis $\mathbf{e}''_3$ by φ_2 to match the Cartesian grain system ($\mathbf{e}'''_1$, $\mathbf{e}'''_2$, $\mathbf{e}'''_3$). For cubic systems the latter set is identical to the reciprocal axes ([100], [010], [001]).

$$\boldsymbol{U} = \begin{bmatrix} c(\varphi_1)c(\varphi_2)-s(\varphi_1)s(\varphi_2)c(\phi) & -c(\varphi_1)s(\varphi_2)-s(\varphi_1)c(\varphi_2)c(\phi) & s(\varphi_1)s(\phi) \\ s(\varphi_1)c(\varphi_2)+c(\varphi_1)s(\varphi_2)c(\phi) & -s(\varphi_1)s(\varphi_2)+c(\varphi_1)c(\varphi_2)c(\phi) & -c(\varphi_1)s(\phi) \\ s(\varphi_2)s(\phi) & c(\varphi_2)s(\phi) & c(\phi) \end{bmatrix}. \tag{5.5.24}$$

Here we have used the shorthand c and s for cos and sin, respectively. The reverse relationship is given by

$$\begin{aligned} \varphi_1 &= -\arctan(U_{13}, U_{23}), \\ \phi &= \arccos(U_{33}), \\ \varphi_2 &= \arctan(U_{31}, U_{32}) \end{aligned} \tag{5.5.25}$$

Note that the two-argument inverse tangent $\arctan(x, y)$ computes $\arctan(x/y)$, but returns the correct angle by taking into account which quadrant (x, y) is in.

Calculating the compound rotation of two individual rotations is very cumbersome in the Euler-angle representation. This should be done using one of the other representations.

Sampling: Euler space is non-linear with singularities at $\phi = 0$ and π. In order to sample it uniformly, use of the metric d$\boldsymbol{g}$ is required (Bunge, 1969):

$$\mathrm{d}\boldsymbol{g}(\phi, \varphi_1, \varphi_2) = (1/8\pi^2)\sin\phi \;\; \mathrm{d}\phi \, \mathrm{d}\varphi_1 \, \mathrm{d}\varphi_2. \tag{5.5.26}$$

Projection lines: From a single diffraction event, only the direction of the scattering vector is probed. Measurements will be invariant to a rotation of the sample around this vector. The set of orientations that for given $\mathbf{y}$ and $\mathbf{h}$ fulfil $\mathbf{y} = \boldsymbol{U}\mathbf{h}$ constitutes a curve in orientation space, the so-called projection line for pole-figure inversion. It is evident from equation (5.5.24) that such lines are curved in Euler space.

5.5.9.2. *Rodrigues vectors*

The Rodrigues representation is in several ways more elegant and better suited for numerical work in connection with diffraction data (Neumann, 1991; Morawiec & Field, 1996; Kumar & Dawson, 2000). It is based on the fact that any rotation can be represented in a unique way by a rotation axis $\mathbf{n}$ and a rotation angle ϕ, defined on $[0, \pi]$. In the Rodrigues parameterization these are coupled in the definition of the Rodrigues vector (Frank, 1998):

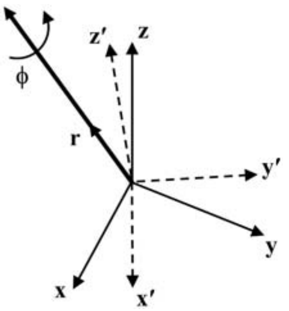

Figure 5.5.10
Definition of the Rodrigues vector $\mathbf{r}$. The coordinate system (x, y, z) is rotated around $\mathbf{n}$ by angle ϕ into (x', y', z'). $\mathbf{r}$ is parallel to $\mathbf{n}$: $\mathbf{r} = \mathbf{n}\tan(\phi/2)$.

$$\mathbf{r} = \tan(\phi/2)\mathbf{n}. \tag{5.5.27}$$

The definition is illustrated in Fig. 5.5.10.

The vector $\mathbf{r}$ can be treated as a vector in Euclidean space, with the exception of points with a rotation angle of π, which are represented by two opposite points in infinity. The axes of this space are colinear with those of the sample system in the sense that a vector $\mathbf{r} = (r_1, 0, 0)$ describes a rotation around the sample x axis.

The relationship to $\boldsymbol{g} = \boldsymbol{U}^{-1}$ is given by

$$g_{ij} = \sum_k \frac{1}{r_k r_k}\left[(1 - r_k r_k)\delta_{ij} + 2r_i r_j - 2\boldsymbol{\varepsilon}_{ijk} r_k\right], \tag{5.5.28}$$

where $\boldsymbol{\varepsilon}_{ijk}$ is the permutation tensor:

$$\boldsymbol{\varepsilon}_{ijk} = \begin{cases} +1 & \text{if } (i, j, k) \text{ is } (1, 2, 3), (2, 3, 1) \text{ or } (3, 1, 2), \\ -1 & \text{if } (i, j, k) \text{ is } (3, 2, 1), (1, 3, 2) \text{ or } (2, 3, 1), \\ 0 & \text{otherwise: } i = j \text{ or } j = k \text{ or } k = i. \end{cases} \tag{5.5.29}$$

The reverse relationship (determining $\mathbf{r}$ given $\boldsymbol{g}$) is given by

$$r_i = \sum_{j,k} \frac{\boldsymbol{\varepsilon}_{ijk} g_{jk}}{1 + \mathrm{Tr}(\boldsymbol{g})}, \tag{5.5.30}$$

where $\mathrm{Tr}(\boldsymbol{g})$ is the trace of $\boldsymbol{g}$. The result $\mathbf{r}_3$ of two rotations, first $\mathbf{r}_1$ and then $\mathbf{r}_2$, is

$$\mathbf{r}_3 = \frac{\mathbf{r}_1 + \mathbf{r}_2 - \mathbf{r}_1 \times \mathbf{r}_2}{1 - \mathbf{r}_1 \cdot \mathbf{r}_2}. \tag{5.5.31}$$

Sampling: The metric d_{ij} and the volume element dV are

$$d_{ij} = \frac{1}{(1 + r^2)^2}[(1 + r^2)\delta_{ij} - 2r_i r_j], \tag{5.5.32}$$

$$\mathrm{d}V = [\det(d_{ij})]^{1/2} = \frac{\mathrm{d}r_1 \, \mathrm{d}r_2 \mathrm{d}r_3}{1 + r^2}. \tag{5.5.33}$$

Evidently this leads to complications for $\mathbf{r} \to \infty$ (that is, for low crystal symmetry, *cf.* Section 5.5.11). On the other hand, for $\phi \to 0$ rotations become commutative. This is reflected in the fact that the metric becomes linear. As an example, for orientation distributions characterized by $\phi < 10^\circ$, the space is Euclidean within an accuracy of better than 1%.

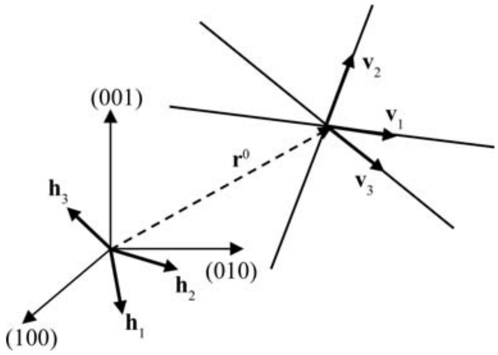

Figure 5.5.11

Symmetry of projection lines through point $\mathbf{r}^0$ in Rodrigues space. The directions of three normalized (h, k, l) vectors ($\mathbf{h}_1$, $\mathbf{h}_2$, $\mathbf{h}_3$) are marked. The associated projection lines pass through $\mathbf{r}^0$ with directions ($\mathbf{v}_1$, $\mathbf{v}_2$, $\mathbf{v}_3$).

Projection lines: A key fact is that the projection lines for pole-figure inversion are straight lines. Specifically, for a given set of vectors $\mathbf{h}$ and $\mathbf{y}$, the projection line is given by

$$\mathbf{r} = \mathbf{r}^0 + t\frac{\mathbf{h} + \mathbf{y}}{1 + \mathbf{h}\cdot\mathbf{y}}, \quad -\infty < t < \infty, \tag{5.5.34}$$

$$\mathbf{r}^0 = \frac{\mathbf{h} \times \mathbf{y}}{1 + \mathbf{h}\cdot\mathbf{y}} = \tan(\phi_0/2)\mathbf{n}, \tag{5.5.35}$$

where $\mathbf{r}^0$ is the rotation from $\mathbf{h}$ into $\mathbf{y}$ with the minimum rotation angle ϕ_0. The second term in equation (5.5.32) corresponds to an arbitrary rotation around the symmetric position $\mathbf{h} + \mathbf{y}$.

For $\phi \to 0$ the expression for the projection line simplifies to

$$\mathbf{r} = \frac{1}{2}(\mathbf{h} \times \mathbf{y}) + \frac{t}{2}(\mathbf{h} + \mathbf{y}). \tag{5.5.36}$$

As a first application of the Rodrigues-vector formalism let us address the following question: for a given orientation $\mathbf{r}^0$, what is the geometry of the projection lines observed?

The answer is illustrated in Fig. 5.5.11, where the full Rodrigues space is used. Assume that the detection geometry and intensity allow the observation of the set of reflections ($\mathbf{h}_1$, $\mathbf{h}_2$, …, $\mathbf{h}_N$). Then it follows that the associated projection lines are straight lines passing through $\mathbf{r}^0$ with the ith line pointing in the direction

$$\mathbf{v}_i = \frac{(\boldsymbol{I} + \boldsymbol{U})\mathbf{h}_i}{1 + \mathbf{h}_i'\boldsymbol{U}\mathbf{h}_i}. \tag{5.5.37}$$

As the expression conserves angles between vectors, the set ($\mathbf{v}_1$, $\mathbf{v}_2$, …, $\mathbf{v}_N$) is a rotation of the set ($\mathbf{h}_1$, $\mathbf{h}_2$, …, $\mathbf{h}_N$). In other words the projection lines associated with a given orientation exhibit the underlying crystal symmetry.

5.5.9.3. *Unit quaternions*

The theory of unit quaternions and their applications to orientations is well developed (Altmann, 1986; Conway & Smith, 2003; Kuipers, 1999; Morawiec, 2004; Meister & Schaeben, 2005). In this section we give only a skeletal development, providing the most relevant definitions.

5.5.9.3.1. *Quaternion basics*

A quaternion $\mathbf{q}$ is a 4-tuple (a, b, c, d) of real numbers. The product of two quaternions is defined by

$$(a_1, b_1, c_1, d_1)(a_2, b_2, c_2, d_2) = (a_3, b_3, c_3, d_3), \tag{5.5.38}$$

where

$$\begin{aligned} a_3 &= a_1a_2 - b_1b_2 - c_1c_2 - d_1d_2,\\ b_3 &= a_1b_2 + b_1a_2 + c_1d_2 - d_1c_2,\\ c_3 &= a_1c_2 - b_1d_2 + c_1a_2 + d_1b_2,\\ d_3 &= a_1d_2 + b_1c_2 - c_1b_2 + d_1a_2. \end{aligned} \tag{5.5.39}$$

Since the non-commutative multiplication is associative, we can use unambiguously the notation $\mathbf{pqr}$ for the product of the three quaternions $\mathbf{p}$, $\mathbf{q}$ and $\mathbf{r}$. Note also that (1, 0, 0, 0) is an identity element; *i.e.*, for any quaternion $\mathbf{q}$ we have $(1, 0, 0, 0)\mathbf{q} = \mathbf{q} = \mathbf{q}(1, 0, 0, 0)$.

The norm of the quaternion (a, b, c, d) is defined by

$$||(a, b, c, d)|| = (a^2 + b^2 + c^2 + d^2)^{1/2}. \tag{5.5.40}$$

It is often helpful to introduce the notation (a, $\mathbf{b}$), where $\mathbf{b}$ is the 3D vector (b, c, d), to abbreviate the quaternion (a, b, c, d). In this way, the conjugate of the quaternion $\mathbf{q} = (a, \mathbf{b})$ is defined as $\overline{q} = (a, -\mathbf{b})$. The conjugate of the product of two quaternions is the reversed product of their conjugates; *i.e.*, $\mathbf{q}_1\mathbf{q}_2 = \overline{q_2 q_1}$.

5.5.9.3.2. *Relation between unit quaternions and orientations*

The set of unit quaternions consists of quaternions whose norm is 1. They form SO(3), the 3-sphere in 4-space, similar to *e.g.* the Earth surface being a 2-sphere in 3-space. From this it follows that unit quaternion space is bounded, the product of two unit quaternions is a unit quaternion, and the conjugate of a unit quaternion is also a unit quaternion.

Every unit quaternion $\mathbf{q}$ defines an orientation, as it can be expressed as

$$\mathbf{q} = (a, \mathbf{b}) = [\cos(\varphi/2), \mathbf{n}\sin(\phi/2)], \tag{5.5.41}$$

where the unit vector $\mathbf{n} = \mathbf{b}/||\mathbf{b}||$ defines the axis and $\varphi = 2\arccos(a/||\mathbf{b}||)$ defines the angle of rotation. Note that $\mathbf{q}$ and $-\mathbf{q}$ define the same orientation. In fact, this mapping from SO(3) to orientation space (*i.e.*, Rodrigues space, Euler-angle space *etc.*) is a 2-to-1 mapping.

A particularly useful and elegant consequence of this approach is that the rotation represented by the unit quaternion $\mathbf{q}_1$ followed by the rotation represented by the unit quaternion $\mathbf{q}_2$ is the composite rotation represented by $\mathbf{q}_2\mathbf{q}_1$.

It follows from equations (5.5.27) and (5.5.41) that there is a gnomonic relationship between Rodrigues vectors and unit quaternions. This implies that one can go back and forth, *e.g.* for visualization in Rodrigues space and for calculations in quaternion space.

Via equation (5.5.41) we can compute for every unit quaternion $\mathbf{q}$ the corresponding $\mathbf{n}$ and φ, and thereby the corresponding Rodrigues vector, and *vice versa*.

The relationship from $\mathbf{q} = (a, b, c, d)$ to $\boldsymbol{U}$ is given by

$$\boldsymbol{U} = \begin{pmatrix} 2(a^2 + b^2) - 1 & 2(bc - ad) & 2(bd + ac) \\ 2(bc + ad) & 2(a^2 + c^2) - 1 & 2(cd - ab) \\ 2(bd - ac) & 2(cd + ab) & 2(a^2 + d^2) - 1 \end{pmatrix}. \tag{5.5.42}$$

The inverse relationship (determining $\mathbf{q}$ given $\boldsymbol{U}$) is, owing to the $\mathbf{q}$ and $-\mathbf{q}$ ambiguities, not uniquely defined. We give only one formula, which is appropriate if and only if $U_{11} + U_{22} + U_{33} \geq -1$:

$$
\begin{aligned}
a &= \frac{1}{2}(U_{11} + U_{22} + U_{33} + 1)^{1/2},\\
b &= \frac{1}{4a}(U_{32} - U_{23}),\\
c &= \frac{1}{4a}(U_{13} - U_{31})\\
d &= \frac{1}{4a}(U_{21} - U_{12}). \qquad (5.5.43)
\end{aligned}
$$

5.5.9.3.3. *Distance*

Following Alpers *et al.* (2007), we define the distance d between two orientations $\mathbf{q}_1$ and $\mathbf{q}_2$ by

$$d(\mathbf{q}_1, \mathbf{q}_2) = \min_{s_1, s_2 \in S} r(\mathbf{q}_1 s_1, \mathbf{q}_2 s_2), \qquad (5.5.44)$$

where S is the set of symmetry rotations given by crystal symmetry (see Section 5.5.11) and r is

$$r(\mathbf{q}_1, \mathbf{q}_2) = 1 - |a_3| = 1 - |\cos(\varphi_{12})|. \qquad (5.5.45)$$

In other words, the distance d is the minimal r when comparing all permutations of symmetry operations. For computing it is relevant to note that it is sufficient to loop over the symmetry operations once, as we can rewrite (5.5.44) to be

$$d(\mathbf{q}_1, \mathbf{q}_2) = \min_{s \in S} r\big((1, 0, 0, 0), s\mathbf{q}_2\overline{\mathbf{q}_1}\big). \qquad (5.5.46)$$

Usually in materials-science literature, the distance $d(\mathbf{q}_1, \mathbf{q}_2)$ is specified by the associated angle of disorientation, which is defined as that ϕ in the range $[0, 180^\circ]$ for which $\cos(\phi/2) = 1 - d$.

Sampling: Knowing that $a^2 + b^2 + c^2 + d^2 = 1$, a discretization by three parameters is possible. The ideal way to do so is not known to the presents authors. Alpers *et al.* (2007) and Kulshreshth *et al.* (2009) chose to sample in a regular grid over the components b, c and d in the interval $[-1, 1]$, allowing only values that satisfy $b^2 + c^2 + d^2 \leq 1$. This sampling leads to neighbouring voxel elements having misorientations that increases with the distance to $\mathbf{q} = (1, 0, 0, 0)$.

Projection lines: In unit-quaternion space the projection lines become circles. Following Meister & Schaeben (2005), the circle for a given set of $\mathbf{h}$ and $\mathbf{r}$ is defined by (under condition $\mathbf{h} \times \mathbf{r} \neq 0$) the two orthogonal unit quaternions $\mathbf{q}_1$ and $\mathbf{q}_2$,

$$\mathbf{q}_1 = \left(\cos(\phi/2), \frac{\mathbf{h} \times \mathbf{r}}{||\mathbf{h} \times \mathbf{r}||}\sin(\phi/2)\right), \quad \mathbf{q}_2 = \left(0, \frac{\mathbf{h} \times \mathbf{r}}{||\mathbf{h} \times \mathbf{r}||}\right), \qquad (5.5.47)$$

where ϕ is defined as the angle between $\mathbf{h}$ and $\mathbf{r}$, that is

$$||\mathbf{h} \times \mathbf{r}|| = 2\cos(\phi/2). \qquad (5.5.48)$$

With these definitions the circle is defined as

$$C(q_1, q_2) = \big\{q(t) = q_1 \cos t + q_2 \sin t\colon\ t \in [0, 2\pi]\big\}. \qquad (5.5.49)$$

5.5.9.4. *Bounding cubes*

The Rodrigues-vector representation has the advantage of straight projection lines, but the disadvantage of singularities and a rather complex formalism for adding orientations [equation (5.5.31)]. Unit quaternions, on the other hand, are not associated with singularities, and exhibit a very simple formula for addition, but the projection lines are circles [equation (5.5.49)].

In 2009, a new formalism was proposed by Kazantsev *et al.* (2009), which combines the superior properties of both representations. The representation is based on a gnomonic projection of SO(3) onto bounding cubes. In order to illustrate the concept, we initially reduce the dimension of the problem by one and consider the corresponding gnomonic projection of SO(2) – the unit sphere in conventional 3D space – onto a union of bounding squares. As illustrated in Fig. 5.5.12, the sphere can be inscribed by the boundary 3-cube, made up of six bounding squares. The sphere can be divided into six patches similar to **abcd**. By drawing straight lines from the origin O to the bounding squares, each point on the sphere is projected onto one and only one point in one of the bounding squares. The bounding squares can be unfolded, that is, mapped onto 2D space. The result is that $F_{\pm 1}$, $F_{\pm 2}$, $F_{\pm 3}$ constitute the unfolded 3-cube.

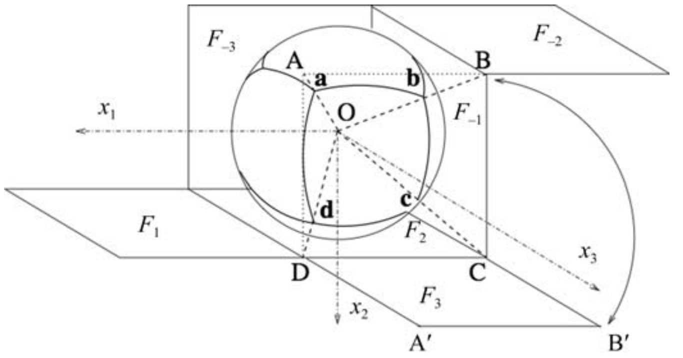

Figure 5.5.12
Three-dimensional illustration of the concepts of bounding squares. The bounding square ABCD (unfolded A′B′CD) is a gnomonic projection of patch **abcd** on the unit sphere centred at O (see text). From Kazantsev *et al.* (2009). Copyright IOP Publishing. All rights reserved.

For the actual problem at hand, SO(3) – the unit sphere in 4D space – is inscribed by the bounding 4D hypercube, made up of eight bounding cubes. The gnomonic projection maps SO(3) onto this union of eight bounding cubes, which again can be unfolded, that is, mapped onto 3D space. The result is that $F_{\pm 1}$, $F_{\pm 2}$, $F_{\pm 3}$, $F_{\pm 4}$ constitute the unfolded 4D hypercube. Given the 2-to-1 mapping of SO(3) on orientations, four bounding cubes are sufficient for representing orientation space.

If $\mathbf{Q} = (q_1, q_2, q_3, q_4)$ is a unit quaternion, let

$$q^{\max} = \max\big\{|q_1|, |q_2|, |q_3|, |q_4|\big\}. \qquad (5.5.50)$$

Then the gnomonic projection is defined by

$$Q \rightarrow (1/q^{\max})Q \in F_{\operatorname{sign}(qk)k}, \qquad (5.5.51)$$

where $F_{\operatorname{sign}(qk)k}$ is the boundary cube given by

$$q^{\max} = q_k \operatorname{sign}(q_k). \qquad (5.5.52)$$

This gnomonic projection (5.5.51) is closely related to the gnomonic projection from SO(3) onto Rodrigues space (5.5.41). This can envisioned as conventional infinite Rodrigues space being replaced by four finite 'versions of Rodrigues space': the bounding cubes. The metric properties are the same.

The projection lines in the bounding-cube representation are a collection of straight linear segments, bounded inside 4, 6 or 8 of the bounding cubes. Attention is required to keep track of the entry and exit of projection lines, but computationally efficient methods have been presented (Kazantsev *et al.*, 2009).

In conclusion, the virtue of the bounding-cube representation is that the singularity has been avoided, while the space is still 'linear'. As an example of an application, algebraic reconstruction algorithms for reconstructing orientation distributions functions (ODFs) can be made orders of magnitude faster in a 'linear' space, which has made it possible to reconstruct ODFs with an unprecedented angular resolution of 0.1°. In the future, the bounding-cube representation is expected to play a role in future algorithms for 3D reconstruction of grain and orientation maps.

5.5.10. Representation of elastic strain

For reference we provide a formalism for deriving the elastic strain tensor and – *via* Hookes law – the corresponding stress tensor.

5.5.10.1. *Definition of strain*

The strain is a perturbation of the local lattice. It is represented by a symmetric 3 × 3 matrix, the strain tensor, $\boldsymbol{\varepsilon}$. Notably, $\boldsymbol{\varepsilon}$ is defined in direct-space coordinates, not in reciprocal space. Hence for each position we define a Cartesian system with axes $(\hat{x}_d, \hat{y}_d, \hat{z}_d)$, with $\hat{x}_d$ parallel to **a**, $\hat{y}_d$ in the plane of **a** and **b**, and $\hat{z}_d$ perpendicular to that plane. By analogy with (5.5.7), the transformation between the crystal basis and the laboratory basis is given by a matrix:

$$\boldsymbol{A} = \begin{pmatrix} a & b\cos\gamma & c\cos\beta \\ 0 & b\sin\gamma & -c\sin\beta\cos\alpha^* \\ 0 & 0 & c\sin\beta\sin\alpha^* \end{pmatrix}. \tag{5.5.53}$$

Now chose a direct-space reference coordinate system and let $\boldsymbol{A}_0$ relate the undeformed Cartesian grain system to this reference, while $\boldsymbol{A}$ relates the deformed Cartesian grain system to the same reference. Furthermore, let $\boldsymbol{T}$ be given by

$$\boldsymbol{T} = \boldsymbol{A}\boldsymbol{A}_0^{-1}. \tag{5.5.54}$$

Then, by definition the strain tensor is

$$\boldsymbol{\varepsilon}_{ij} = \tfrac{1}{2}(\boldsymbol{T}_{ij} + \boldsymbol{T}_{ji}) - \boldsymbol{I}_{ij}, \tag{5.5.55}$$

where $\boldsymbol{I}$ is the identity matrix. This strain tensor, which is defined as the deformation of the lattice relative to the undeformed Cartesian grain system, is sometimes known as the linear Lagrangian strain tensor (Schlenker *et al.*, 1978).

With this general formalism, the relation between the diffraction geometry and the strain is *via* the metric $\boldsymbol{B}$, defined in (5.5.7). If $\boldsymbol{B}$ is known, $\boldsymbol{A}$ can be derived, from which follows $\boldsymbol{\varepsilon}$ by (5.5.54) and (5.5.55). Inversely, if $\boldsymbol{\varepsilon}$ is known, $\boldsymbol{T}$ can be obtained by rearranging (5.5.55); then $\boldsymbol{B}$ can be derived from $\boldsymbol{A} = \boldsymbol{T}\boldsymbol{A}_0$.

Note that the elastic strain tensor calculated above refers to the local Cartesian grain coordinate system. Under the assumption that the orientation of the grain does not change with the deformation, that is $\boldsymbol{U} = \boldsymbol{U}_0$, the strain tensor in the sample coordinate system is given by

$$\boldsymbol{\varepsilon}_{\rm sample} = \boldsymbol{U}\boldsymbol{\varepsilon}\boldsymbol{U}^T. \tag{5.5.56}$$

5.5.10.2. *Strain-to-stress conversion*

The strain tensor $\boldsymbol{\varepsilon}$ is related to the stress tensor $\boldsymbol{\sigma}$ by means of the stiffness tensor $\boldsymbol{C}$, which is a 6 × 6 symmetric matrix where the number of independent terms varies from 21 for triclinic to 3 for cubic space-group symmetry. The easiest way to convert from strain to stress is by writing $\boldsymbol{\varepsilon}$ and $\boldsymbol{\sigma}$ in the Mandel–Voigt notation:

$$\boldsymbol{\varepsilon}^{\rm MV} = \begin{pmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ \sqrt{2}\varepsilon_{23} \\ \sqrt{2}\varepsilon_{13} \\ \sqrt{2}\varepsilon_{12} \end{pmatrix}, \quad \boldsymbol{\sigma}^{\rm MV} = \begin{pmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\sigma_{23} \\ \sqrt{2}\sigma_{13} \\ \sqrt{2}\sigma_{12} \end{pmatrix}. \tag{5.5.57}$$

We now define the orthogonal rotation matrix in the Mandel–Voigt frame as

$$\boldsymbol{U}^{\rm MV} = \begin{pmatrix} \boldsymbol{U}_1^{\rm MV} & \boldsymbol{U}_2^{\rm MV} \\ \boldsymbol{U}_3^{\rm MV} & \boldsymbol{U}_4^{\rm MV} \end{pmatrix}, \tag{5.5.58}$$

where

$$\begin{aligned} \boldsymbol{U}_1^{\rm MV} &= \begin{bmatrix} U_{11}^2 & U_{12}^2 & U_{13}^2 \\ U_{21}^2 & U_{22}^2 & U_{23}^2 \\ U_{31}^2 & U_{32}^2 & U_{33}^2 \end{bmatrix}, \\ \boldsymbol{U}_2^{\rm MV} &= \sqrt{2}\begin{bmatrix} U_{12}U_{13} & U_{11}U_{13} & U_{11}U_{12} \\ U_{22}U_{23} & U_{21}U_{23} & U_{21}U_{22} \\ U_{32}U_{33} & U_{31}U_{33} & U_{31}U_{32} \end{bmatrix}, \\ \boldsymbol{U}_3^{\rm MV} &= \sqrt{2}\begin{bmatrix} U_{21}U_{31} & U_{22}U_{32} & U_{23}U_{33} \\ U_{11}U_{31} & U_{12}U_{32} & U_{13}U_{33} \\ U_{11}U_{21} & U_{12}U_{22} & U_{13}U_{23} \end{bmatrix}, \\ \boldsymbol{U}_4^{\rm MV} &= \begin{bmatrix} U_{23}U_{32} + U_{22}U_{33} & U_{23}U_{31} + U_{21}U_{33} & U_{32}U_{21} + U_{31}U_{22} \\ U_{13}U_{32} + U_{12}U_{33} & U_{13}U_{31} + U_{11}U_{33} & U_{31}U_{12} + U_{32}U_{11} \\ U_{12}U_{23} + U_{13}U_{22} & U_{21}U_{13} + U_{23}U_{11} & U_{12}U_{21} + U_{11}U_{22} \end{bmatrix}. \end{aligned} \tag{5.5.59}$$

Then (5.5.57) can be rewritten as

$$\boldsymbol{\varepsilon}_{\rm sample}^{\rm MV} = \boldsymbol{U}^{\rm MV}\boldsymbol{\varepsilon}^{\rm MV}. \tag{5.5.60}$$

If the stiffness tensor, which is normally given in the Voigt notation, is now rescaled according to

$$\begin{aligned} C_{ij}^{\rm MV} &= C_{ij} \ \forall\ i,j \in \{1,2,3\}, \\ C_{ij}^{\rm MV} &= \sqrt{2}C_{ij} \ \forall\ i \in \{1,2,3\}, j \in \{4,5,6\}, \\ C_{ij}^{\rm MV} &= \sqrt{2}C_{ij} \ \forall\ i \in \{4,5,6\}, j \in \{1,2,3\}, \\ C_{ij}^{\rm MV} &= 2C_{ij} \ \forall\ i,j \in \{4,5,6\}, \end{aligned} \tag{5.5.61}$$

the conversion goes as

$$\boldsymbol{\sigma}^{\rm MV} = \boldsymbol{C}^{\rm MV}\boldsymbol{\varepsilon}^{\rm MV} \tag{5.5.62}$$

and

$$\boldsymbol{\sigma}_{\rm sample}^{\rm MV} = \boldsymbol{U}^{\rm MV}\boldsymbol{\sigma}^{\rm MV} = \boldsymbol{U}^{\rm MV}\boldsymbol{C}^{\rm MV}\boldsymbol{\varepsilon}^{\rm MV} = \boldsymbol{U}^{\rm MV}\boldsymbol{C}^{\rm MV}(\boldsymbol{U}^{\rm MV})^T\boldsymbol{\varepsilon}_{\rm sample}^{\rm MV}. \tag{5.5.63}$$

The reason for using the Mandel–Voigt notation rather than the traditional Voigt notation is that the former preserves the inner product of the tensor while the latter does not. This is of particular importance because in the elastic regime the work is defined as the inner product of $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$.

5.5.11. Crystal symmetry in relation to multigrain samples

In texture literature one introduces both crystal and sample symmetry. For multigrain work – as for single grain work – there is no sample symmetry. The crystal symmetry operations associated with a given space group can be found in *International Tables of Crystallography*, Volume A (Aroyo, 2016).

Table 5.5.1
Irreducible part of Euler space for the seven Bravais classes

From Randl & Engler (2000).

Bravais class	ϕ_1	ϕ	ϕ_2
Cubic	[0, 360]	[54, 90]	[0, 90]
Tetragonal	[0, 360]	[0, 90]	[0, 90]
Orthorhombic	[0, 360]	[0, 90]	[0, 180]
Hexagonal	[0, 360]	[0, 90]	[0, 60]
Trigonal	[0, 360]	[0, 90]	[0, 120]
Monoclinic	[0, 360]	[0, 90]	[0, 360]
Triclinic	[0, 360]	[0, 180]	[0, 360]

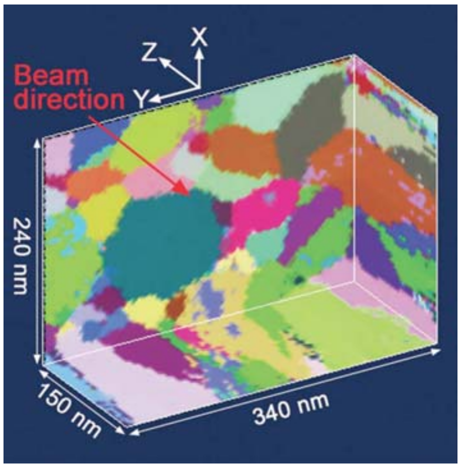

Figure 5.5.13
The TEM equivalent of 3DXRD orientation mapping. The 3D grain-orientation map comprises a subvolume of the fully reconstructed volume within a 150-nm-thick aluminium film specimen. The shades of grey represent different crystal orientations with a tolerance of 2°. The spatial resolution is estimated to be 1 nm. From Liu *et al.* (2011). Reprinted with permission from AAAS.

The crystal symmetry implies that orientation space is divided into a set of N equivalent subspaces, with N being half the number of symmetry operations in the Laue group (*e.g.* 48/2 = 24 for cubic systems; dividing by two allows for the fact that it is not possible to distinguish contributions to the intensity from grains in orientations related by a centre of symmetry). In order to simplify the description we identify one of the subspaces as the fundamental zone. Typically this is chosen to be the subspace around the origin, as this has superior geometric properties in comparison to the other subspaces, such as the orientation space being nearly flat. The output from programs typically refers to the fundamental zone.

5.5.11.1. *Fundamental zone*

The relevant ranges for the Euler representation are given in Table 5.5.1. Note that the threefold axis in cubic materials does not lead to subvolumes that have a rectangular shape in Euler space. The ϕ interval listed in Table 5.5.1 is the one that generates the smallest rectangular box comprising an irreducible volume.

The fundamental zone in Rodrigues space is centred around (0, 0, 0). The geometry of the fundamental zone for various symmetries is described by Morawiec & Fields (1996). The fundamental zone for unit quaternions is centred around (1, 0, 0, 0). The authors have not found a suitable reference to the geometry of the fundamental zone for various symmetries.

5.5.11.2. *Determining the orientation in the fundamental zone*

Given an arbitrary orientation we can determine all the symmetry-equivalent orientations. For each of these we derive the matrix $\boldsymbol{U}_k$. We then calculate the misorientation with respect to the identity matrix, that is, the misorientation with respect to the centre of the fundamental zone:

$$\beta_k = \cos^{-1}\left(\frac{Tr(\boldsymbol{U}_k) - 1}{2}\right). \tag{5.5.64}$$

The symmetry-equivalent orientation with the minimum β_k is the one that represents the fundamental zone.

5.5.11.3. *Use of symmetry-equivalent orientations for strain and stress characterization*

If the system under study is of monoclinic or higher symmetry in the undeformed state, then several different symmetry-equivalent versions of $\boldsymbol{U}$ can be used to describe the orientation of the grain relative to the sample frame. However, when the system is deformed we observe weak symmetry breaking in the lattice permutations. Consequently, in order to extract the evolution of the strain tensor for an individual grain, one must choose a well defined reference frame for the orientation, such that the lattice parameters do not permute from one strain level to the next. This is also important when comparing strain in neighbouring grains. This is done by choosing the symmetry-equivalent version of $\boldsymbol{U}$ that lies in the fundamental zone for each grain in the undeformed state, and then using this same $\boldsymbol{U}$ for all other strain states.

5.5.12. Discussion

In the formalism introduced above we have assumed the specimen to be monophasic. For known phases, extension to multiphase materials is conceptually straightforward, as multi-grain indexing and/or grain-mapping algorithms can be applied repeatedly, once for each phase. An example is the study of martensite formation in TRIP steels by Jimenez-Melero *et al.* (2011).

For grain mapping it may be advantageous to couple mapping based on diffraction contrast with absorption or phase-contrast tomography. Assuming that the density contrast between the phases is sufficient by such hybrid methods, one can first determine a phase map, which is then used as a constraint for the subsequent 3D grain or orientation map. An example of such work is the combined 3DXRD and microtomography study of natural chalk by Sørensen, Hakim *et al.* (2012). Based on existing knowledge, a catalogue of 11 possible phases was made to guide which minority phases to search for in the 3DXRD data.

The 3DXRD methodology has recently been applied to transmission electron microscopy (TEM). Using conical scanning dark-field microscopy in connection with a variant of the *GrainSweeper* reconstruction algorithm, orientation mapping with a spatial resolution in 3D of 1 nm had been demonstrated (Liu *et al.*, 2011). The first example of this was the mapping of a 150-nm-thick foil of nanocrystalline aluminium, see Fig. 5.5.13. The volume in the figure corresponds to a small fraction of the entire illuminated volume, which contained of the order of 1000 grains. However, the acquisition procedure used was slow in the sense that about 100 000 dark-field images were required. It is evident that one of the main limitations of the method (as in TEM tomography) is that it is restricted to electron-transparent foils.

5.6. X-ray diffraction from non-crystalline materials: the Debye model

S. Bates

5.6.1. Outline

In this chapter, the topic of X-ray diffraction from non-crystalline materials will be introduced. Many of the underlying principles behind this work were laid down in the early 1900s by pioneers such as Debye. Since that time, however, the primary focus of X-ray diffraction has been on crystalline materials and structure solution, and much of the early work on non-crystalline materials is not familiar to the diffraction scientist of today. As such, the topics in this chapter are presented at an introductory level from the perspective of an operator using X-ray powder diffraction as a tool to characterize non-crystalline materials.

As a first approximation, non-crystalline materials can be considered to be frozen glassy liquids, and the associated X-ray powder patterns will show a characteristic continuous pattern with a few broad, diffuse halos. There are, however, many diffraction phenomena and classes of materials that will give rise to broad, diffuse features in a measured powder pattern, for example non-crystalline, disordered crystals (Welberry, 2004) and mesophases [such as liquid crystals, plastic crystals or condis (conformationally disordered) crystals (Fu *et al.*, 1994; Chakravarty *et al.*, 2013)]. In each case, the diffuse diffraction contribution arises from a loss of molecular or atomic order. More precisely, diffuse scattering is generated when the local molecular or atomic order differs from the average state of the sample. Within a crystalline system, localized differences might be isolated defects, and for glassy systems, localized differences may relate to short-range order. When X-ray powder patterns exhibit diffuse scattering, this is often referred to as an X-ray amorphous contribution. Within this chapter, diffuse scattering will be used as the general descriptive term rather than X-ray amorphous when the source of the scattering is unknown.

Traditionally, continuous powder diffraction patterns generated by non-crystalline materials have been theoretically described using the Debye diffraction equation, which is based upon the idea of coherent scattering from single atom–atom pairs. This is an ideal starting point for non-crystalline materials, which all exhibit a common atomic level granularity. The bulk of this chapter will be directed towards the Debye diffraction equation and how to implement a Debye diffraction model to characterize experimentally observed continuous diffraction patterns.

In addition to sample-driven diffuse scattering, there are numerous experimental sources of diffuse, continuous X-ray scattering that can include air scatter, fluorescence, Compton scattering and *Bremsstrahlung* radiation. These will vary depending on the diffraction system and the elemental makeup of the sample. Although fluorescence and Compton scattering are both sample dependent and contain elemental information about the sample, for the purposes of diffraction analysis (*i.e.* structural analysis), these contributions along with the instrumental contributions are considered to be background contributions. As diffuse background contributions are essentially continuous like the non-crystalline diffraction component of interest, a critical component of robust analysis of non-crystalline powder patterns will be a data-normalization scheme that includes characterization of the diffuse background. A straightforward normalization procedure can be developed from the Debye diffraction equation and will be referred to as the Debye normalization. Data normalization is such an important part of the analysis of non-crystalline powder patterns that an understanding of the Debye diffraction equation is essential in determining when the Debye normalization can be applied and when it is not appropriate. With appropriate data normalization, non-crystalline powder patterns can be used for quantitative analysis, phase identification and even structural analysis. Because of the essentially continuous diffraction response, chemometric methods (Brereton, 1990; Deming *et al.*, 1988) such as variance and difference analysis along with partial least squares (PLS) and principal component analysis (PCA) become key tools for normalized non-crystalline powder pattern characterization.

5.6.2. Crystalline and non-crystalline: an introduction to the Debye model

The International Union of Crystallography has defined crystalline to refer to any solid that has 'an essentially discrete diffraction diagram' (International Union of Crystallography, 1992). By 'discrete' diffraction diagram it is implied that the measured X-ray diffraction pattern has well defined and resolved diffraction peaks. Inverting the definition, a non-crystalline system can be considered to have a diffraction diagram that is essentially continuous with no discrete diffraction features. The liquid state and solid state are the two high-density states of matter. Generally speaking, the crystalline state is considered to be the equilibrium state for solid forms while the non-crystalline state is considered to be the equilibrium state for liquid forms (Chaikin & Lubensky, 1995). As such, non-crystalline solid forms are usually considered to be metastable or unstable with respect to the underlying crystalline state (if there is one available). For the purpose of powder X-ray diffraction, which probes the average instantaneous local structure, the measured non-crystalline X-ray diffraction from either liquids or solids can be characterized using the same analytical methods. In the following sections, the term non-crystalline will be used to refer to high-density states that are either liquid or solid forms that exhibit an essentially continuous diffraction diagram.

In an ideal sense, the non-crystalline state is one that has the highest symmetry possible for a high-density form, where every atom is equivalent to every other atom in the system. Here 'symmetry' is being used in the mathematical sense where symmetry and entropy may increase together. From the perspective of X-ray diffraction, this ideal high-symmetry state (where every atom is essentially the same average atom) will appear continuous and isotropic on all length scales except the atomic length scale. On the atomic length scale, all ideal non-crystalline systems will exhibit an essential granularity that forms the basis of the characteristic non-crystalline powder pattern. This will be true for large molecular systems, small molecular systems and atomic systems. To achieve the ideal high-symmetry state, the system must be reduced to the common atomic level granularity. In reality, rigid structure within a single molecule and energetic interatomic bonding constraints will resist being deconstructed to a random atomic granularity (depending on the effective temperature of the system). The residual atomic level structure that resists being deconstructed breaks the local continuous symmetry and contributes a unique diffuse scattering component to the continuous powder pattern.

The Debye diffraction equation can be used to model the characteristic diffraction from residual local order based upon the coherent scattering between individual atom–atom pairs. Within the Debye diffraction model, the interference term describing the coherent diffraction intensity for a pair of atoms (A and B) can be written as

$$I(Q)_{\rm interference} = f_A f_B \,{\rm sinc}(Qd_{AB}).$$

The term Q represents the magnitude of the diffraction vector, $\mathbf{Q}$, which can be defined as $4\pi\sin(\theta)/\lambda$, where θ is half the diffraction angle 2θ and λ is the X-ray wavelength (for all calculations within this chapter the X-ray wavelength will be taken to be the mean Cu $K\alpha$ wavelength of approximately 1.5418 Å). Coherent interference is governed by the sinc function, which is defined as ${\rm sinc}(x) = \sin(x)/x$. The term f_A represents the individual atomic form factor of atom A and d_{AB} represents the atom–atom distance between atoms A and B. The coherent interference between diffraction contributions from each atom is represented by the sinc term. The total diffraction from a pair of atoms is then determined by applying the interference term above to every atom–atom combination (A–A, B–B, A–B and B–A) and summing the individual intensity terms:

$$I(Q)_{\rm atom\ pair} = f_A^2 + f_B^2 + 2f_A f_B \,{\rm sinc}(Qd_{AB}).$$

For self-scattering terms A–A and B–B, the distance is zero and the sinc term becomes 1.0.

To calculate the Debye diffraction response for a sample of interest, an atomic level model is required of the coherently related atoms and molecules that make up the sample. The interference term is then applied to every possible atom–atom pair and the resulting coherent intensities summed. Within the framework of the Debye equation, coherently related means atoms that have an essentially constant relative spatial relationship. For example, a single rigid molecule in a low-viscosity liquid might be in continuous motion during a diffraction measurement; however, the intramolecular atom–atom distances remain essentially constant. In this example, the atoms that make up the rigid groups of the molecule are considered to be coherently related for the Debye equation. As a second example, within a perfect single crystal, all the atoms exhibit essentially constant spatial relationships and will, therefore, all contribute to the coherent model. The Debye equation assumes that the coherent scattering from a single pair of atoms is an instantaneous process, with each atom–atom pair scattering independently of all other atom–atom pairs. The total diffraction response from the model sample is, therefore, the sum of the scattered intensities from each coherent atom–atom pair within the model.

In addition to atom coherency, the derivation of the Debye equation implicitly assumes that all orientations of a specific atom–atom pair with respect to the X-ray diffraction vector, $\mathbf{Q}$, are present in the sample. For many non-crystalline and crystalline powder samples this spherical symmetry requirement is satisfied. To help grasp the implicit spherical symmetry requirement within the Debye equation, it can be instructive to consider the application of the Debye equation to both a non-oriented crystalline powder sample and an ideal non-crystalline sample. For a non-oriented crystalline powder sample, within each single crystal, specific atom–atom pairs will be strongly oriented according to the inherent packing symmetry of the crystal. However, the same atom–atom pair will be randomly oriented when averaged throughout the powder sample over many thousands of individual crystals. As the Debye equation calculates the coherently scattered intensity from each individual atom–atom pair (and not the amplitude), the fact that the random orientation is between different crystals in the powder sample is irrelevant to the method. Non-crystalline systems naturally express long-range spherical symmetry with random atom–atom orientation both spatially and temporally. If we consider a specific atom–atom pair within a single molecule in a liquid, then because of the relatively rapid motion of molecules within a non-crystalline liquid from one instantaneous measurement to another, the molecule is likely to have a different orientation with respect to the diffraction vector. As the Debye equation calculates the instantaneous coherently scattered intensity from a specific atom–atom pair, the fact that the random orientation is a time average is also irrelevant to the method. The spherical symmetry requirement inherent in the Debye theory yields a total diffraction response that is also spherically symmetric, depending only on the radial magnitude of the diffraction vector $\mathbf{Q}$. The inherent symmetry of the Debye theory mirrors the inherent symmetry of a powder diffraction pattern collected on an ideally random crystalline powder sample. The relationship between powder patterns and the Debye diffraction response will be explored in later sections.

The Debye equation can in principle be used to calculate total diffraction responses from any material that exhibits random orientation either spatially or temporally, even if there is considerable instantaneous locally average order present. However, building representative atomic level models can be a challenge. To model crystalline systems, the atomic model must be large enough to naturally express the symmetry extinction rules, which often requires many thousands of atoms. For realistic non-crystalline materials, the challenge is to develop multiple instantaneous models sufficient to express conformational flexibility and variation in local packing arrangements (*i.e.* configurational entropy). This will also involve many thousands of atoms and can present a considerable computational challenge. In subsequent sections, the term 'locally average' order will be used to refer to a local ensemble of atom–atom distances that commonly occur within a sample. The averaging is performed over the time of the measurement and the volume of the sample with each atom–atom coherent diffraction event being local and instantaneous. Within a non-oriented crystalline powder, for example, the locally average order can be represented by the crystalline symmetry. For a non-crystalline material, the locally average order can be represented by an instantaneous cluster of molecules that commonly forms over the duration of the measurement.

The absence of any discrete features within a non-crystalline powder pattern is indicative of the absence of any average 'crystalline'-like order within the sample; *i.e.* macroscopically, the samples exhibit no specific average structure. However, the various halos and bumps that are observed in a non-crystalline powder pattern arise from the locally average order within the sample. For diffraction measurements, the specific atoms involved in the locally averaged order need not be chemically bound to each other, just spatially correlated. For organic molecules used as working examples within the following sections, the locally averaged order can arise from either intramolecular or intermolecular relationships. These form the internal and external terms of the Debye diffraction intensity sum. Organic molecules will typically have a well defined molecular structure, the rigid parts of which will give reproducible atom–atom distances within a non-crystalline sample. This represents the locally average intramolecular order. However, the observed average length scales of the intramolecular order will be limited by the length scale of commonly occurring structure (*e.g.* C—C bonds) within the molecule and its inherent conformational flexibility. In a non-crystalline system, a molecule is free to explore its available conformations without the constraints of periodicity; as such, molecular rigidity will directly influence the observed non-crystalline powder pattern.

The demands of high local packing density combined with the specific shape of organic molecules will often favour characteristic packing configurations (cybotaxis; Stewart, 1928). The atom–atom distances between molecules that exhibit specific local packing configurations represent the locally average intermolecular order. Because of the constraints of van der Waals type interactions between organic molecules, as a rule of thumb, intermolecular atom–atom distances are usually larger than 3.0 Å. For the Cu $K\alpha$ X-ray wavelength, 3.0 Å is approximately 30° 2θ. Thus, as a general rule, features observed in a non-crystalline powder pattern above about 30° 2θ arise from locally average intramolecular order. Features observed at angles lower than 30° 2θ can be due to either inter- or intramolecular order, but are typically due to local average intermolecular order.

5.6.3. Application of the Debye equation to a single molecule

The diffraction equations developed within this chapter will be based around the diffraction vector, **Q**, which defines a distance (magnitude) and direction in diffraction space. For non-crystalline materials, which will typically be isotropic in nature, diffraction space will be essentially spherically symmetric about the origin, and the variable of interest will be the magnitude of the diffraction vector Q. As expressed earlier, the magnitude can be written as $4\pi\sin(\theta)/\lambda$ or, using the Bragg transformation, the magnitude can be expressed as $2\pi/d$, where d is a characteristic distance within the sample. However, it must be pointed out that halos observed for non-crystalline materials do not follow Bragg's law and that the fundamental local distances in a non-crystalline sample can only be approximated through the use of the Bragg transformation. A rule of thumb (Guinier, 1994) suggests that a local distance x underlying an observed non-crystalline halo can be related to the Bragg d (calculated from the halo position) through the expression ($1.1d < x < 1.25d$). The exact nature of the relationship will depend on the local packing symmetry and the slope of the atomic form factor.

The Debye diffraction equation is a deceptively simple kinematic diffraction equation, being a sum over the scattered intensity from each atom–atom pair in the molecular model under study. However, the Debye equation expresses the total diffraction from a model sample and as such can give rise to complex calculated diffraction patterns that can be difficult to interpret from the perspective of Bragg or Laue diffraction. Furthermore, the formal application of the Debye equation requires detailed molecular/atomic models that fully express the structural features of interest.

The formal Debye diffraction intensity equation for a model of coherently related atoms can be written as (James, 1948)

$$I_D(Q) = \sum_{i=1}^{n} f_i^2 + 2\sum_{i,j=1,i\neq j}^{n} f_i f_j \sin(Qd_{ij})/(Qd_{ij}),$$

where the indices i and j run over all atoms in the model ($1 \rightarrow n$), f_j represents the individual atomic form factors, and d_{ij} is the atom–atom distance for each pair of different atoms i and j. The individual atomic form factors, f_j, implicitly depend on the magnitude of the diffraction vector, Q, and the X-ray wavelength used. The second term within the Debye equation is a weighted sinc function that generates the structural interference effects observed for coherently ordered systems. For large Q, the sinc function tends towards zero and the Debye equation reduces towards the independent coherent intensity function (James, 1948), which is the incoherent sum of the squared atomic form factors for all atoms i within the model. Although all atoms are scattering independently and incoherently with respect to each other, electrons within each atom are scattering coherently; hence the term 'independent coherent intensity':

$$I_{\rm ind}(Q) = \sum_{i=1}^{n} f_i^2.$$

As Q approaches zero, the Debye equation tends towards the coherent intensity function, which is the coherent sum of the atomic form factors for all atoms i within the model, squared:

$$I_{\rm coh}(Q) = \left(\sum_{i=1}^{n} f_i\right)^2.$$

The independent coherent intensity, $I_{\rm ind}(Q)$, scales with the number of atoms in the model system, while the coherent intensity, $I_{\rm coh}(Q)$, scales with the square of the number of atoms. At larger values of Q, the first term in the Debye equation is likely to dominate, and the scattered intensity from any model (sample) should approach the independent coherent intensity function. This is an important asymptotic behaviour at large Q that allows data measured on different samples and different X-ray instruments to be normalized to a common intensity framework, which is a required first step for robust analysis of measured non-crystalline powder patterns. The asymptotic high-angle behaviour of the Debye equation forms one aspect of the Debye normalization of measured powder patterns.

As Q approaches zero, the Debye equation collapses to the coherent intensity function that represents the maximum coherently scattered intensity when all atoms in the model are scattering in phase. This will typically only occur close to zero Q (the 000 reflection for crystalline materials) but may also occur at other Bragg-peak positions for simple atomic crystals (*e.g.* the 400 reflection for silicon).

For the purposes of exploring the Debye equation in more detail, the organic molecule mannitol ($C_6H_{14}O_6$) will be used as an initial example. The physical molecular structure used in the Debye model was extracted from a beta mannitol crystal structure [Cambridge Structural Database (CSD; Groom *et al.*, 2016) refcode DMANTL07 (Kaminsky & Glazer, 1997)] (see Fig. 5.6.1).

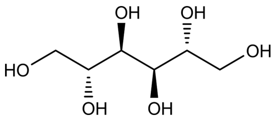

Figure 5.6.1
A chemical structure diagram for mannitol.

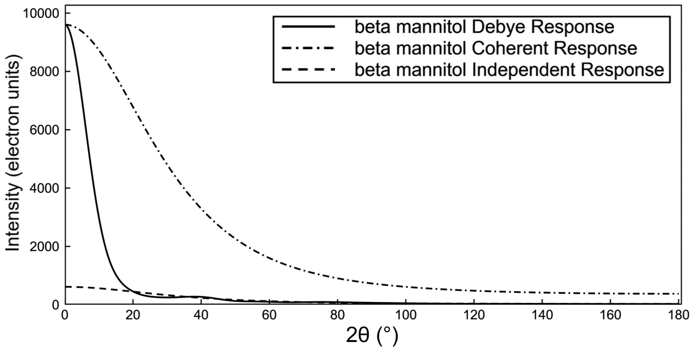

Figure 5.6.2
Calculated Debye diffraction response for a single mannitol molecule displayed with the coherent and incoherent diffraction responses. The *y* axis is in electron units.

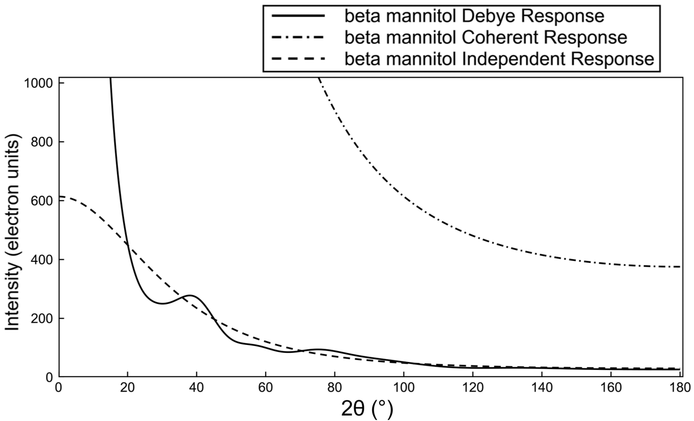

Figure 5.6.3
Zoomed-in view of Fig. 5.6.2 to show the oscillatory coherent diffraction response from a single mannitol molecule and the asymptotic high-Q behaviour approaching the independent coherent diffraction response.

Assuming that the non-crystalline sample of interest can be described as an ensemble of randomly packed non-interacting single mannitol molecules, and that the mannitol molecules are rigid (which, essentially, they are), then a single mannitol molecule is statistically representative of the locally average structure within the sample. This assumes that all molecules in the non-crystalline system scatter X-rays independently and incoherently with respect to each other, *i.e.* a complete absence of any intermolecular order. In principle, it might be expected that the Debye equation as applied to a single mannitol molecule should, therefore, give a reasonable description of the form of the expected diffraction response for the ideally random non-crystalline sample. In practice, as the Debye equation expresses the total diffraction response from any given molecular model, there are model-specific diffraction phenomena that have to be considered before a representative powder pattern can be calculated. In this mannitol example, the individual diffraction components generated by the Debye equation will be investigated from a rational and practical perspective. Figs. 5.6.2 and 5.6.3 show the calculated Debye diffraction response for a single mannitol molecule plotted against the independent, $I_{\rm ind}(Q)$, and coherent, $I_{\rm coh}(Q)$, diffraction functions. As a reality check, the $Q \to 0$ value for coherent intensity should tend towards the square of the number of electrons in a single mannitol molecule. Mannitol has 98 electrons per molecule giving a maximum coherent intensity response of 9604 electron units for a single molecule. The $Q \to 0$ value for the independent intensity should tend towards the sum of the squared number of electrons per atom. For $C_6H_{14}O_6$ this sum of squares is 614 electron units. The falloff in intensity observed in Fig. 5.6.3 for the independent diffraction function reflects the inherent Q dependence of the squared atomic form factors. For organic materials, the intensity falloff as a function of Q will be more severe than for inorganic materials.

Fig. 5.6.2 shows the $Q \to 0$ response for the Debye intensity function approaching the coherent diffraction function while Fig. 5.6.3 shows the asymptotic high-Q behaviour approaching the independent coherent diffraction response. The calculated Debye response has a dominating low-angle peak corresponding to the coherent scattering of all atoms in the model at small scattering angles. Measured diffraction patterns of organic molecular non-crystalline materials will typically exhibit a broad diffraction halo in the range of about 15.0 to 25.0° 2θ. This broad diffraction feature usually represents the highest diffraction intensity in the measured data. The continuously increasing diffraction intensity below about 60.0° 2θ observed in the calculated Debye response, Fig. 5.6.3, does not follow the intensity trend typically observed experimentally. While the calculated Debye diffraction response in Fig. 5.6.3 accurately represents the diffraction from a single mannitol molecule, it is not representative of a real bulk non-crystalline sample. The Debye diffraction model is a total diffraction model requiring that the sample be fully described within the associated molecular model. Following a thought experiment from James (1948), if the non-crystalline model is expanded from a single mannitol molecule to incorporate M random mannitol molecules with each molecule being incoherently related to every other molecule, then the sample diffraction response is simply the sum of the individual molecular Debye diffraction intensities over all M molecules:

$$I_{\rm sample}(Q) = M \times I_D(Q).$$

Within this model, the predicted intensity as $Q \to 0$ is simply $(M \times I_{\rm coh})$, which is incorrect. As with all molecular samples, the predicted intensity as $Q \to 0$ must be $M^2 \times I_{\rm coh}$. The missing intensity is due to the coherent diffraction contribution of all molecules in the physical sample at zero diffraction angle. For an ensemble of molecules in a solid continuum, the appearance of this low-angle coherent diffraction response is related to the physical ‘shape’ of the sample itself. The sample ‘shape’ is the physical bounding envelope containing all the randomly packed molecules. The role of ‘shape’ and molecular packing will be considered in more detail in Sections 5.6.11 and 5.6.12. For now, the ‘shape’ contribution is considered to be the small-angle scattering contribution from the physical sample. To continue the thought experiment, as a first approximation, the dominating low-angle Debye response can be taken to be related to the small-angle scattering response of a single free-standing molecule. A bulk non-crystalline sample will contain individual molecules embedded in an essentially isotropic continuum of electron density. As such, the small-angle scattering contribution from the physical shape of a single molecule will not be observed, being replaced by the small-angle scattering due to the bulk sample shape.

Various models have been proposed in an attempt to describe the dominating small-angle response (Debye, 1915; Guinier, 1994; James, 1948) in a manner that allows it to be mathematically removed from the calculated powder pattern. To remove the single-molecule small-angle X-ray scattering (SAXS) response within the spirit of the Debye equation, a molecular model would have to be generated containing many hundreds or thousands of randomly packed molecules, giving a volume large enough such that the ensemble SAXS response sharpens up and moves to lower angles. In this case, the calculated pattern more closely resembles measured non-crystalline powder patterns. However, it can be a challenge to generate a set of packed molecules that has an essentially random character and the computational overhead in applying the Debye equation can be significant for large molecular clusters. To provide a partial solution to the SAXS response based upon single-molecule models, Menke published a modification to the original Debye equation (James, 1948).

5.6.4. The Debye–Menke equation

To account for the high-density packing of complex molecules, Menke extended the Debye equation to include a molecular scattering function and a radial distribution function for each molecule (Menke, 1932). Following the review of the Menke extension as presented by James (1948), the molecular scattering function is expressed as

$$I_{\rm Menke}(Q)=\sum_{i=1}^{n}\sum_{j=1}^{n}f_i f_j \frac{\sin(Ql_{ci})}{Ql_{ci}}\frac{\sin(Ql_{cj})}{Ql_{cj}},$$

where l_{cj} is the distance of atom j from the defined origin of the molecular model. Although the Debye equation is independent of any real-space origin, when applying the Menke extension to the Debye equation, it is critical that the real-space origin of the atomic coordinates is coincident with the scattering centre of the model. The molecular scattering function essentially represents the coherent scattering from concentric shells of atoms about the defined molecular origin.

In Fig. 5.6.4, the Menke molecular scattering function for mannitol is plotted along with the calculated Debye response for a single mannitol molecule. The traditional Guinier small-angle scattering response (Guinier, 1994) for a radius of gyration, R_g, of about 2.78 Å is also displayed for comparative purposes:

$$I_{\rm Guinier}(Q)=I_0\exp\left(-Q^2R_g^2/3\right).$$

The Menke and Guinier scattering profiles are effectively similar descriptions of the small-angle scattering from a single free-standing mannitol molecule.

Traditionally, the shape-driven SAXS response for non-crystalline diffraction is subtracted from the Debye response, thus removing the central dominant component from the calculated diffraction profile. Although the extension to the Debye equation as originally presented by Menke included a radial probability distribution function in addition to the molecular scattering function, the Debye–Menke equation as used within this chapter can be expressed as

$$I_{\rm DM}(Q)=\left[\sum_{i=1}^{n}f_i^2+2\sum_{i,j=i,i\neq j}^{n}\frac{f_i f_j\sin(Qd_{ij})}{Qd_{ij}}\right]-\sum_{i=1}^{n}\sum_{j=1}^{n}f_i f_j\frac{\sin(Ql_{ci})}{Ql_{ci}}\frac{\sin(Ql_{cj})}{Ql_{cj}}.$$

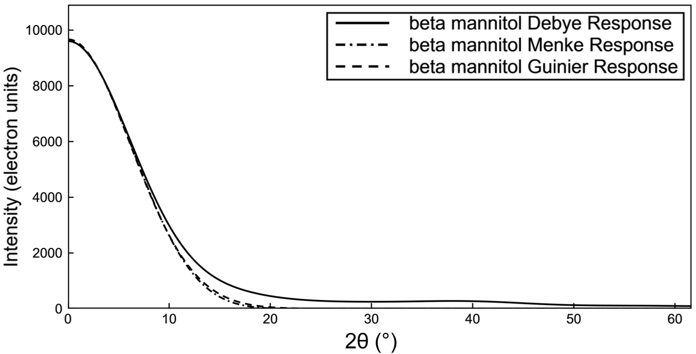

Figure 5.6.4
The Menke molecular scattering function displayed along with the Debye diffraction response and Guinier small-angle scattering response for a single mannitol molecule.

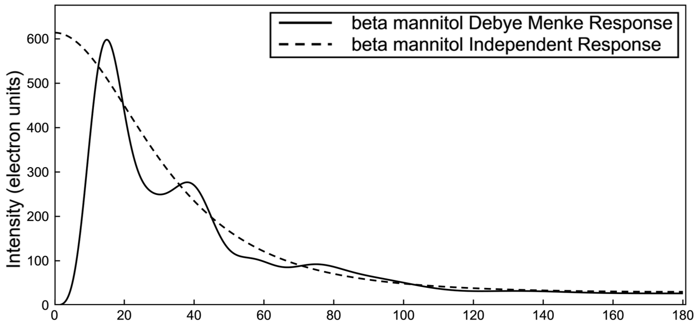

Figure 5.6.5
The diffraction response from a single mannitol molecule as calculated by the Debye–Menke equation displayed with the independent coherent scattering function.

The resulting Debye–Menke intensity function ($I_{\rm DM}$) for mannitol is shown in Fig. 5.6.5.

From Fig. 5.6.5, it can be seen that at large angles (high Q) the asymptotic form of the Debye–Menke intensity function approaches the independent coherent intensity function [$I_{\rm ind}(Q)$] while oscillating about that function. One component of the Debye normalization as applied to measured data is to scale all data to oscillate about the same independent coherent response at large measurement angles. The atomic composition of the sample and the X-ray wavelength used to collect the data will define the angular range required in order to observe the asymptotic high-angle behaviour. When using Cu $K\alpha$ X-rays, measurements will have to be made to relatively large 2θ angles in order to observe this asymptotic behaviour for organic systems. In Fig. 5.6.5, the calculations for mannitol were performed out to 180° 2θ and the oscillatory asymptotic behaviour of the Debye–Menke intensity function can be clearly observed. For many inorganic non-crystalline systems, the full asymptotic behaviour might not be observable when using Cu $K\alpha$ X-rays.

The relationship between the Debye–Menke intensity function ($I_{\rm DM}$) and the independent coherent intensity function ($I_{\rm ind}$) as displayed in Fig. 5.6.5 suggests a second aspect to the Debye normalization. The total diffraction intensity under the Debye–Menke curve (*i.e.* integrated intensity) approaches the integrated intensity for the independent coherent intensity function. This asymptotic integrated intensity behaviour again requires measurements out to high wavevectors in order to be approximately true and is related to the integrated intensity rules proposed by Vainshtein (1994). Following Vainshtein, the structural coherences that generate diffraction features are expressed in the summation over the various sine terms (Fourier terms). When averaged over a sufficient range in diffraction space, all the sine terms will tend to zero. As such, the total integrated intensity of X-rays scattered from a single molecular system should be a constant and independent of the structural details. In the absence of absorption, the constant is related to the atomic number density and illuminated volume of the sample. More specifically, with respect to the Debye equation, the structural interference terms are driven by weighted sinc functions. The integrated intensity of a sinc function is driven by the central halo, which is removed by the Menke correction. This suggests that if the central scattering component is ignored (which is realistic for samples greater than a few nanometres in size) and data are collected out to high enough diffraction angles, then the total integrated intensity for crystalline and non-crystalline materials of the same molecule should be the same and should approach the integrated intensity of I_{ind}. When applied to measured data, the instrumental intensity response (*e.g.* Lorentz and polarization factors) modifies the observed diffraction response, removing any absolute normalization possibility based upon the Debye equation. As such, a practical normalization procedure for measured data might require that each non-crystalline powder pattern be scaled such that the observed high-angle intensity asymptotically approaches (and oscillates about) a common intensity trend and that the data have common integrated intensity. This is a reasonable normalization procedure provided that the atomic compositions of the samples being studied are similar. Data normalization is such a critical component for the characterization of diffraction from non-crystalline systems that these rules of thumb will be investigated in more detail in Sections 5.6.7 to 5.6.10.

5.6.5. Verification of the Debye–Menke intensity function

The Debye–Menke intensity function (I_{DM}) for a single mannitol molecule, Fig. 5.6.5, shows a well defined low-angle halo at about 14.5° 2θ. In Fig. 5.6.6, the I_{DM} is plotted along with the full Debye intensity function, I_D, for mannitol; note that the dominant low-angle halo is not visible in I_D because of the huge SAXS contribution. Since the 14.5° halo is not visible in the full Debye intensity function, it may potentially be an artifact induced by subtraction of the Menke intensity due to the non-spherically symmetric mannitol. Using the Bragg relationship to convert this halo position to distance gives an effective interatomic spacing of about 6.1 Å. In order to verify whether this interatomic spacing is an inherent part of the mannitol molecular structure, a histogram of atom–atom pair distances within a mannitol molecule was determined and this is plotted in Fig. 5.6.6 along with I_{DM}.

To derive the histogram displayed in Fig. 5.6.6, each atom–atom distance d in the molecule is transformed to the corresponding diffraction-vector magnitude Q_d (*i.e.* $Q_d = 2\pi/d$) and expressed as a unitary Gaussian function with the standard deviation in Q of 0.01 and weight given by the atom-pair structure factor. The histogram is built up by accumulating all the unitary Gaussians for each atom–atom distance. The validity of using a Bragg transformation to relate single atom–atom distances to a position in diffraction space is questionable for non-crystalline systems but may provide a useful reference framework if used with care. The histogram as plotted essentially corresponds to the first-order coherent diffraction from a structure with characteristic distances defined by the individual atom–atom distances. The two primary halos observed at about 14.5 and 40.0° 2θ in I_{DM} are reproduced within the histogram, suggesting that they are characteristic features of a rigid mannitol molecule.

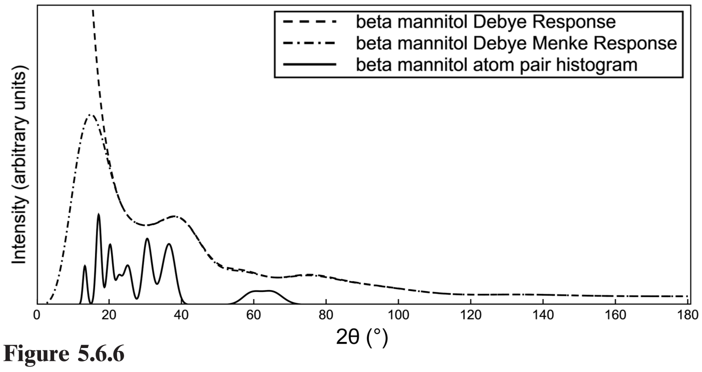

Figure 5.6.6
Overlay of the Debye and Debye–Menke response for mannitol with a weighted histogram of atom–atom pair distances within mannitol. The y axis is in arbitrary units.

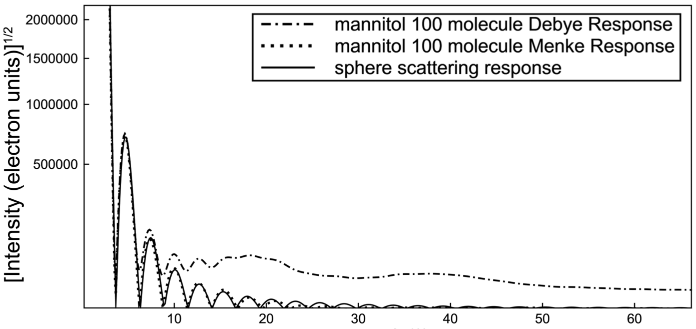

Figure 5.6.7
Calculated X-ray scattering responses for 100 mannitol molecules packed into a sphere of radius 1.71 nm. Note that the y axis is now the square root of the electron units to enhance the visibility of the small-angle scattering oscillations.

To further demonstrate that the Menke correction to the Debye equation removes the $Q \to 0$ small-angle scattering response arising from finite-sized molecular models, 100 mannitol molecules were 'randomly' packed into a sphere of radius 1.71 nm using the program *PACKMOL* (Martínez *et al.*, 2009). *PACKMOL* is a useful program for generating initial pseudo-random packing configurations for organic molecules and was used several times in the work described in this chapter whenever random packing configurations of a large number of molecules were required. To generate uniform high-density packing configurations, the model mannitol molecule is used without the attached hydrogen atoms. The small-angle scattering response from the packed sphere can be calculated using the sphere scattering formula:

$$I_{\mathrm{sphere}} = \left[3(\sin x - x\cos x)/x^3\right]^2,$$

where the variable $x = QR$, with R being the sphere radius. The Debye and Menke responses for the packed sphere of mannitol molecules and the calculated sphere scattering intensity are displayed in Fig. 5.6.7.

The Menke response as shown in Fig. 5.6.7 clearly exhibits extensive low-angle oscillations that extend out to diffraction angles greater than 20° 2θ. When the Menke response is compared with the calculated small-angle scattering response for a uniform sphere of radius 1.71 nm, the correlation is clearly visible. There are some differences between the sphere scattering and the Menke response at higher angles due to the granularity of the packed mannitol molecules and the lack of a smooth sphere surface. However, the correspondence is close enough to demonstrate further that the Menke response is an effective correction for small-angle scattering within the Debye model. (It should be mentioned that the Menke correction derives the small-angle scattering response in the Fraunhofer diffraction limit, which is an acceptable approximation for small clusters of molecules and in particular spherically symmetric samples.)

5.6.6. Background removal, intensity normalization and choice of X-ray optics

The analysis of non-crystalline powder patterns will typically require a different set of analytical tools than those employed for crystalline material analysis. The continuous nature of non-crystalline powder patterns makes them ideally suited to chemometric data analysis, which characterizes variance among individual data sets. As an additional consideration, being metastable (or unstable) solid forms, non-crystalline materials will change over time and will also change depending on the production pathway. This inherent variable nature further suggests that chemometric methods will be a primary analytical tool for the characterization of non-crystalline materials. A common requirement for the many chemometric approaches is appropriate data normalization. Normalization of a set of analytical data is an attempt to remove variances amongst the individual data sets that are spurious with respect to the analytical variance of interest. For powder diffraction measurements, spurious variances may include such variables as instrument intensity, instrument background, sample mass and sample packing density. Ideally, for chemometric analysis, the only unknown variability within the measured data after normalization should come from the intrinsic sample properties and not from the instrument or extrinsic sample variance.

The Debye equation suggests two fundamental intensity normalization approaches that can be applied to non-crystalline powder diffraction patterns. The first is that the total scattered analytical intensity from a sample should approach the integrated intensity under the independent scattering function. The second is that the high-angle data should asymptotically oscillate about the independent scattering curve. An additional practical constraint that may also be applied requires that the non-crystalline diffraction response should return to the instrumental baseline at low diffraction angles. The application of the constraint that forces the analytical signal to return to the baseline at low diffraction angles implicitly assumes that the non-crystalline sample being studied does not exhibit strong small-angle scattering from any micro-voids or internal density variation. As such, this final constraint, when used, should be applied with care.

Although the Debye equation suggests potential data normalization procedures, the traditional expression of the Debye equation is as raw diffraction intensity with no terms relating to how this diffraction response would appear as measured data. The appearance of the measured data will in part depend on the diffraction instrument configuration and geometry used. Each diffraction instrument will leave ‘fingerprints’ on the measured data that in principle have to be removed to enable full Debye modelling. Some of the fundamental instrumental contributions include diffuse background, angular resolution (peak width), intensity response and spectral purity. For non-crystalline material characterization, of greatest importance with respect to instrument optimization are well defined and smoothly varying background and intensity response functions. Ideally, the instrumental background should be low and the intensity response (diffraction signal) high. For ease of modelling, the instrumental spectral purity (energy resolution) should be as close to monochromatic as realistically possible. Because of the continuous nature of non-crystalline diffraction, the instrumental angular resolution is usually a secondary consideration.

Determining an instrumental background is typically a critical first step in employing data normalization procedures, as instrumental background intensity will not scale according to the same rules as the diffraction signal from a sample. As such, the instrumental background intensity must be either removed from the measured data or built into the intensity normalization procedure. Characterizing and/or removing instrumental background is a required data pre-processing step when dealing with powder patterns from non-crystalline samples. Because of the critical role played by instrumental background contributions in the analysis of non-crystalline data, the inherent instrumental background and its variability are key considerations in the choice of diffraction optics and geometry.

For crystalline X-ray diffraction, the instrumental intensity response function is usually expressed in terms of a Lorentz factor and polarization term. While the polarization term will be unchanged, the Lorentz factor as applied to the Debye equation differs from either the single-crystal or powder Lorentz terms. The differences arise from the inherent spherical integration that is implicit within the Debye equation and its continuous rather than discrete nature (James, 1948). For this initial discussion of data normalization, the role of the instrumental intensity response will not be considered. However, the instrumental intensity response and the differences in Lorentz factor will be discussed as part of the instrumental intensity modelling and advanced data normalization in Section 5.6.8.

In addition to the continuous nature of the diffraction response, non-crystalline materials are typically metastable and may exhibit variability and relaxation over the duration of the diffraction measurement. In order to observe the initial state of the non-crystalline sample, rapid data collection may, therefore, be required. The requirement for rapid data-collection capability should be balanced with the requirement for high count rates in the sample diffraction response and low instrument background. A good solution for laboratory measurements has proven to be a static or scanning position-sensitive detector (PSD) with diffracted-beam optics essentially open (relaxed). In this geometry, the powder diffraction data can be rapidly acquired in a series of loops or frames. A comparison of the powder patterns across the multiple loops or frames can be used to identify any propensity for physical or chemical instability over the duration of the measurement. The frames that show a consistent powder pattern can be summed to recover the high diffraction intensity required for robust analysis. Although open diffracted-beam optics can lead to significantly higher instrumental backgrounds, the simplicity of the X-ray optics tends to give a consistent and continuous background response that forms the basis of a more robust analysis.

At the present time, one of the most direct approaches to determining an instrumental background response is to measure a blank sample under the same conditions as the analytical sample. For reflection measurements, both the instrumental intensity response and background can be optimized by using offcut single-crystal low-background sample holders (*e.g.* silicon or quartz) with a shallow well. A suitable blank might be the holder itself or the holder plus a crystalline powder that has few reflections in the measurement range of interest. Ideally, the chosen crystalline ‘background’ sample should be of a similar atomic makeup to the analytical sample to minimize the impact of absorption differences. If a crystalline powder blank is used, then the Compton scattering, *Bremsstrahlung*, thermal diffuse scattering and defect scattering from the blank sample must be accounted for in order to isolate the pure instrumental background. The idea behind the blank sample measurement is to generate a continuous instrumental background response that

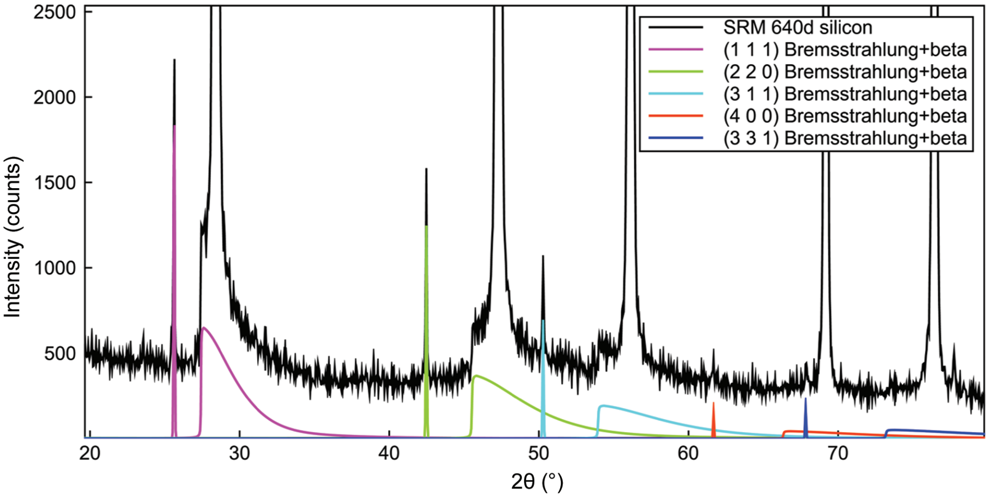

Figure 5.6.8

Measured Bragg–Brentano data for SRM 640d depicting the diffuse background and calculated *Bremsstrahlung* contributions. The individual calculated responses also include the Cu $K\beta$ Bragg peak from $K\beta$ X-rays that pass through the beta filter.

can be built into the intensity normalization procedure. For many reflection geometries, an empty low-background sample holder will give a suitable blank response that can be directly measured, but crystalline powder blanks have an additional advantage in that the crystalline peak intensities may also be used to track the instrumental intensity response function. As a general rule, it is not recommended that non-crystalline materials be used as holders for non-crystalline samples, as it can be difficult to isolate the non-crystalline holder pattern from the non-crystalline pattern of interest. For example, glass capillaries will often exhibit subtly different non-crystalline patterns from one capillary to another and may also give different patterns from one location to another on the same capillary.

An example of using a crystalline powder reference to extract the instrumental background is illustrated in Figs. 5.6.8 and 5.6.9 for NIST SRM 640d silicon. The data were collected using a Cu $K\alpha$ tube source on a diffractometer in Bragg–Brentano reflection geometry using a beta filter and open secondary optics; no active optical components (*e.g.* monochromator or mirror) were used. For this type of X-ray optics, scattering of *Bremsstrahlung* radiation contributes a significant intensity to the observed background level. *Bremsstrahlung* radiation is the continuous white X-ray background generated by all solid-anode X-ray sources, emitted by electrons during deceleration within the anode. Like synchrotron X-ray radiation, high-energy *Bremsstrahlung* is often plane polarized. For crystalline materials, the same crystalline planes that diffract the primary Cu $K\alpha$ X-rays will also diffract the white background continuum. As such, each crystalline Bragg peak will exhibit a characteristic *Bremsstrahlung* diffuse background (and Cu $K\beta$ peak). When a beta filter is used in the diffracted beam, the diffuse *Bremsstrahlung* background will exhibit a distinctive sharp step corresponding to the beta filter absorption edge. This background step can be used to identify the magnitude of the *Bremsstrahlung* diffuse component for each diffraction peak. In Fig. 5.6.8, the derived *Bremsstrahlung* contribution for each of the main crystalline Si peaks is presented along with the residual beta peak from the Cu $K\beta$ X-rays that pass through the beta filter. Because of the white radiation source, the *Bremsstrahlung* diffuse contribution becomes broader for peaks at higher diffraction angles. For the reflection Bragg–Brentano X-ray optical path used to collect the data in Fig. 5.6.8, the integrated intensity of the *Bremsstrahlung* contribution is approximately 7% of the total Bragg peak area. Although the diffuse *Bremsstrahlung* component is driven by the white background from the X-ray source and will be further modified by active X-ray optical components in the beam path, its appearance in the measured data is dependent on the coherent structure of the sample. As such, it is generally treated as a sample-dependent contribution to the diffuse scattering rather than an inherent instrumental background. An inspection of Fig. 5.6.8 suggests that once the *Bremsstrahlung* diffuse peaks have been removed, the measured background is essentially flat at about 300 counts. This flat background is, however, not the instrumental background as it is, for the most part, due to Compton scattering and thermal diffuse scattering from the Si powder sample. Individual modelling of Compton scattering will be discussed in Section 5.6.9, but the final theoretically calculated background response for powdered crystalline Si as measured using open Bragg–Brentano optics is shown in Fig. 5.6.9. The derived instrumental background contribution as depicted in Fig. 5.6.9 rapidly falls towards zero at large diffraction angles away from the main beam.

For characterization of crystalline powder samples, it is an accepted practice to routinely run validation standards in order to verify instrumental performance with respect to absolute peak positions, peak width, linearity and intensity (Cline, 1992; see also Chapter 3.1). For non-crystalline material analysis, routine validation standards should be run to verify both the instrumental background and instrumental intensity response. Although the powder silicon standard SRM 640d is not specifically recommended as either an intensity or background standard, it can be used to derive and validate continuous background and intensity response functions. Derivation of the instrumental intensity response is discussed in Section 5.6.8. Instrumental backgrounds for transmission measurements can be significantly higher than for reflection measurements, as the scatter of X-rays from the primary incident beam before the sample can pass through the sample and X-ray optics into the detector. A further diffuse component that may be observed for transmission measurements is X-ray scatter from any window or container materials that the incident X-rays pass through. For powder samples that can be prepared as free-standing films or wafers, then, in principle, the sample holder may require no window material or supporting material in the X-ray beam. For liquid or powder samples that cannot be prepared as free-standing solids, polymer films can be used to make a sandwich holding the sample, which is then mounted in standard transmission sample holders. To minimize these additional diffuse background components for transmission measurements, it is good practice to use thin (~3 μm) low-scattering polymer windows such as Etnom (Chemplex Industries) or Mylar (SPEX CertiPrep).

A worked example concerning data normalization for semi-quantitative analysis using transmission data is discussed in the following section.

5.6.7. Application of the Debye normalization to semi-quantitative analysis

As previously discussed, there are numerous sources of diffuse X-ray diffraction intensity that should ideally be removed before analysing non-crystalline powder patterns. However, for the specific case of semi-quantitative analysis of organic materials, many of the sample-dependent contributions will be very similar from sample to sample because of their similar elemental composition. Any small differences in the diffuse contribution from each phase of interest are likely to scale with the relative masses of each phase present in the sample (the validity of this assumption will be investigated below). With consistent and careful powder diffraction measurements using the same mass of sample each time, it may be possible to perform semi-quantitative analysis utilizing an instrumental background as measured on a blank sample. Within this chapter, semi-quantitative analysis refers to the determination of the relative masses of the phases of interest within a set of samples without using specially prepared calibration or validation standards. This is typically achieved by using full-pattern fitting and/or chemometric methods to characterize variance between individual data sets collected on an ensemble of samples. As a worked example, within this section, a series of sucrose lyophilizates with varying water content will be analysed to determine the residual water content. Each sample was isolated using thief sampling at different points within the final drying cycle. The water content is expected to vary with the time the sample spent in the final drying phase. More details of sample preparation and discussion of a full-pattern fitting method have been presented previously (Bates *et al.*, 2013); in this section, the same data will be analysed using an alternate chemometric variance technique to demonstrate the robustness of the Debye normalization.

The X-ray powder patterns were collected using a Rigaku SmartLab system in a transmission geometry using a convergent-incident-beam mirror and linear PSD (D'teX). The convergent beam was focused through an environmental cell onto the detector plane. In addition to the X-ray mirror and linear detector, the only other X-ray optics used for this measurement were passive slits to define the beam footprint and reduce parasitic background. The secondary (detector) optical path was essentially wide open, which gives a high but reproducible instrumental background and an instrumental intensity response function that is smooth and easy to model. The use of an environment cell to hold each sample was required because of the inherent instability of the lyophilizates with respect to temperature and humidity. Humidity is often a critical parameter requiring control when characterizing non-crystalline organics, as water is an effective plasticizer for these systems and can significantly accelerate both physical and chemical instability. In order to collect consistent powder patterns on the sucrose lyophile samples, the samples were mounted in a dry glove box ($\ll 0.3\%$ relative humidity) into an environmental cell which used double Etnom (Chemplex Industries) X-ray windows as a barrier to the ambient humidity. The double Etnom window allows about 1 h of sample stability, which is sufficient to collect multiple powder pattern frames.

The combination of the double Etnom environmental cell and open secondary optics gives a relatively high instrumental background that must be modelled out of the data to perform the semi-quantitative analysis. The background model was derived from a direct measurement of the empty environmental cell (blank). For each measured data set, the blank background and the measured sample data are scaled with respect to each other. The residual analytical data are then calculated by removing the scaled background from the scaled measured sample data. The relative scaling is performed to ensure that the integrated intensity of the residual analytical signal is a constant for all samples with the high-angle data asymptotically approaching the same signal level. For a more robust background model, the measured blank response should be corrected for absorption through the transmission sample. Any diffuse background components originating before the sample (*i.e.* air scatter) will have to pass through the sample before reaching the detector. For different sample thicknesses and packing densities, the absorption correction will be slightly different. To avoid an explicit absorption correction, a small linear damping term was applied to the blank response as an approximate absorption term. The degree of damping is a refinement variable along with the two scale factors in order to achieve consistent Debye normalization across all analytical data sets.

In this first approximation to Debye normalization, there are three variables: scale factors for the measured data and blank data, plus the degree of linear damping for the blank data. The conditions that define the correct solution are matching integrated intensity for the residual analytical data and asymptotic high-angle data (in order to converge correctly, an additional constraint requiring matching data at the low-angle background point may also be required). This approach to Debye normalization is simple enough to be routinely performed using Microsoft *Excel* or similar software. The integrated intensity normalization and high-angle asymptotic behaviour matching both implicitly assume that the same atom types and relative concentrations are present in all samples being studied. When the atomic compositions are very different between the various phases in the samples, then a bias is introduced into the subsequent analysis. Despite the potential for bias, the Debye normalization as presented here transforms the measured non-crystalline powder patterns into a suitable form for chemometric analysis.

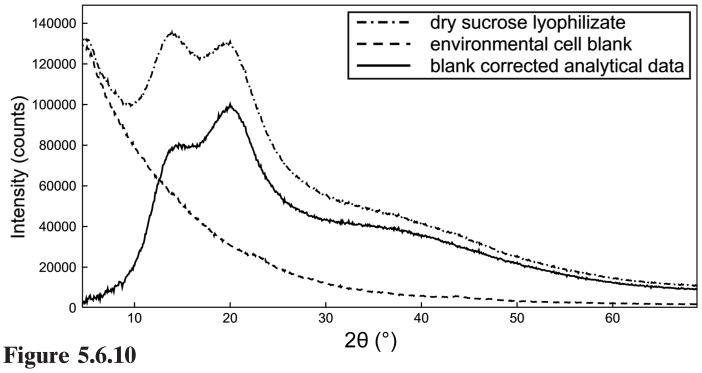

Figure 5.6.10
Measured non-crystalline powder pattern for a dry sucrose lyophilizate compared with the scaled blank background and resulting analytical signal.

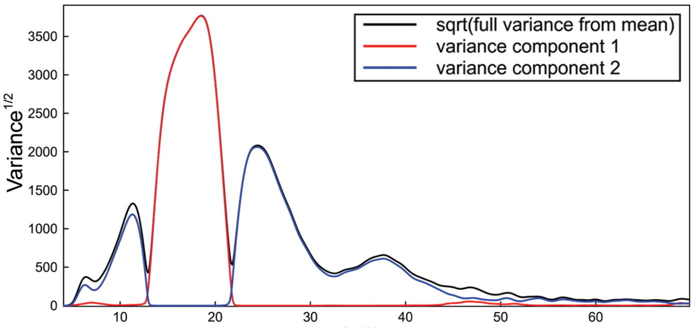

Figure 5.6.12
Square root of the full data ensemble variance from the mean display with two orthogonal principal variance components (expressed as real positive components).

Fig. 5.6.10 shows an example of the measured data for a dry sucrose lyophilizate compared with a scaled blank background and residual analytical signal. In Fig. 5.6.11, the resulting analytical data for dry and partially dry sucrose lyophilizates are compared to demonstrate the Debye normalization.

Visually, the two analytical data sets in Fig. 5.6.11 are similar with closely matching halo positions and relative intensities, but they are not the same. The difference between the two non-crystalline powder patterns is a result of the residual water content in the partially dry sample. For continuous and normalized data sets like those presented in Fig. 5.6.11, chemometric analysis provides a series of useful techniques for characterizing the variance between individual data files within an ensemble of data sets. There are a number of different variance-based chemometric techniques that could be employed to characterize the normalized data and extract the impact of residual water on the local sucrose structure (Brereton, 1990; Deming *et al.*, 1988). A simple approach that makes use of the Var.P(), Correl() and Solver() functions in Microsoft *Excel* is outlined below. The first step is to define principal variance components for the data ensemble. Taking N normalized observed powder patterns corresponding to different residual water contents, the mean and variance of the data ensemble can be defined as follows using *Excel* functions:

$$I_{\rm mean}(2\theta) = {\rm Average}\big[I_{\rm obs}(2\theta, 1)\ldots I_{\rm obs}(2\theta, N)\big],$$

$$\mathrm{SV}(2\theta) = \big\{{\rm Var.P}[I_{\rm obs}(2\theta, 1)\ldots I_{\rm obs}(2\theta, N)]\big\}^{1/2}.$$

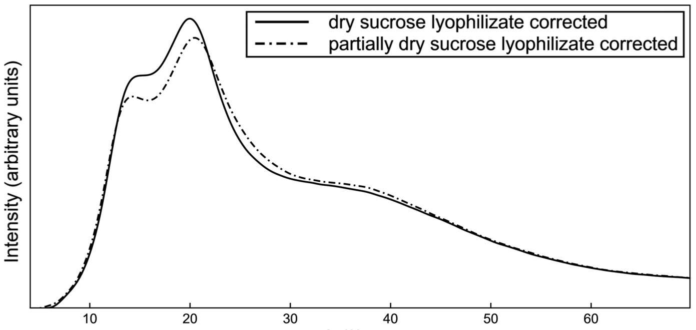

Figure 5.6.11
Normalized analytical data for dry and partially dry sucrose lyophilizates. Each analytical data set has the same integrated intensity and matching asymptotic behaviour towards 70° 2θ. An additional constraint of matching low-angle analytical signal was also imposed during the normalization.

The resulting square root variance [SV(2θ)] for the sucrose lyophilizates is presented in Fig. 5.6.12. Visual inspection of Fig. 5.6.12 indicates that the peak variance response occurs at about 18° 2θ. The position X of the peak variance response is used to define a correlation function for all variances with respect to the variance at X:

$$C(2\theta)|_X = {\rm Correl}\big[I_{\rm obs}(2\theta = X, 1)\ldots I_{\rm obs}(2\theta = X, N), \\ I_{\rm obs}(2\theta, 1)\ldots I_{\rm obs}(2\theta, N)\big].$$

The correlation function is expressed as a real positive variance component using the expression

$$\mathrm{VC}_X(2\theta) = \mathrm{SV}(2\theta)\big[C(2\theta)|_X - 1\big]/2.$$

In Fig. 5.6.12, the first real positive variance component as determined for X = 18° 2θ is plotted as variance component 1. Variance component 1 describes the central strong variance observed in the data but does not describe the complete observed variance. Using the residual variance, a second variance component can be defined using the strongest undescribed variance response at X = 24° 2θ. This second real positive variance component is plotted in Fig. 5.6.12 as variance component 2. The two variance components as displayed in Fig. 5.6.12 show no significant cross-correlation and are therefore essentially orthogonal with respect to each other and represent the principal variances within the data ensemble. The derived two-component model describes all the significant variance in the data ensemble.

The final step in the *Excel* chemometric model is to use the Solver() function in combination with the essentially orthogonal variance components to describe each of the individual normalized powder patterns. Each model powder pattern is constructed using

$$I_{\rm model}(2\theta) = I_{\rm mean}(2\theta) + \mathrm{SF}_1\mathrm{VC}_1(2\theta) + \mathrm{SF}_2\mathrm{VC}_2(2\theta),$$

where the SF_i terms are the individual variance component scale factors used as variables by the Solver() function to achieve the best fit to the individual normalized powder patterns. Within the standard Solver() model, the variance component scale factors must be allowed to assume positive or negative values. The best fit was determined using a full-pattern least-squares error minimization. The least-squares error to be minimized can be written as

$$\mathrm{LSE} = \sum_{2\theta}\big[I_{\rm obs}(2\theta) - I_{\rm model}(2\theta)\big]^2.$$

The resulting optimized scale factors give a quantitative measure of how far each powder pattern is displaced from the mean powder pattern. Each of the thief samples had independent residual water content analysis performed using an averaged KF (Karl Fisher) and IR absorption procedure allowing the opti-

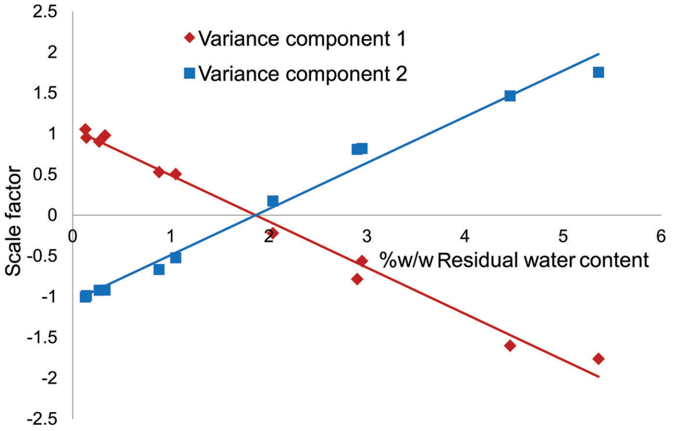

Figure 5.6.13

mized scale factors to be plotted against determined residual water content; the reader is referred to the original reference (Bates *et al.*, 2013) for discussion of a more quantitative method.

The optimized scale factors shown in Fig. 5.6.13 for the variance components are essentially mirror images of each other, which further supports the conclusion that the normalized powder data represent a binary system. The scale-factor response is effectively linear within the region of interest down to the lowest residual water levels of less than 0.2%(*w*/*w*). This is a surprising level of sensitivity for a non-crystalline semi-quantitative method. Following the International Council for Harmonization of Technical Requirements for Pharmaceuticals for Human Use (ICH) guidelines Q2(R1) (ICH Harmonized Tripartite Guideline, 1994), the limit of detection, LOD, for the simple chemometric variance method can be determined using the slope of the response lines in Fig. 5.6.13 and the standard deviation of the response σ,

$$\mathrm{LOD} = 3.3\sigma/\mathrm{slope}.$$

For the data displayed in Fig. 5.6.13, the calculated LOD is about 0.75%(*w*/*w*) residual water in the sucrose lyophilizates.

From Fig. 5.6.13, scale factors of (1, −1) for the two orthogonal variance components allow the reconstruction of the 'driest' sucrose lyophilizate reference pattern and scale factors of (−2, 2) will reconstruct the 'wettest'. Setting the scale factors to say (−10, 10) will reconstruct a theoretical reference pattern for a lyophilizate with significant water content. A plot of the 'dry' sucrose lyophilizate with free water and the calculated 'wet' reference pattern is shown in Fig. 5.6.14. The calculated 'wet' sucrose reference as derived from the measured variance as a function of water content is significantly different from either the 'dry' sucrose or free-water powder patterns. The uniqueness of the calculated 'wet' reference pattern suggests that the residual water is combining with the sucrose to form a new solid/liquid phase with a different local structure than either water or non-crystalline sucrose. From a liquid-state perspective, the water is miscible within the non-crystalline sucrose at the molecular level. Miscibility at the molecular level essentially gives a single-phase system for each level of residual water content. However, across multiple samples with different residual water levels, a miscible system may also appear as a binary system. Whether the interaction between water and non-crystalline sucrose is a miscibility or solubility process, the chemometric analysis clearly demonstrates the binary nature of the sucrose:water system with no free water being observed.

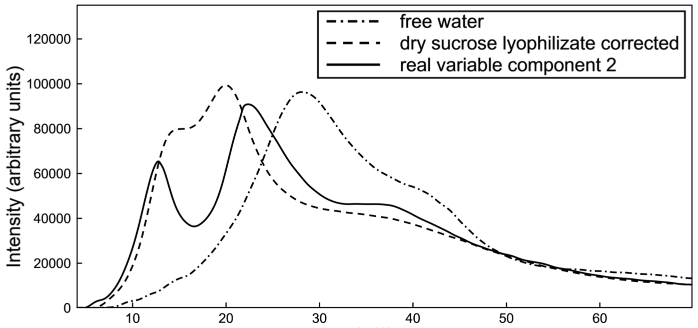

Figure 5.6.14
Normalized non-crystalline X-ray powder patterns for 'dry' sucrose, free water and a hypothetical 'wet' sucrose reference (variable component).

The miscibility behaviour of residual water within the lyophilized sucrose matrix is in part the reason why the simple chemometric analysis gives a linear response down to residual water contents of less than 0.2%(*w*/*w*). The X-ray measurements are picking up changes in the local 'dry' sucrose non-crystalline matrix induced by the miscibility/solubility. As such, the structural impact of each water molecule is magnified through the number of sucrose molecules involved in the local molecular interaction. These data demonstrate that the presence of even small amounts of residual water or solvent within an organic non-crystalline matrix can have significant consequences on the local structure if there is miscibility.

The lyophilized sucrose and residual water problem illustrates that with minimal data processing using Microsoft *Excel*, powder patterns collected on a laboratory X-ray diffraction instrument can be routinely used to study changes in local non-crystalline/glassy structure at the per cent level.

5.6.8. Correction for the instrumental intensity response

The appearance of powder diffraction data will be directly influenced by the diffraction instrument used to measure the data. For X-ray powder diffraction, the primary instrumental factors are background, angular resolution (peak width), spectral purity and intensity response function. In previous sections, the instrumental background and some aspects of spectral purity have been discussed. While the angular resolution is a critical parameter for the study of crystalline materials, for non-crystalline samples the instrumental intensity response function is more important. Ideally, the instrumental intensity response should be smoothly varying as a function of measurement angle and in addition should be straightforward to model analytically. With measured powder patterns for non-crystalline materials having an essentially smooth and continuous appearance, any discrete changes in the instrumental intensity response function will have a significant impact on the appearance of the measured data. Furthermore, structural characterization of non-crystalline powder patterns, whether through the use of pairwise distribution functions or direct analysis, requires that the instrumental intensity response be removed from the measured data, hence the requirement that the intensity response be relatively straightforward to model analytically.

For a laboratory X-ray powder system, the traditional analytical descriptions of the instrumental intensity response include the polarization correction, the Lorentz correction and relevant optical component corrections. For crystalline materials and powders, the Lorentz–polarization (LP) terms have been extensively discussed in various textbooks (*e.g.* James, 1948; Warren, 1990; Reynolds, 1989). The polarization term is essentially governed by the instrumental geometry, which is also affected by the choice of X-ray source and method of spectral resolution (*i.e.* monochromator). In contrast, the Lorentz factor depends on the type of sample being studied (for example, single-crystal, oriented powder or random powder) and the type of analysis being performed (for example, discrete peak intensity measurement or continuous total diffraction). For non-crystalline materials, the polarization factor remains unchanged from the traditional expression. The Lorentz factor, however, will follow a different form to that traditionally used for powder diffraction. The rationale behind the traditional Lorentz factor for powder measurements and how analysis of non-crystalline materials changes the required Lorentz factor is discussed later in this section.

One of the simplest X-ray optical systems to model with respect to the intensity response function and one that is available in most X-ray diffraction laboratories is the Bragg–Brentano reflection geometry. The Bragg–Brentano geometry is a symmetrical reflection geometry designed to measure X-ray powder patterns by scanning in a single radial direction in diffraction space (Q). The appropriate Lorentz factor for the Bragg–Brentano geometry is effectively a combination of two geometric terms that affect the measured diffraction intensity. The first geometric term, which is common to most diffraction measurements used to determine the Bragg peak intensity (*i.e.* its area), is often described as being related to the speed at which the diffraction measurement sweeps through the diffraction condition. For scans through single-crystalline peaks, this Lorentz term is traditionally expressed as $1/\sin(2\theta)$. The second geometric term is invoked for powdered materials consisting of numerous randomly oriented small crystals and expresses how the number of crystals contributing to the measured peak intensity changes as a function of measurement angle. Traditionally, this second Lorentz term is written as $1/\sin(\theta)$. Combining the two Lorentz terms together gives an intensity correction factor proportional to $1/[\sin(\theta)\sin(2\theta)]$, which is generally accepted as the default Lorentz factor when using Laue or Bragg diffraction theory to describe observed crystalline powder peak intensities. In contrast to Bragg and Laue diffraction theories, the Debye diffraction theory implicitly models the spherical symmetry present in ideal powders and non-crystalline materials, and the diffraction intensity is expressed as a continuous function in diffraction space. As such, the traditional Lorentz powder term is not required for either non-crystalline or crystalline powder data when used as continuous functions within a Debye diffraction model. More general derivations of the Lorentz term applicable to different diffraction geometries determine how the measurement volume in diffraction space intersects with the sample's diffracted intensity distribution. The impact of passive X-ray optical components such as slits and active components such as monochromators and mirrors on the measurement volume can be complex to describe accurately from first principles and the reader is referred to Zuev (2008), Kavanagh *et al.* (2012) and Fewster (2014) for more information.

The simplicity of the X-ray optics when coupled with the potential for low instrumental background makes Bragg–Brentano optics one of the more useful optical configurations for the characterization of non-crystalline materials, especially when used with a PSD to enhance count rate. Despite the simplicity of the Bragg–Brentano optics, suitable intensity standards are usually required in order to verify and refine the intensity response model. In the absence of non-crystalline intensity standards for X-ray diffraction, various crystalline materials are usually measured in order to track the instrumental intensity response as a function of measurement angle. In addition to the usual requirements for a powder diffraction intensity standard (random orientation and random particle statistics), the sample must produce a sufficient number of well defined free-standing diffraction peaks to cover the measurement range of interest (*i.e.* 2.0 to 150.0° 2θ for a laboratory Cu $K\alpha$ system). The difference between the calculated relative peak intensity and the observed relative peak intensity can be used to determine the instrumental intensity response. As the goal of the relative peak intensity study is to determine the instrumental contribution, the calculated crystalline peak intensities used should be raw unit-cell structure factors.

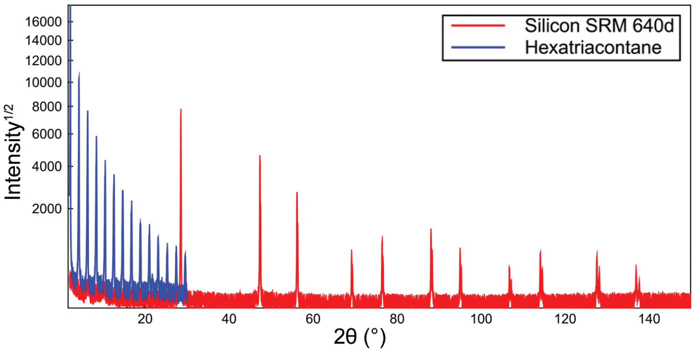

Figure 5.6.15
Measured powder patterns for an aligned hexatriacontane intensity reference and the silicon powder standard SRM 640d. Data were collected in Bragg–Brentano reflection geometry using a graphite diffracted-beam monochromator. The intensity is plotted on a square root scale.

Ideally, when measuring organic materials, the best practice is to use crystalline organic intensity standards to mimic the transparency and absorption sample effects. Hexatriacontane is one such organic crystalline material that can be used to map the instrumental intensity response for reflection measurements at low angles. When crystalline, the long-chain molecules are aligned to give a layered (plate-like) crystal structure with one large crystal unit-cell parameter (~48.4 Å) normal to the crystalline plates and two smaller unit-cell parameters (~7.42 and 5.57 Å) within the plane of the plates. When packed into a (top-loaded) reflection holder, the individual crystalline plates self-align (*i.e.* show preferred orientation) to create a sample that functions like an X-ray diffraction grating. The measured diffraction pattern for hexatriacontane out to 30° 2θ is shown in Fig. 5.6.15 on a square root scale. The first ten harmonic diffraction peaks from ~2.0 to ~21.0° 2θ are free standing and clearly visible. Being harmonics of the same diffraction planes, each peak will have the same theoretical structure factor (same number and type of coherently diffracting atoms). The variation of the observed peak intensity as a function of diffraction angle is a direct measure of the instrumental intensity response combined with the atomic form factor. An effective coherent atomic form factor can be readily calculated for hexatriacontane ($C_{36}H_{74}$) using values from atomic form-factor tables (Warren, 1990). The effective atomic form factor can also be approximated using a single carbon atom. When performing instrument intensity response calibration, the form of the Lorentz factor for specific calibration samples has to be allowed for. With the aligned hexatriacontane sample acting like a diffraction grating, the

Table 5.6.1
Analytical peaks for hexatriacontane (top) and silicon (bottom) listed by Miller index (*hkl*)

The atomic form factor squared has been normalized to 1 at $Q = 0$; values were derived from the tables in Warren (1990). The phase term is an intensity-modification term related to the ratio of in-phase and out-of-phase atoms for each reflection *hkl*. The Lorentz-difference column adjusts for the oriented nature of hexatriacontane, and the scale value for silicon is an arbitrary value to bring silicon into reference with hexatriacontane. The values in the column 'Final relative intensity', when scaled, should follow the observed peak areas (integrated intensity). The (511) silicon peak is overlapped with a weaker (333) peak, which has a multiplicity of 8. In this table the (511) multiplicity of 24 is used rather than an averaged value.

Miller index (*hkl*)	Effective atomic $(f)^2$	Multiplicity	Phase	Lorentz difference	Scale factor	Final relative intensity

(533)	0.1748	24	0.5	1	×	0.477

expected Lorentz factor for the observed peak intensities will more closely follow the single-crystal form [$\sim 1/\sin(2\theta)$] than the usual powder form {$\sim 1/[\sin(\theta)\sin(2\theta)]$} discussed previously.

With an aligned hexatriacontane sample, the instrumental intensity function can be followed out to about 30° 2θ using harmonic reflections. A second crystalline intensity standard is, therefore, required to map the instrument intensity response out to the higher angles used to study non-crystalline materials. While the silicon powder standard SRM 640d is not intended as an X-ray diffraction intensity standard, in practice the material can be used to map the variation in the instrumental intensity response as it gives eight peaks with self-consistent intensity out to 140° 2θ; see Fig. 5.6.15. Silicon will have a higher linear X-ray absorption coefficient than organic materials and as such will exhibit a subtly different 2θ intensity dependence. To offset the impact of absorption on the effective illuminated sample volume, the sample thickness can be kept to a minimum for all samples. For all reflection measurements presented within this chapter, offcut single-crystal silicon low-background sample holders were used with a 10 mm diameter and a depth of less than 0.1 mm.

For hexatriacontane, the harmonic peaks have the same unit-cell structure factor and multiplicity. To bring the powder silicon peak intensities towards an equivalent constant structure-factor response, the observed intensities for the silicon powder will have to be corrected for their individual multiplicities and ratio of in-phase and out-of-phase Si atoms within the unit cell. Table 5.6.1 contains a list of the analytical peaks for silicon and hexatriacontane along with approximate correction factors for the multiplicity plus the unit-cell phase correction. The final conversion factor in Table 5.6.1 includes the Lorentz-factor difference between hexatriacontane (aligned powder) and silicon (random powder). The effective squared atomic form factors in Table 5.6.1 for silicon and hexatriacontane have been normalized to 1 at $Q = 0$. Applying the correction factors and effective atomic form factors will give a series of observed peak intensities at different diffraction angles corresponding to a constant unit-cell structure factor for silicon and single unit-cell structure factor for hexatriacontane. The residual angular dependence of these observed peak intensities will be driven by the instrumental intensity response. The values in Table 5.6.1 should enable an instrumental intensity response function to be derived for any typical laboratory Bragg–Brentano system using Cu $K\alpha$ X-rays [with the effective atomic form factor squared derived from data presented by Warren (1990)].

To verify the general form of the instrumental intensity function, measured powder data for hexatriacontane and silicon were collected using two Rigaku SmartLab Bragg–Brentano systems with different detector configurations. The first system was configured with a graphite monochromator and a scintillation detector, while the second system used a beta filter plus a scanning PSD (D'teX). Peak heights were extracted from the four measured powder patterns and used to model the Lorentz factor. The traditional Lorentz factors and instrument intensity functions are defined for integrated peak intensities. However, for non-crystalline materials without discrete peaks, the instrument intensity function is used to remove the instrumental contribution point by point from the observed data. As such, the Lorentz factor and instrument intensity function of interest are continuous functions defined for every data point. To model this continuous function, peak heights are used for the silicon and hexatriacontane reference data rather than integrated peak intensities. To ensure consistency across the complete measured range, the individual observed peak profiles were fitted using the primary spectral components from a copper X-ray tube in order to isolate only the $K\alpha_1$ peak height. For crystalline reference material that gives instrumentally limited peak widths, the observed $K\alpha_1$ peak heights will be directly related to the 'final relative intensity' as presented in Table 5.6.1. For both detector systems, the inherent continuous Lorentz factor, L, was taken to be

$$L \simeq \frac{\cos^m(\theta)}{\sin^n(\theta)}.$$

The polarization term (with no monochromator) was taken to follow the traditional form

$$P = \frac{[1 + \cos^2(2\theta)]}{2}.$$

The continuous form of the Lorentz factor expressed above allows direct application of the calculated instrumental intensity response function to crystalline and non-crystalline samples as well as for Bragg/Laue and Debye modelling. Some idealized Lorentz terms for a reflection powder measurement are

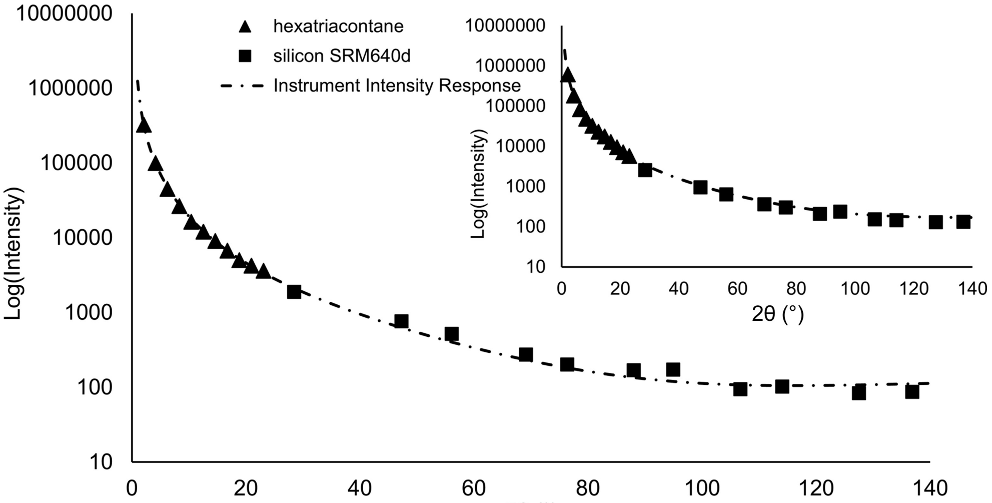

Figure 5.6.16
Reduced integrated peak intensities for hexatriacontane and Si SRM 640d plotted on a log scale with a derived analytical instrumental intensity response function using the core response function with m = 0.0 and n = 2.1. The main plot displays data collected using a scanning PSD while the inset displays data collected using a graphite monochromator.

$$L_{\text{non-crystalline}} \rightarrow \text{Debye} \simeq 1;\, n \rightarrow 0,$$

$$L_{\text{oriented powder}} \rightarrow \text{Bragg} \simeq 1/\sin(\theta);\, n \rightarrow 1,$$

$$L_{\text{random powder}} \rightarrow \text{Bragg} \simeq 1/\sin^2(\theta);\, n \rightarrow 2.$$

To determine the instrumental intensity response, the extracted peak heights for the reference crystalline hexatriacontane and silicon are first corrected by applying the final correction factors from Table 5.6.1 and then removing angular dependence due to the effective squared atomic form factors. An arbitrary scale factor was applied to the resulting silicon peak intensities to bring them into coincidence with the resulting hexatriacontane peak intensities. The 2θ intensity dependence of the corrected peak heights (see Fig. 5.6.16) was then modelled using the Lorentz and appropriate polarization factors. Least-squares minimization was performed using the Microsoft *Excel* Solver() function with m, n and a general scale factor as the primary variables. The overall fit to the observed intensity behaviour as displayed in Fig. 5.6.16 is good over about six orders of magnitude. The resulting minimized value for the sine power coefficient (n) was about 2.1 for both detector configurations: close to the ideal value of 2.0. The cosine power coefficient (m) was minimized to zero for both sets of data, indicating that the idealized Lorentz factors closely describe the observed instrumental intensity response.

The inherent Lorentz-factor difference between diffraction-peak raw unit-cell structure factors (Bragg) and peak intensities as calculated by the Debye equation can be illustrated for a hypothetical silicon nanocrystal, as shown in Fig. 5.6.17. Using the *Mercury* CSD 3.9 software package (Macrae *et al.*, 2008) to generate a packed 5 × 5 × 5 unit cell for silicon resulted in an atomic model of a silicon single-crystal nanocube with a cube axis of about 2.715 nm. The atomic nanocube was used as input for the Debye intensity calculation. The Bragg calculation used the unit-cell structure-factor intensity for each diffraction peak (hkl) and assigned a normalized Gaussian peak about the calculated Bragg position. The width of the Gaussian profile for each silicon peak was determined using the Scherrer equation:

$$\beta = K\lambda/D\cos(\theta).$$

The peak integral breadth (β) is expressed in radians and the crystal size parameter (D) was set to 3 nm. The Scherrer constant (K) was taken to be 0.88 and the X-ray wavelength was taken to be the mean Cu $K\alpha$ wavelength of 0.15418 nm.

The resulting Bragg intensity was divided by the $\sin^2(\theta)$ Lorentz-factor difference and scaled to account for the difference in the number of atoms in the crystalline unit cell and the complete nanocrystal. The peak-intensity variations as a function of 2θ for both the Debye- and Lorentz-corrected Bragg simulated powder patterns are essentially the same, confirming the inherent Lorentz-factor difference between the two theoretical diffraction approaches. There are, however, some notable differences in the nanocrystalline diffraction response as calculated by the two different methods. The Debye calculation, being a total diffraction calculation, will generate Laue interference effects (*Pendellösung* fringes) because of the finite size and flat surfaces of the single silicon nanocube.

The choice of an appropriate Lorentz term to describe the instrument intensity response depends on a number of factors that include instrumental geometry, sample symmetry and the theoretical framework being used to model the measured data. For the Bragg–Brentano optical configurations used in this study the ideal Lorentz factors were found to describe the instrumental response, and, as such, no formal Lorentz correction is required for measured data in order to transform them into the Debye reference frame. The absence of a Lorentz correction is another benefit to using Bragg–Brentano reflection configurations for routine analysis of non-crystalline materials.

It should be noted that, in addition to the Lorentz and polarization terms, the Bragg–Brentano optics have a low-angle intensity damping term arising from over-illumination of the sample. For a fixed-slit optical system, depending on the divergence slit size and sample size, at low enough incident angles onto the sample the incident-beam footprint will be larger than the sample size. As a consequence of the over-illumination, the

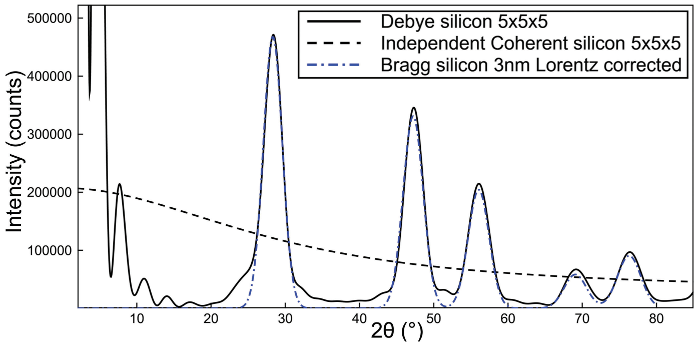

Figure 5.6.17
Calculated powder patterns for a ~3 nm silicon nanocube using both Debye and Bragg diffraction equations. The Bragg calculation has been scaled to account for the difference in the number of silicon atoms and modified by multiplying by the $\sin^2(\theta)$ Lorentz difference. The independent coherent limit for the full nanocube is shown for comparison.

sample will only intersect a small component of the full incident beam, thus reducing the observed diffracted intensity at lower angles. To minimize over-illumination, the powder measurements presented in this chapter were taken with narrow divergence slits (around 1/6°) with sample widths of 10 mm or more. Under these measurement conditions, significant intensity damping (>80%) due to over-illumination was limited to occur below about 9.0° 2θ. A complete instrumental intensity model requires that the low-angle over-illumination be described; however, owing to the nature of the Debye normalization procedure discussed in the following section, it is more important to describe accurately the high-angle intensity response.

5.6.9. The full Debye normalization procedure

After correcting for the instrumental intensity response, the full Debye normalization is applied to scale the measured X-ray diffraction intensity to an absolute electron-unit reference frame. For any structural characterization based upon non-crystalline powder patterns, this transformation from measured intensity to absolute electron units is a critical data pre-processing step. From a preliminary investigation of the Debye equation, two scattering limits were identified that can be used to normalize measured powder patterns:

(i) Coherent limit (all atoms in a model system scattering coherently – the coherent intensity function).
(ii) Independent limit (all atoms in a model system scattering independently – the independent coherent intensity function).

When the measured data have been transformed to electron units, a third scattering limit can be introduced:

(iii) Incoherent limit (Compton scattering – individual electron scattering).

For a particular model system, the coherent limit describes the maximum possible diffraction intensity from a material when all atoms are scattering coherently. After correcting for multiplicity, no diffraction peak intensity (including the sample SAXS peak) can exceed the coherent limit. The derivation of the coherent limit requires knowledge of the crystalline unit cell or the local coherent structure and is therefore dependent on the 'structure' of a material. The independent limit, however, is independent of the structure, as it is an atomic level scattering response that scales with the number of atoms. The independent limit is usually expressed with respect to the basic chemical unit (*e.g.* a single molecule) but can also be derived for a crystalline unit cell for absolute comparison with the coherent limit. The independent limit forms the mean scattering response from a model system and helps to define the total integrated scattering intensity expected from the model system. The total sample scattering intensity and its relationship with the independent limit is related to Vainshtein's conservation of diffraction intensity, which also predicts that the total integrated scattering intensity from a model system will be essentially independent of any 'structure' that might be present. The incoherent limit (Compton scattering) is a second structure-independent limit, depending only on the atomic makeup of a sample. The Compton scattering will also scale with the number of atoms in the model system, which allows a direct comparison with the independent limit based upon the same chemical unit or crystal unit cell.

Compton scattering represents the independent scattering from each of the electrons within a single atom (James, 1948). The quantum-level interaction that gives rise to Compton scattering removes energy from the incident X-rays, causing an increase in the X-ray wavelength for the emitted (scattered) X-ray. The wavelength shift increases as a function of scattering angle. The modification of the X-ray wavelength by the incoherent scattering process gives rise to the alternative term 'modified scattering response' (Warren, 1990). As with the atomic form factors, the Compton scattering response for different atoms has been tabulated, allowing a direct calculation of the incoherent limit for any crystalline or non-crystalline molecular model (*e.g.* Warren, 1990). When used for Debye normalization, however, an approximation can be used to derive the incoherent limit using the same atomic form factors as required to derive the coherent and independent limits. For an atomic model with n atoms, the approximate form can be expressed as

$$I_{\rm incoherent}(Q) \simeq \sum_i^n \frac{(Z_i - |f_i|^2/Z_i)}{B^3},$$

where Z is the total number of electrons within an atom and f is the atomic form factor. B represents the Briet–Dirac correction arising from individual electron 'recoil' when impacted by an incident X-ray. The recoil correction describes the change in X-ray wavelength. For Cu $K\alpha$ X-rays, B can be approximated by

$$B \sim 1 + 0.0744[\sin(\theta)/\lambda]^2.$$

The Briet–Dirac recoil correction can also be used to estimate the wavelength modification of the Compton scattering over the complete diffraction range for Cu $K\alpha$ X-rays. Out to 160°, the increase in wavelength is about 3%. This change is small enough that for many laboratory X-ray powder diffraction systems the Compton scattering will not be discriminated against by active optical components such as monochromators or mirrors in the diffraction beam path. As such, the incoherent limit can be used as a general lower limit to help scale measured data on an absolute electron scale; no real X-ray scattering intensity is expected to be observed below the Compton scattering limit. Despite the usefulness of Compton scattering as a scaling limit, the Compton scattering itself is one of the many diffuse X-ray scattering contributions to measured powder data and should typically be removed within a data pre-processing step in order to isolate the 'coherent' scattering response. Additionally, changes in the Compton scattering response can in principle be used for rudimentary elemental analysis.

To illustrate the full Debye normalization and transformation of measured data to electron units, glassy indomethacin will be used as a worked example. As noted earlier, the inherent continuous spherical symmetry introduces changes to the traditional Lorentz correction used for powder data when Debye modelling is to be performed. As such, for modelling non-crystalline materials and normalization *via* the Debye method, the working form of the LP factor (core instrument intensity response function) was taken to be

$$\mathrm{LP}_{\rm non\text{-}crystalline} \rightarrow \mathrm{Debye} \simeq \frac{\cos^m(\theta) \times [1+\cos^2(2\theta)]}{2\sin^{n-2}(\theta)}.$$

The instrument intensity function modelling performed in the previous section for two-reflection Bragg–Brentano systems returned values of $n \sim 2.1$ and $m \sim 0.0$. For the modelled Bragg–Brentano systems the Lorentz factor was, therefore, essentially removed from the instrument intensity function correction when powder data were to be used for Debye modelling or normalization. Fig. 5.6.18 displays a measured non-crystalline powder

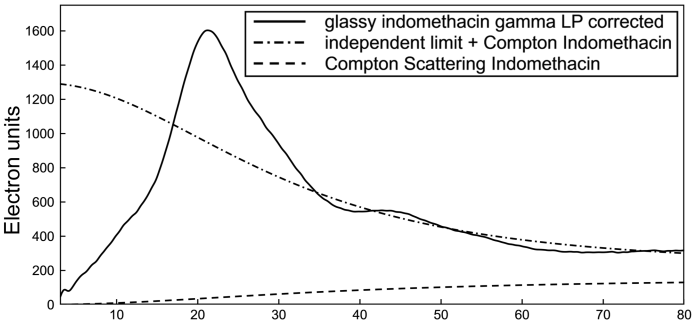

Figure 5.6.18
Non-crystalline powder pattern for glassy indomethacin after correction for the Bragg–Brentano instrument intensity response. The independent and incoherent limits as derived for a single indomethacin molecule are also displayed.

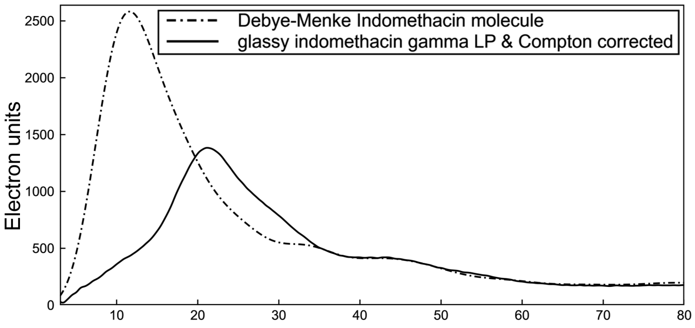

Figure 5.6.20

pattern for indomethacin after correcting for the Bragg–Brentano instrument intensity response function as expressed above. The original crystalline powder sample was melted and quenched in a low-background Si sample holder to enable real-time measurement without disturbing the non-crystalline sample. The resulting indomethacin glass was stable enough for routine X-ray powder data collection.

The scaling of the intensity-corrected measured data to absolute electron units uses both the independent and incoherent limits as guides. No measured scattering should lie below the incoherent limit, and the combined independent and incoherent response becomes the asymptote for the high-angle data. In Fig. 5.6.18, a single indomethacin molecule was used to define the absolute electron scale. The scale of the incoherent limit (Compton scattering) will approach the number of electrons at large scattering angles, which is 186 for indomethacin ($C_{19}H_{16}NO_4Cl$).

The glassy indomethacin non-crystalline powder pattern was collected out to 80° 2θ, which is a larger angular range than often employed for organic crystalline systems. However, even with this extended range, it may be non-trivial to define exactly where the asymptotic oscillatory behaviour develops. In Fig. 5.6.18 it should be noted that the high-angle asymptote has been taken to be the independent limit plus the Compton scattering response.

For organic molecules, the higher-angle oscillatory behaviour (>30° 2θ for Cu $K\alpha$ X-rays) is most often due to the rigid atomic structure within a single molecule. Fortunately, for many organic systems, the molecule and the rigid structures that define the molecule are known. As an example, the structure for a single indomethacin molecule is shown in Fig. 5.6.19.

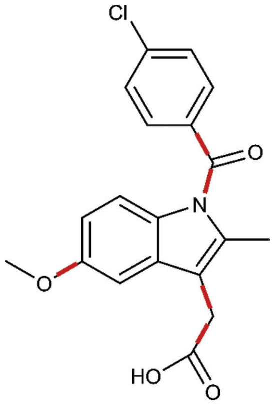

Figure 5.6.19
A single indomethacin molecule with the five significant torsion degrees of freedom indicated in red.

From a known molecular structure, the Debye–Menke calculation can be used to derive the expected high-angle response. In Fig. 5.6.20, the intensity-corrected non-crystalline powder pattern for indomethacin is displayed after correcting for Compton scattering. The calculated Debye–Menke response for a single indomethacin molecule is plotted with the corrected non-crystalline powder pattern. The observed data above about 30° 2θ closely follow the calculated Debye–Menke response, suggesting that scaling the intensity-corrected measured powder pattern to the independent and Compton scattering limits is an effective approach to transform the measured data to absolute electron units.

Below 30° 2θ, the calculated single-molecule curve diverges significantly from the measured non-crystalline powder pattern. Scattering arising from the longer-length-scale atom–atom distances within the molecule is heavily damped for the glassy solid of indomethacin. Damping of the scattering intensity expected for longer-length-scale atom–atom correlations has been observed for all organic molecular systems independent of molecule size or rigidity. The divergence between the calculated Debye–Menke response and observed data at low angles suggests that a single independent rigid molecule is not a complete model for the residual structure present within glassy indomethacin. A more robust model of glassy indomethacin including the impact of non-crystalline packing density on the low-angle Debye response will be investigated in Sections 5.6.12 and 5.6.13.

This worked example for glassy indomethacin not only demonstrates the use of Compton scattering and the independent limit as a means to transform measured powder patterns into electron units, but also suggests that the calculated rigid-molecule high-angle Debye response may provide a more robust transformation tool. This is especially true when using powder data not measured out to high enough diffraction angles in order to fully develop asymptotic behaviour with respect to the independent limit. Furthermore, as melt–quench glassy indomethacin can be reproducibly made in the laboratory, the sample may be used to verify and refine the derived high-angle instrument intensity response function. [Melt–quench indomethacin can be made directly in a low-background silicon holder by heating the holder to a few degrees above the melting point (~453 K for the gamma crystalline form). Once at temperature, powdered crystalline indomethacin added to the holder should immediately melt. When the holder is full of liquid indomethacin, the sample should be allowed to naturally cool to ambient temperature in a relatively dry atmosphere. Undisturbed glassy indomethacin should be stable for many months in the holder.]

5.6.10. Application of the Debye normalization procedure

For non-crystalline material analysis, normalization and background modelling procedures are two prerequisites for subsequent analysis, much like peak picking and profile fitting are prerequisites for the analysis of crystalline materials. A common application for organic non-crystalline materials is the characterization of powder patterns corresponding to materials produced under different conditions. Because of the metastability of non-crystalline solids, non-crystalline materials can be significantly affected by the choice of production processes and storage conditions, which may result in materials with very different physical and chemical properties. An appropriate normalization procedure allows a rational analysis of absolute variances between non-crystalline powder patterns that may be correlated with physical or chemical properties.

While the single-molecule Debye response can provide the basis for a robust normalization procedure, one of its challenges is the dependence on the molecular structure. In the non-crystalline state, the removal of crystalline packing constraints enables individual molecules to explore all energetically available molecular conformations. To assess the variance introduced by molecular conformation on the Debye response, a number of different energetically favourable conformations should be modelled. If the molecule of interest exhibits different crystalline polymorphs, then equilibrium molecular conformations can be extracted from the crystal structures without resorting to molecular modelling. As an example, indomethacin, which was used in the previous illustration of the Debye normalization procedure, has two relatively common crystal forms. The stable polymorph is gamma (CSD refcode INDMET; Kistenmacher & Marsh, 1972) and the metastable polymorph is alpha (CSD refcode INDMET02; Chen *et al.*, 2002). The gamma polymorph is triclinic ($P\bar{1}$) with a single unique molecule in the asymmetric unit, while the alpha polymorph is monoclinic ($P2_1$) with three unique molecules in the asymmetric unit. Between them, the two crystalline polymorphs contain four different equilibrium molecular conformations. In addition to the four crystalline molecular conformations, the molecular modelling program *SPARTAN* (Wavefunction, Inc., 2016) was used to minimize a generic indomethacin molecule *in vacuo* and in a water environment. In Fig. 5.6.21, the Debye–Menke curves for the four equilibrium molecular conformations and the two energy-minimized conformations are plotted along with Compton- and LP-corrected observed data for glassy indomethacin. All Debye–Menke curves displayed in Fig. 5.6.21 are similar, with the largest variance being at low angles for the larger atom–atom distances. Although indomethacin is a small organic molecule (about 322 Da), it exhibits five significant torsional degrees of freedom (see Fig. 5.6.19) allowing multiple molecular conformations. Despite the inherent molecular flexibility, the equilibrium and minimized conformations give calculated Debye curves that are essentially the same at higher diffraction angles ($>30^\circ\ 2\theta$). This behaviour reflects the robustness of short-distance atom–atom correlations within rigid molecular segments and supports the use of the high-angle Debye response as a suitable asymptotic limit for robust data normalization.

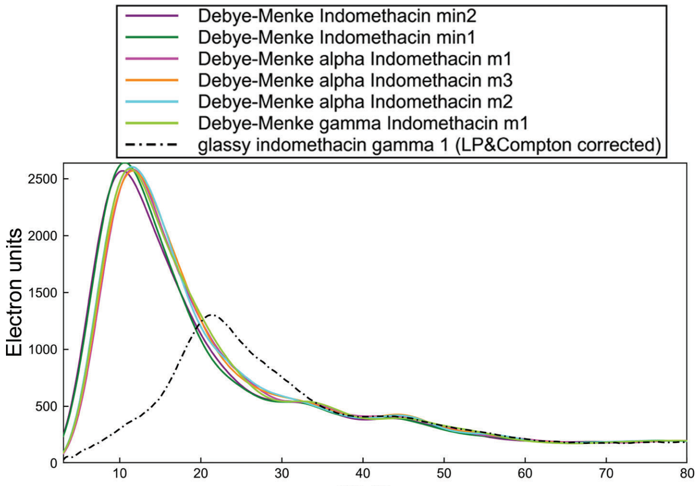

Figure 5.6.21
Non-crystalline indomethacin data after intensity correction and removal of the Compton response displayed with the Debye–Menke curves for different indomethacin molecular conformations.

With non-crystalline diffraction responses being essentially continuous in nature, chemometric variance-based data analysis procedures provide useful analytical methods for the investigation of production-induced difference between solid forms. With any variance-based analytical method, the spurious variances that might affect the analysis should be controlled. This requires well defined and well controlled experimental methodology. For example, the Bragg–Brentano reflection geometry is sensitive to sample presentation and requires a consistent flat and level sample with the sample surface aligned to the instrument reference surface. To investigate the impact of sample presentation for Bragg–Brentano reflection measurements, two different melt–quench procedures were performed using gamma indomethacin. In the first procedure, about 20 mg of powdered gamma indomethacin was mounted in a silicon low-background holder with a flat and level surface. The sample holder was then placed on a hotplate set to 453 K. Once the powder had completely melted, the holder was placed on the bench top and allowed to cool to ambient temperature. As the glassy indomethacin has a higher bulk density than the packed powder, the resulting sample surface was slightly lower than the instrument reference height. In the second preparation, the silicon low-background holder was heated to 453 K and 20 mg of powdered gamma indomethacin was slowly added. The sample holder was again placed on the bench top and allowed to cool to ambient temperature. The second preparation procedure produced a curved sample surface which was higher than the instrument reference height at the sample centre. The glassy form of indomethacin has a glass transition temperature, T_G, of about 309 K, about 10 to 15 K higher than the ambient measurement temperature. The resulting glassy indomethacin data are displayed in Fig. 5.6.22 after performing an LP correction and removal of the Compton response. After following the full Debye normalizing procedure, the principal difference between the two data sets occurs at the primary halo. The halo position remains unchanged but the second preparation technique gives a slightly higher intensity. Sample preparation techniques and sample masses require careful control to ensure robust variance analysis.

Glassy indomethacin can be made from either the alpha or the gamma crystalline polymorph. The gamma crystal form melts at about 434 K while the alpha crystal form melts at about 429 K. The glassy forms originating from both the alpha and gamma crystalline forms have the same glass transition temperature ($T_G \simeq 309$ K) when measured under the same conditions. Using both the alpha and gamma forms to make the glassy material allows investigation of two different potential production variances. The first is the effect of the melting point and the second is the effect of the starting crystalline form. For preparation from the gamma

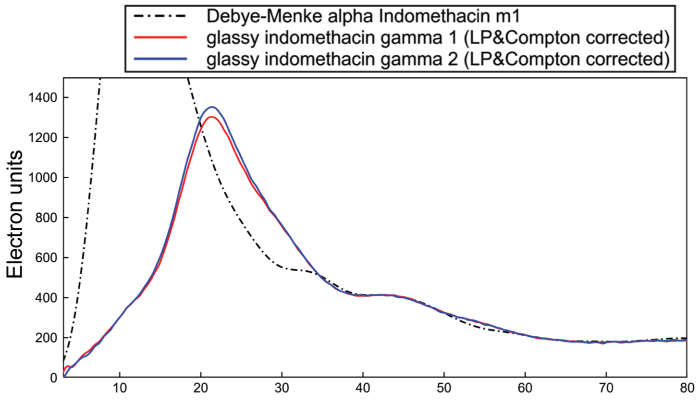

Figure 5.6.22

form, the hotplate was set to 453 K, while for the alpha form the hotplate was set to 448 K. Glassy samples were prepared using the level powder preparation technique investigated earlier. The resulting data are displayed in Fig. 5.6.23. Diffraction responses for the two glassy indomethacin samples are essentially the same and independent of production temperature and starting crystalline polymorph. The close agreement between the two glassy diffraction responses illustrates the reproducibility of the Debye normalization procedure when used in conjunction with controlled experimental conditions.

As a second comparative example, the glassy forms of (*R*,*S*)-ibuprofen (*R* + *S* racemic mixture) and *S*-ibuprofen were studied. The two crystal forms have very different melting points. (*R*,*S*)-ibuprofen melts at about 349 K while *S*-ibuprofen melts at about 325 K. The two crystal forms [(*R*,*S*) CCDC refcode IBPRAC (McConnell, 1974), (*S*) CCDC refcode JEKNOC10 (Freer *et al.*, 1993)] exhibit similar molecular packing and hydrogen-bonding relationships. The glassy forms of both *S*- and (*R*,*S*)-ibuprofen exhibit the same glass transition temperature of about 226.5 K and also exhibit the same change in heat capacity at T_G. The glassy forms were made as described previously, with the full, flat and level powder method using about 20 mg of material. The target hotplate temperature was about 20 K above the melt temperature. The ambient measurement conditions were between 65 and 70 K higher than the glass transition temperature; therefore, strictly speaking, the samples as measured were equilibrium super-cooled liquids and not glassy. Both super-cooled liquid samples were stable enough to collect high-quality diffraction data, with the *R*,*S* form being stable for extended periods of time. The molecular form of ibuprofen is displayed in Fig. 5.6.24 and the full Debye normalized (LP- and Compton-corrected) measured data are displayed in Fig. 5.6.25.

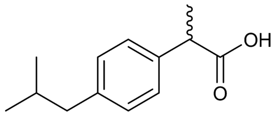

Figure 5.6.24
A chemical structure diagram for ibuprofen.

The observed non-crystalline X-ray powder diffraction (XRPD) data for *R*,*S*- and *S*-ibuprofen are very similar after Debye normalization. However, over multiple samples, the primary halo for the *S*-ibuprofen form appears to exhibit slightly increased intensity. The effect of this small intensity difference on the molecular packing description for ibuprofen will be investigated in Section 5.6.13.

While the indomethacin samples that were produced in different ways exhibited no significant variance in the non-crystalline diffraction response and the ibuprofen samples exhibited marginal differences, an example of a non-crystalline system that exhibits significant variability depending on the production method is simvastatin (Graeser *et al.*, 2008). When made through a melt–quench process, the non-crystalline form is stable for many months under ambient conditions. However, when made using cryo-grinding, re-crystallization begins within minutes of the system being exposed to ambient conditions. The melting point for simvastatin is about 412 K and the glass transition temperature of the melt–quench form about 305 K. The cryo-ground form exhibits a significantly broader glass transition event with an onset point about 10 K lower than that observed for the melt–quench material. Fig. 5.6.26 shows the measured powder patterns for the two different preparations of non-crystalline simvastatin after removing the instrumental background, applying the Debye normalization and subsequent removal of the Compton scattering. The data were collected in reflection Bragg–Brentano mode using a looping measurement to capture multiple frames. Only a single frame could be collected on the cryo-ground material before it began to re-crystallize, hence the slightly distorted profile. The resulting non-crystalline powder patterns both asymptotically approach the Debye–

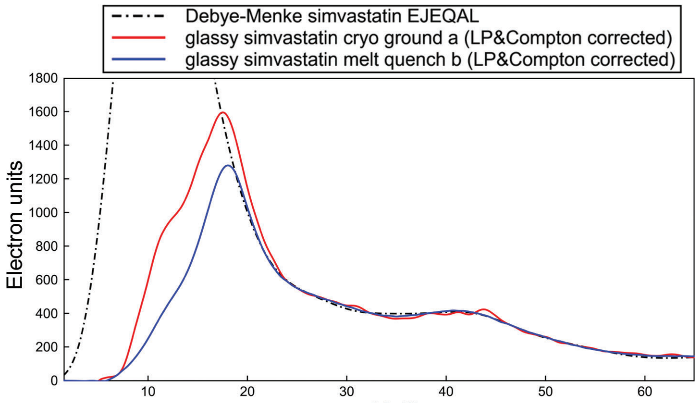

Figure 5.6.26
Normalized non-crystalline powder patterns for melt–quench and cryo-ground simvastatin displayed with the calculated Debye–Menke response for a single molecule of simvastatin.

Menke response at the highest measurement angles but have slightly different total diffraction intensities. As measured, the two powder patterns appear very similar, but after normalization significant differences become apparent. For the more stable melt–quench material, the primary low-angle halo moves to higher diffraction angles and more closely follows the independent limit. A similar trend relating material stability to X-ray diffraction profile shape has been observed using pair distribution function (PDF) analysis of API:polymer (where API is an active pharmaceutical ingredient) solid dispersions (see, for example, Velec *et al.*, 2005).

For non-crystalline sample preparation methods that are solvent based, residual solvent can distort the measured powder pattern in addition to changing the physical and chemical properties of the non-crystalline system. As explored in Section 5.6.7, low levels of residual solvent (<1%) can have a marked effect on the observed non-crystalline profile as a consequence of miscibility. The same is true of moisture picked up by the sample when exposed to ambient conditions. In this simvastatin example, both melt–quench and cryo-grinding are solvent-free sample preparation methods, so the observed differences in the non-crystalline powder patterns are associated with structural differences within the non-crystalline state rather than because of miscibility with a second component.

The normalized observed powder patterns for simvastatin, Fig. 5.6.26, are displayed with the Debye–Menke calculation for a single molecule. The molecular structure for simvastatin used for the Debye–Menke calculation as displayed in Fig. 5.6.27 was taken from the known crystal structure (CCDC refcode EJEQAL; Cejka *et al.*, 2003). As was observed for indomethacin, the higher-angle data corresponding to short distances within a single simvastatin molecule follow the calculated Debye–Menke response, but at low angles the observed data diverge significantly from the Debye–Menke calculation. The measured response for the melt–quench material more closely follows the higher-angle single-molecule Debye–Menke response from about 20° 2θ (less than about 4.4 Å) than the response for the cryo-ground material does. This suggests that the melt–quench material only exhibits local order related to the irreducible structures within a single simvastatin molecule. As pointed out above, close agreement between the observed non-crystalline data and the Debye–Menke response at higher angles and the damping of the low-angle halo both appear to be indicators of increased physical stability with respect to other non-crystalline forms of the same molecular entity. A more detailed analysis of the non-crystalline states of simvastatin and their related physical stabilities is in preparation. The origin of the low-angle difference between calculated and observed non-crystalline powder patterns and why certain materials diverge from the Debye–Menke response will be explored in Section 5.6.12.

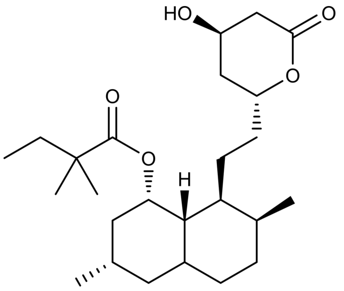

Figure 5.6.27
A chemical structure diagram for simvastatin.

5.6.11. Universal appearance of non-crystalline powder patterns

While modelling non-crystalline powder patterns within the spirit of the Debye method can be time-consuming and complex because a representative atomic level model is needed, some general observations can be made through direct inspection of normalized powder patterns. Pairwise distribution function (PDF) analysis (see Chapter 5.7) may also be used to provide direct analysis of measured non-crystalline powder patterns. One of the first observations when inspecting non-crystalline powder patterns is that the powder patterns appear visually similar to each other independent of the size, complexity or atomic composition of the constituent molecules. From the Debye–Menke theory, large rigid molecules should exhibit low-angle halos consistent with the long intramolecular distances present within the molecule. Furthermore, the nature of the X-ray measurement (*i.e.* the atomic form factor and Lorentz–polarization correction) should force these long-distance halos at low angles to have increased measured intensity relative to the shorter-distance halos. Yet, from the examples presented in this chapter, it is clear that the observed lower-angle response is significantly less than predicted. This loss of low-angle response forces the observed diffraction halos to lie within a narrow range of 2θ values. In Fig. 5.6.28, the normalized observed non-crystalline powder patterns for molecules of different levels of complexity and size are displayed together. The lowest-angle halo corresponds to melt–quench simvastatin, the middle halo is from melt–quench indomethacin and the higher-angle halo is for liquid

Normalized observed non-crystalline powder patterns (LP and Compton corrected) plotted with primary halo responses using a microstrain model with a microstrain variable of about 22%.

water. The data have been normalized to give similar halo peak intensities and are plotted on an arbitrary *y*-axis scale.

In addition to the absence of low-angle features, one of the most striking features of this plot is that the width of the primary halos increases as a function of the position of the halo. This is a common observation for molecular organic systems and can be considered to be a universal property of molecular glassy systems. A similar phenomenon of increasing peak width with increasing measurement angle is observed for crystalline diffraction peaks due to microstrain. Indeed, the universal feature of non-crystalline halo width can be described using a microstrain diffraction formula: integral breadth (2θ in radians) = $4\varepsilon\tan(\theta)$, where ε is the microstrain variable and takes a value of approximately 0.22 for non-crystalline halos. Calculated Gaussian profiles using the microstrain formula with a microstrain variable of about 22% are shown along with the normalized data in Fig. 5.6.29. The Gaussian heights and positions are taken directly from the primary halo in each normalized data set.

A more useful description of the universal halo width can be derived by describing random packing as an incremental type of disorder (*e.g.* random walk) and deriving an effective length scale of coherent order. Peak-broadening expressions have been derived by many authors (for example, Scherrer, 1918; Stokes & Wilson, 1944; Williamson & Hall, 1953; Warren & Averbach, 1950; Langford, 1980; Karen & Woodward, 1998) to address specific characterization needs. A general expression will be presented here that is amenable to many types of disorder including thermal vibration, point defects, microstrain and loss of long-range order. The general expression is based upon the Fourier-transform approximation for kinematic diffraction phenomena (Cowley, 1995; Guinier, 1994) and as such is based on the average atomic structure of a material. This is in direct contrast to the Debye theory, which is based upon the instantaneous local atomic structure. For simplicity, the average sample material in real space with respect to a spatial vector $\mathbf{r}$ will be considered to consist of a periodic lattice function $g(\mathbf{r})$, a generic atom type with electron-density function $\rho(\mathbf{r})$ and a bounding shape function $h(\mathbf{r})$ that limits the order length scale. A vector description based on $\mathbf{r}$ is used for real-space properties, as these properties may vary in different directions within the sample material. Along any single direction within the sample from an arbitrary origin, the average internal electron-density distribution can be mathematically described by

$$\text{directional electron density} \simeq [\rho(\mathbf{r}) * g(\mathbf{r})]h(\mathbf{r}),$$

where $*$ indicates convolution. The structure expression informs us that the atomic electron density appears around each lattice site and that the lattice is constrained to lie within a specific boundary. Applying a Fourier-transform convolution rule gives the diffraction amplitude from the model structure when the diffraction vector lies along the specific direction described by the structure expression,

$$\text{diffraction amplitude} \simeq [g(\mathbf{Q}) * h(\mathbf{Q})]\rho(\mathbf{Q}),$$

where $f(\mathbf{r}) \leftrightarrow f(\mathbf{Q})$ implies a Fourier transform. In the diffraction amplitude expression, the shape function is now convoluted with the lattice function, giving shape 'broadening' around every diffraction peak. In the amplitude expression, the atom contribution becomes a multiplicative constraining envelope limiting the diffraction amplitude as a function of $\mathbf{Q}$. Amplitude envelopes and intensity damping are the roles typically played by atomic form factors and unit-cell structure factors along with average vibrational disorder like the Debye–Waller thermal factor. The lattice, shape and atom functions are generic enough containers to hold a range of different physical structures. For example, the atom function could describe atoms, molecules, unit cells or supra-molecular structures. Essentially, any fundamental building block of a solid-state system can be substituted into the atom function. Any local atomic contributions not included within the average structure will give rise to diffuse scattering and are not described by this specific Fourier-transform approach. Local deviations from the average structure will be considered in more detail in Section 5.6.12.

This very simple diffraction amplitude expression allows the conceptual modelling of disorder affecting the lattice, the atoms and/or the bounding shape, and will be used throughout this chapter to explore different types of disorder. The utility of the Fourier-transform approach comes from the use of lattice, atom and shape functions that pass through the Fourier transform. Tables of Fourier-transform pairs can be found online (http://www.thefouriertransform.com/pairs/fourier.php; http://uspas.fnal.gov/materials/11ODU/FourierTransformPairs.pdf) and in a number of diffraction textbooks (Cowley, 1990; Guinier, 1994). Two common transform pairs that will be used to derive a peak-broadening expression are the infinite periodic lattice and the Gaussian function:

$$\begin{aligned}&\text{Periodic lattice with spacing } (d) \text{ in } \mathbf{r}\text{: } g(\mathbf{r})\\ &\quad\leftrightarrow \text{periodic lattice with spacing } (2\pi/d) \text{ in } \mathbf{Q}\text{: } g(\mathbf{Q}),\end{aligned}$$

$$\begin{aligned}&\text{Gaussian: } g(\mathbf{r}) = \left[\frac{1}{(2\pi)^{1/2}\sigma_r}\right]\exp\left[-\mathbf{r}^2/(2\sigma_r^2)\right]\\ &\quad\leftrightarrow \text{Gaussian: } g(\mathbf{Q})\exp\left[-(\mathbf{Q}\sigma_r)^2/2\right].\end{aligned}$$

What is important to note from the Gaussian pair is that a real-space Gaussian with a standard deviation of σ_r becomes a Gaussian in diffraction space with the inverse standard deviation of $(1/\sigma_r)$. Returning to the peak-broadening model, if on average over all crystalline regions in the system the finite-size shape effect is taken to be a Gaussian distribution with a standard deviation of σ_D, then the amplitude peak broadening will also be Gaussian in nature with a standard deviation of $(1/\sigma_D)$. As measurements are performed on diffraction intensity not amplitude, the standard deviation of the measured Gaussian peak broadening becomes: $1/(2^{1/2}\sigma_D)$.

With respect to non-crystalline molecular systems, the rigid structures within a molecule act like building blocks for the non-crystalline material. For a high-density system where molecules pack to minimize the free volume, the building blocks tend to exhibit a directionality driven by either intermolecular bonding constraints or the physical shape of the building block through van der Waals type short-range interactions. In addition, within a non-crystalline solid, molecular building blocks are also not able to occupy the same location in space at the same time. The combination of directionality and self-avoidance suggests that a self-avoiding and directed random walk might provide a realistic model as to the nature and consequences of random packing in a solid non-crystalline system made up from molecular building blocks. A directed self-avoiding random walk introduces a disorder that cumulatively increases for each subsequent block (step) along a specific packing direction. Cumulative disorder models have been used extensively to model diffraction from disordered systems [*e.g.* paracrystalline systems and disorder in clay minerals (Reynolds, 1989; Guinier, 1994, chapters 3, 6, 7 and 9)].

In the cumulative disorder model considered here, the nearest-neighbour relationship between two general molecules (the basic units) is used to define a packing direction **r** and an effective nearest-neighbour packing distance (the step). Projecting the packing distance out to longer distances along **r** creates the expectation of a simple periodic lattice $G(\mathbf{r})$. In reality, because of the random packing, as we proceed along the virtual lattice, each subsequent molecule is likely to be increasingly displaced from the ideal lattice point, creating the cumulative disorder. For a self-avoiding random walk, the standard deviation that describes the probability distribution of any specific molecule about the ideal lattice position is given by

$$\text{Standard deviation} = CN^{(1-X)},$$

where N is the step number away from the original molecule along the virtual lattice and C expresses how directed each random step is towards the preferred packing direction. For self-avoiding random walks X typically takes a value lying between 0.5 and 0.8 depending on the nature of the random walk. If we use a Gaussian probability distribution to describe the random step, then C is the standard deviation associated with the directional packing of nearest neighbours and $X = 0.5$.

In Fig. 5.6.30, a general directed random walk probability distribution is displayed, showing the cumulative uncertainty in the location of subsequent building blocks along the virtual lattice. The probability function describing the potential location of a specific molecule has been modelled as a unit-area Gaussian function. The sum over all the normalized Gaussian probability functions for all steps generates an effective probability distribution function for the building blocks as a function of distance from the chosen original block. The effective probability function is continuous at larger distances with unitary probability. For real systems, the continuous unitary probability corresponds to the effective molecular number density. It should be no surprise that the one-dimensional distribution function visually appears like a radial density distribution function for 'random' packing of solid spheres (Zernicke & Prins, 1927; Hosemann, 1951; Hosemann & Bagchi, 1962). The one-dimensional distribution function acts as an effective lattice within the Fourier diffraction derivation. This effective lattice is driven by the inherent shape of the molecule and is not necessarily related to any crystalline lattice. In real non-crystalline systems, the random packing will be three-dimensional in nature, the one-dimensional distribution being a simplification for strong molecular anisotropy.

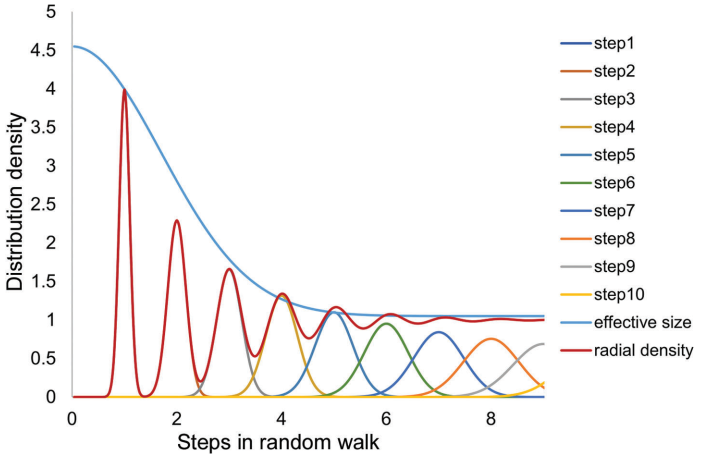

Figure 5.6.30
Cumulative disorder in the relative position of a building block as a function of steps away from the starting block. The sum of the individual probabilities appears like a radial distribution function typical of randomly packed spheres. The decay in the peaks of the sum gives an effective length scale over which spatial correlation occurs.

The cumulative incremental disorder as shown in Fig. 5.6.30 (the lattice) introduces an effective size that defines a region where some spatial correlation exists between building blocks. The effective size distribution illustrated in Fig. 5.6.30 is again based upon a Gaussian distribution to directly tie into the peak-broadening expression. The standard deviation of the Gaussian effective size function can be expressed as a number of steps, N_s, which can be converted to a physical size using the length of each step (*i.e.* the size of the building block), dN_s. This allows the diffraction amplitude peak broadening to be expressed as

$$\text{Random walk peak broadening standard deviation}\,(Q_p) = \sigma(Q_p) \cong \frac{1}{dN_s},$$

where N_s is the standard deviation of the effective size in number of steps and d is the effective step size given by the halo position $[d \simeq \lambda/(2\sin\theta)]$. The random-walk effective size, therefore, gives a size-broadening term that varies with the observed peak position. Using the random-walk size term, Fig. 5.6.29 can be re-created using a fixed N_s value. Fig. 5.6.31 shows the re-created plot using a value of $2^{1/2}N_s = 1$. The halo broadening observed for non-crystalline materials can therefore be described by a random packing procedure where the effective length scale of the coherent order is limited to nearest-neighbour distances alone. As such, universal halo widths observed for non-crystalline materials can be thought of as being the broadest peaks observable at any measurement angle for a one-dimensional molecular lattice. The Gaussian peak widths can be converted to a more traditional volume-averaged effective crystal size as described by the Scherrer equation [integral breadth (2θ in radians) $= K\lambda/(D_v\cos\theta)$] by noting that for $K = 0.95$, $D_v \simeq 2.225d \times 2^{1/2}N_s$.

For the derivation of the random-walk halo width, the nature of the solid-state building block is not defined. The block might be an entire molecule, or a rigid segment of a much larger molecule, or even atomic in nature. Whatever the individual building blocks, the model is based upon the hypothesis that there exists a characteristic spacing d that describes how the blocks are packed together. As a first approximation, that characteristic spacing has been derived from an observed halo posi-

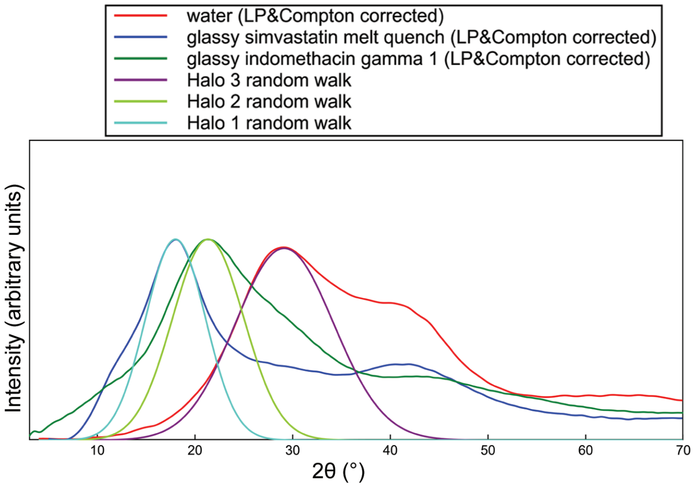

Figure 5.6.31
Normalized observed non-crystalline powder patterns (LP and Compton corrected) plotted with primary halo responses using a random-walk size model with $2^{1/2}N_s = 1$.

Debye–Menke response for mannitol compared with the mean simulated powder pattern for high-density randomly packed mannitol based upon multiple 100 molecule clusters generated using *PACKMOL*.

tion. Based upon the random-packing model, the observed non-crystalline universal halo width serves to signify that the solid-state building blocks are randomly packed and may not give any specific information on non-crystalline domain sizes or even molecular sizes. The observation that, in the non-crystalline solid state, the residual structure can be described by random packing of irreducible rigid building blocks is consistent with the high-symmetry description where ideally every atom (building block) becomes equivalent to every other atom (building block) within the system.

The self-avoiding random walk model proposed above is effectively a one-dimensional virtual lattice and implicitly assumes a preferred packing direction between neighbouring molecules. This preferred packing can appear in high-density systems driven by molecular shape or bonding constraints. This inherent asymmetry in local order can also be explicitly built within a general Debye model by constructing molecular models that show the expected preferred packing directions, although it can be challenging to construct models that effectively demonstrate randomness. A one-dimensional lattice model is an idealistic view of real non-crystalline materials and does not reflect their inherent spherical symmetry and isotropic nature. However, the Fourier-transform diffraction approach and lattice model provide useful insights into the nature of non-crystalline materials.

5.6.12. Steps towards an effective lattice model of high-density randomly packed materials

We have seen in the previous section how random packing in dense systems can lead to the natural formation of an effective lattice when the nearest-neighbour relationships between basic units have some directionality. Furthermore, the cumulative disorder associated with such a lattice can provide a framework for modelling the universal halo width phenomena of molecular non-crystalline systems. A second universal feature of molecular non-crystalline systems is the significant damping of scattering from longer-length-scale atom–atom correlations, which causes the observed diffraction intensity at lower angles to be significantly less than the predicted intensity from the Debye equation. One hypothesis is that the low-angle damping arises from conformational disorder. As an example, in Fig. 5.6.21, which shows the calculated Debye response from different low-energy and equilibrium conformations of a single indomethacin molecule, the variance in the low-angle response is larger than the variance in the higher-angle response. The low-angle variance reflects the conformation-induced changes in longer-distance atom–atom relationships. To allow for the conformational flexibility expected for non-crystalline systems, the Debye responses for the various possible conformations can be summed to give a single effective Debye response for an average molecule. While the higher-angle average response will remain relatively unchanged from a single molecule, the lower-angle response will be broadened and damped. Nevertheless, the conformation-induced low-angle intensity loss is not sufficient to describe the significant observed low-angle damping. Furthermore, the same intensity damping is also observed for small rigid molecules.

A second hypothesis is that low-angle intensity damping arises from the type of intermolecular packing present in the non-crystalline system. To investigate the role played by packing and packing density on the calculated Debye responses, a series of random dense packing studies was performed using rigid mannitol molecules. Mannitol molecules (with hydrogen atoms removed) can be readily packed to give a simulated high-density randomly packed system that allows the direct observation of the effect of packing on a calculated Debye response without the additional complexity of changes in conformation. *PACKMOL* was used to determine multiple packing configurations for mannitol with forced high and medium packing density. For the high-density packing, 100 mannitol molecules were constrained within a sphere radius of 15.75 Å with an allowed closest approach distance of 2.8 Å. For the medium-density packing, the sphere radius was expanded to 17.0 Å and the closest approach distance was set to 3.0 Å. Multiple packing configurations were generated using different random seeds, and the calculated powder patterns for each configuration were summed together to approximate a random system. The mean Debye response for the high-density packing exercise is displayed in Fig. 5.6.32 along with the Debye response of a single mannitol molecule. The mean high-density response displays some discontinuities due to the finite number of packing runs performed. A larger number of independent packing runs would be required in order to approach a smooth mean Debye response corresponding to an isotropic and random system. Nevertheless, the mean Debye response clearly demonstrates suppression of the lower-angle diffraction intensity. The high-density packing model was based upon a rigid mannitol molecule, which suggests that high-density molecular packing alone is a sufficient requirement to drive the observed low-angle intensity damping.

This exercise on mannitol dense packing is fully within the spirit of the Debye approach in that molecular models were constructed that naturally express the features of interest for the system under investigation. However, owing to the computational overhead imposed by this avenue of study, approximate forms of the Debye equation have been proposed (James, 1948; Menke, 1932; Warren, 1990) that can be applied without resorting to large-scale molecular models. One useful approximation is the introduction of a lattice function to describe molecular packing in bulk systems. In this approximation, the Debye function is applied to just the basic unit, and the lattice function takes care of the random packing. To investigate the relationship between the Debye diffraction equation and the Fourier lattice model, a simplified approach to a total diffraction model as outlined by Cowley (1990, chapter 5) will be followed. This approach makes use of the generalized Patterson function (the self-correlation function), which can be stretched to encompass the Debye formalism.

In the Patterson-function approach, the same expression used to determine the directional electron-density distribution in the previous section will be used. For this derivation, it will be assumed that the sample is large when compared with the molecule size and the length scale of local order. This allows the sample shape to be removed from the expression. As previously, the non-crystalline sample is assumed to be composed of basic units (molecules) that can be described by a three-dimensional electron-density function $\rho_0(\mathbf{r})$. Within the high-density non-crystalline state the average packing of the basic units is assumed to follow a four-dimensional 'lattice' function $g(\mathbf{r}, t)$, where t indicates time. Following Cowley, the electron-density distribution within the sample can be expressed as

$$\rho(\mathbf{r}, t) = \rho_0(\mathbf{r}) * g(\mathbf{r}, t).$$

This reflects a non-crystalline system where the basic unit has a specific electron-density distribution that is not time dependent but a packing function that may change over time. The general Patterson or self-correlation function becomes

$$P(\mathbf{r}, t) = [\rho_0(\mathbf{r}) * \rho_0(-\mathbf{r})] * [g(\mathbf{r}, t) * g(-\mathbf{r}, -t)].$$

Taking the Patterson function of the basic unit to be

$$P_0(\mathbf{r}) = \rho_0(\mathbf{r}) * \rho_0(-\mathbf{r})$$

and the distribution Patterson to be

$$G(\mathbf{r}, t) = g(\mathbf{r}, t) * g(-\mathbf{r}, -t),$$

then the general Patterson can be written as

$$P(\mathbf{r}, t) = P_0(\mathbf{r}) * G(\mathbf{r}, t).$$

One of the primary advantages of this approach is the direct Fourier-transform relationship between the Patterson function and the measured diffracted intensity: $P(\mathbf{r}, t) \leftrightarrow I_P(\mathbf{Q}, t)$. As such, the Patterson function can be experimentally determined. Applying the Fourier-transform convolution rule,

$$I_P(\mathbf{Q}, t) = \left|F_0(\mathbf{Q})\right|^2 \left|G(\mathbf{Q}, t)\right|^2,$$

where $P_0(\mathbf{r}) \leftrightarrow |F_0(\mathbf{Q})|^2$ and $G(\mathbf{r}, t) \leftrightarrow |G(\mathbf{Q}, t)|^2$ are direct Fourier-transform pairs.

The time variation is included within the general Patterson function for more liquid-like non-crystalline systems whose local intermolecular packing arrangements may change over the duration of a single measurement. However, X-ray diffraction measurements on the laboratory scale are usually considered to be instantaneous measurements. As such, the time dependence should more accurately be expressed as a time average over all instantaneous intensities. For a solid non-crystalline system, the local molecular-packing arrangements are considered to be static over the duration of a typical measurement. However, from point to point in a bulk sample, the packing arrangements may change. In this sense, the diffraction measurements on both liquid and solid non-crystalline samples are essentially configurational averages over many instantaneous diffraction events. For the basic unit, the configuration average can be expressed as an average over the rotational degrees of freedom θ and ϑ:

$$\langle P(\mathbf{r})\rangle = \langle \rho_0(\mathbf{r}, \theta, \vartheta) * \rho_0(\mathbf{r}, \theta, \vartheta) * g(\mathbf{r}, \theta, \vartheta) * g(\mathbf{r}, \theta, \vartheta)\rangle_{\theta,\vartheta}.$$

The configurational averaging as expressed above represents essentially the same spherical averaging as applied during the derivation of the Debye diffraction equation and gives a spherically symmetric Patterson function dependent on a single scalar distance.

In the random-walk example, the presence of an effective lattice was due to the preferred packing that occurs between nearest neighbours. This suggests that the angular symmetry of the basic unit will be reflected in the angular symmetry of the packing function. If, however, as a first approximation the symmetry relationship is broken between the basic unit and packing function, then the spherically averaged Patterson can be expressed as

$$\langle P(\mathbf{r})\rangle = \langle \rho_0(\mathbf{r}, \theta, \vartheta) * \rho_0(\mathbf{r}, \theta, \vartheta)\rangle_{\theta,\vartheta} * \langle g(\mathbf{r}, \theta, \vartheta) * g(\mathbf{r}, \theta, \vartheta)\rangle_{\theta,\vartheta}$$

which through the Fourier convolution relationship gives the diffraction intensity:

$$I_P(\mathbf{Q}) = \langle |F_0(\mathbf{Q}, \theta, \vartheta)|^2\rangle \langle |G(\mathbf{Q}, \theta, \vartheta)|^2\rangle$$

where $\langle \rho_0(\mathbf{r}, \theta, \vartheta) * \rho_0(\mathbf{r}, \theta, \vartheta)\rangle_{\theta,\vartheta} \leftrightarrow \langle |F_0(\mathbf{Q}, \theta, \vartheta)|^2\rangle$ and $\langle g(\mathbf{r}, \theta, \vartheta) * g(\mathbf{r}, \theta, \vartheta)\rangle_{\theta,\vartheta} \leftrightarrow \langle |G(\mathbf{Q}, \theta, \vartheta)|^2\rangle$ are direct Fourier transform pairs. The basic unit diffraction intensity is expressed as a spherically averaged self-correlation and is effectively the Debye diffraction intensity. This suggests that within the above approximations the total Debye diffraction intensity of a densely packed non-crystalline form can indeed be represented by a form that includes a lattice function:

$$I_D(Q) \sim I_{0,D}(Q) L_D(Q),$$

where $I_{0,D}(Q)$ is the usual Debye diffraction intensity from the basic unit and $L_D(Q)$ is the diffraction intensity due to an effective lattice. The effective lattice function is a spherically averaged diffraction intensity. During the derivation of the expression, in order to extract the effective lattice function from the basic unit Debye response, the symmetry relationship between the basic unit and the lattice function was broken. As a consequence of the loss of this symmetry relationship, the expression as derived is only rigorously applicable in cases when either the basic unit and/or the lattice function have spherical symmetry in real space. The same spherical symmetry constraints also apply to the Menke shape-correction term explored in Sections 5.6.4 and 5.6.5.

The most frequently referenced spherically symmetric lattice function with respect to the Debye diffraction model is the spherical exclusion zone. For both liquid and solid non-crystalline systems, due to the effectively instantaneous nature of the X-ray diffraction event, molecules (basic units) are not observed to occupy the same space during the diffraction event. As such, each basic unit has an effective exclusion zone around it that defines

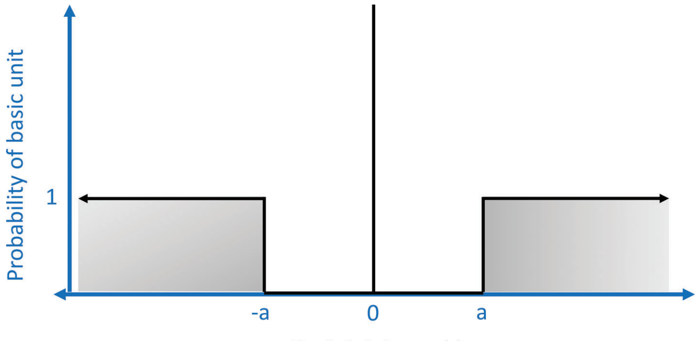

Figure 5.6.33
Schematic representation of a spherical exclusion zone centred on each basic unit.

the closest approach possible for neighbouring basic units. For molecular glasses, the exclusion zone is one of the sources of rigidity as the density increases. In Fig. 5.6.33, a schematic representation of the spherical exclusion zone is presented as a function of radial distance from the centre of a general basic unit. At the origin lies a delta function that places the central basic unit. For a distance of *a* around the central basic unit, there is zero probability of finding another basic unit. This defines the exclusion zone of radius *a*. Outside the exclusion zone the probability of finding another basic unit is unity in all directions and at all distances. In the exclusion-zone representation, there exists no short-range inter-unit order except for the exclusion zone itself.

The diffraction amplitude for a spherical exclusion zone of radius *a* with central delta function can be written as

$$G_{\rm SE}(Q) = 1 - \emptyset(Qa)$$

where $\emptyset(Qa)$, the sphere diffraction amplitude, is given by the usual expression,

$$\emptyset(Qa) = \frac{3[\sin(Qa) - (Qa)\cos(Qa)]}{(Qa)^3}.$$

The effective lattice function is now given by

$$L_{D,{\rm SE}}(Q) = |G_{\rm SE}(Q)|^2.$$

Fig. 5.6.34 shows the simulated impact of a spherical exclusion zone and the implied effective lattice on the calculated Debye–Menke response for mannitol (without hydrogen atoms). Sphere radii of 3.0, 2.5 and 2.0 Å were modelled, showing the increasing low-angle damping for increasing packing density (smaller exclusion-zone radii). For comparative purposes, the results for the high-density random packing exercise are also presented. The high-density packing fixed the closest approach between neighbouring mannitol molecules to be 2.8 Å, which is slightly larger than the molecular radius of gyration (~2.5 Å without hydrogen atoms). The exclusion-zone radii were chosen to bracket both the closest approach distance and the radius of gyration. Mannitol is essentially a linear molecule, yet the application of a spherical exclusion zone to the single-molecule Debye–Menke response provides a reasonable approximation as to the calculated Debye response from high-density randomly packed mannitol.

One of the primary goals of this chapter was to arrive at a theoretical diffraction framework that allowed the calculation of powder patterns for ideal molecular non-crystalline solids. Ideal non-crystalline solids are defined as exhibiting no short-range inter-atom order except for the rigid segments of the individual molecules (basic units). Based upon the mannitol example, the inclusion of a spherical exclusion zone and the implied effective lattice allow the Debye diffraction response for a single molecule to be extended to represent a densely packed ideal non-crystalline solid. Using this composite Debye approach, in principle, given a molecular entity or basic unit (dimer, trimer, unit cell *etc.*) the expected powder pattern for the corresponding ideal non-crystalline solid can be calculated.

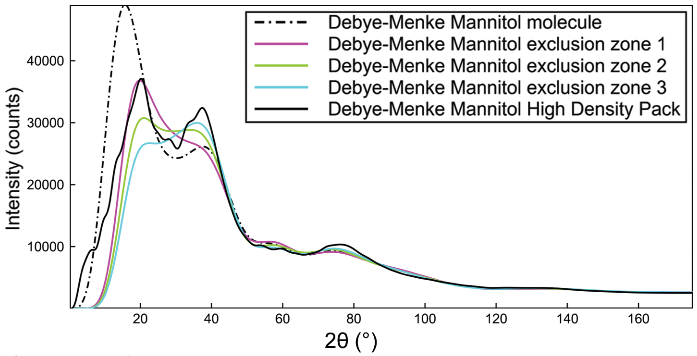

Figure 5.6.34
Effect on the calculated Debye–Menke single-molecule response for mannitol of a hard-sphere exclusion zone. Sphere radii of 3.0, 2.5 and 2.0 Å were chosen based upon the radius of gyration for mannitol. For comparative purposes, the calculated mean Debye–Menke response for the high-density random packing exercise is also displayed. Data have been scaled to 100 mannitol molecules (without hydrogen atoms).

Before considering practical examples of non-crystalline solids, it is instructive to extract the function form of $L_D(Q)$ directly from the calculated powder pattern for packed rigid mannitol molecules. From the observed powder diffraction intensity after full Debye normalization and transformation into electron units, the effective Debye lattice function can be derived by dividing by the Debye response for a single basic unit:

$$L_D(Q) \simeq I_{{\rm obs},D}(Q)/I_{0,D}(Q).$$

To extract the effective lattice function for the calculated response for the mannitol high-density random packing, the normalized observed diffraction intensity can be replaced by the Menke-corrected Debye response scaled to a single molecule. Using the Menke-corrected Debye response removes the shape effects of the small model size.

The extracted effective lattice function for the high-density packing exercise is shown in Fig. 5.6.35 along with the calculated effective lattice function for a spherical exclusion zone with radius 2.6 Å. The general shape and oscillatory nature are reproduced by the calculated function, but the magnitude of the oscillations is larger in the function extracted from the 100

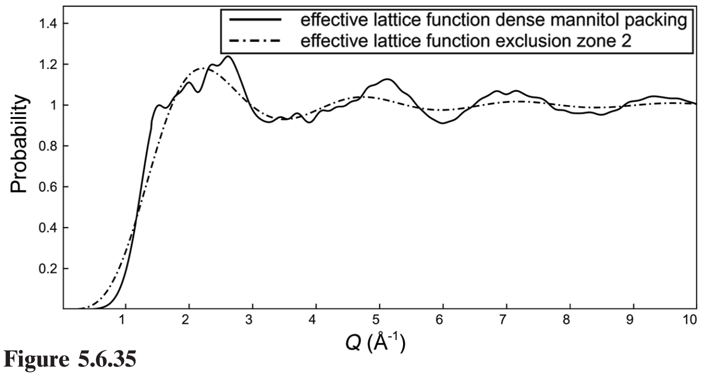

Figure 5.6.35

randomly packed molecules. The closest approach distance was fixed for the high-density random packing to be 2.8 Å, which is similar to the displayed exclusion-zone radius.

Fig. 5.6.36 displays the equivalent effective lattice function extracted from the low-density mannitol packing exercise compared with the calculated lattice function derived from a spherical exclusion zone with radius 3.0 Å. During the low-density random packing of mannitol the nearest approach distance was set to 3.0 Å, which matches the radius of the displayed spherical exclusion zone lattice function. The general shape and oscillatory nature are reproduced by the calculated function but, as with the high-density packing, the magnitude of the oscillations is larger in the function extracted from the 100 randomly packed molecules.

Extracted lattice functions for the randomly packed low-density and high-density mannitol models are visibly more complex than the calculated lattice functions for spherical exclusion zones. Some of the additional complexity may come from the random-packing methodology and the limited sampling size, but overall the extracted data suggest a more complex packing. Within the Debye modelling methodology, any more complex packing model must maintain the inherent spherical symmetry. One approach to constructing more complex spherically symmetric effective lattice functions makes use of a core–shell-type of formulism as employed for small-angle scattering data modelling (for example, Pedersen, 1997). An example three-level core–shell model is illustrated in Fig. 5.6.37, which also breaks down the cumulative diffraction influence of the concentric spherical probability functions. When assembling the cumulative diffraction responses for the concentric spherical contributions, it is important to normalize the cumulative amplitude to be equal to unity as Q approaches zero.

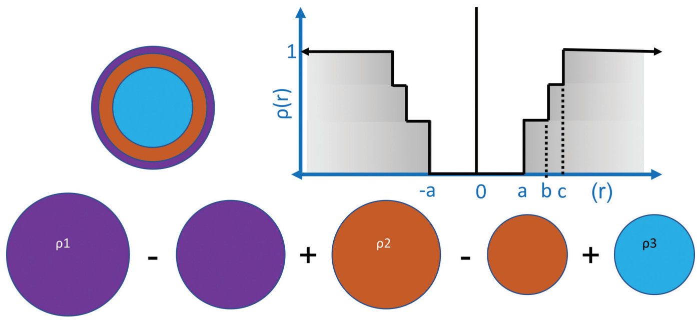

Figure 5.6.37
Schematic illustration of a spherical core–shell-type model to describe more complex exclusion zones and packing models for basic units.

Using the same formalism as for the spherical exclusion zone, the core–shell effective lattice function for the three-sphere model illustrated in Fig. 5.6.37 can be written as

$$G_{\rm SE}(Q) = \frac{1}{M_3}\Big\{1 - [\rho_1 V_1 Ø(Qc) + (\rho_2 - \rho_1) V_2 Ø(Qb) + (\rho_3 - \rho_2) V_3 Ø(Qa)]\Big\}$$

where V_1 is the spherical volume corresponding to exclusion distance c and M_3 is the normalizing constant:

$$M_3 = \rho_1 V_1 + (\rho_2 - \rho_1) V_2 + (\rho_3 - \rho_2) V_3.$$

The individual exclusion probabilities and distances were refined using the *Excel* Solver function in order to achieve the best fit between the calculated and extracted effective lattice functions. For the high-density mannitol random packing example, the best fit to the extracted effective lattice function using a three-sphere concentric lattice model is displayed in Fig. 5.6.38. The overall goodness of fit for the three-sphere lattice function is an improvement over the single spherical exclusion zone. For the high-density mannitol model, the molecular pair distribution and atomic pair distribution can be directly extracted from the molecular centres and atomic coordinates. The molecular pair distribution is displayed along with the three-sphere model in Fig. 5.6.39. The molecular pair distribution was calculated from a single random packing run using the coordinates of the molecular centres. The spiky nature of the pair distribution reflects the challenges of random packing for small sample sizes.

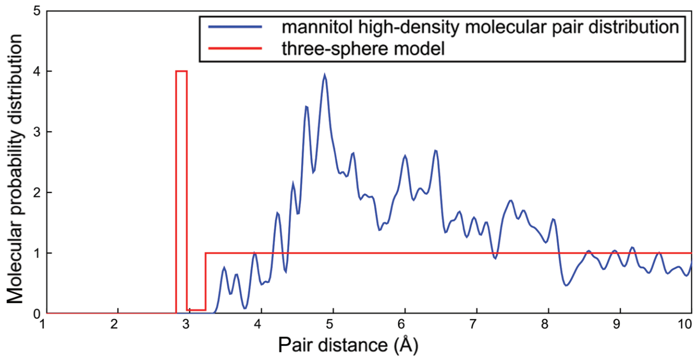

Figure 5.6.39
Molecular centre pair distribution extracted from high-density mannitol packing compared with a three-sphere effective lattice model. The three-sphere effective lattice model has an inner exclusion zone of radius 2.81 Å followed by a narrow high-probability zone of 0.15 Å corresponding to four molecular nearest neighbours.

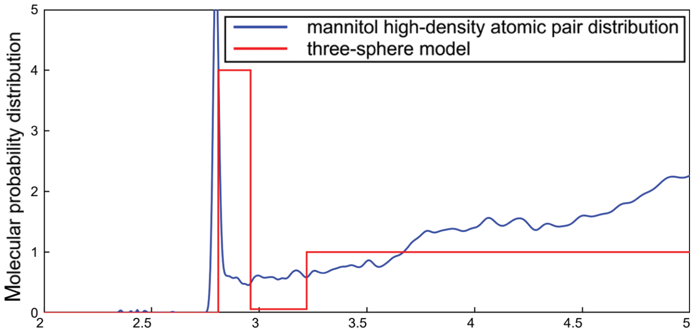

Figure 5.6.40
Normalized atom pair distribution extracted from high-density mannitol packing compared with a three-sphere effective lattice model. The atom pair distribution displays only intermolecular relationships.

The intermolecular nearest-neighbour distance for the high-density model is centred around 5 Å (consistent with known crystal structures) with an average coordination number of about 4. The molecular nearest-neighbour coordination number is reproduced in the three-sphere model, but the effective exclusion zone distance is clearly not related to intermolecular distances. In Fig. 5.6.40 a normalized atom pair distribution is displayed along with the three-sphere effective lattice model. The atom pair distribution was normalized by removing all intermolecular atom–atom distances and reducing to a molecular electron scale. The single strong intermolecular atom–atom distance (~2.8 Å) occurs at the same distance as the primary spherical exclusion zone. The nature of the high-density mannitol packing is clearly driven by the packing algorithm and the closest approach limit. Nevertheless, the model allows a demonstration of the utility of the effective lattice function method in combination with the Debye model.

5.6.13. Practical application of the effective lattice function determination

The glassy phase of indomethacin presents an instructive example of the step-by-step procedure used to determine an effective lattice function from measured data. The first prerequisite is that the measured non-crystalline XRPD response has to be normalized following the full Debye normalization. This includes a correction for both the instrumental background and the core instrument intensity response function, in addition to removal of the Compton scattering and any significant absorption or multiple-scattering contributions. Fig. 5.6.20 shows the full Debye normalization for glassy indomethacin where the high-Q response in the measured data follows the high-Q response of the molecular entity.

Once the measured data have been normalized, an appropriate basic unit for the effective lattice should be identified. Typically, the initial basic unit selected will be a single molecule. The effective lattice, as derived within the Debye approach, is based upon spherical symmetry. As such, any local ordering or specific chemical bonding should ideally be developed within the choice of basic unit. The selection of potential basic units can be partially automated using databases of common packing motifs, crystal structures of similar molecules and/or from molecular simulations. The choice of basic unit gives the appropriate Debye response function, $I_{0,D}(Q)$, with which to derive the effective lattice functions. For each basic unit, an effective lattice function, $L_D(Q)$, was extracted using iterative optimization of spherically symmetric core–shell models within the Microsoft *Excel* Solver module. The final 'best fit' core–shell lattice function was then combined with the corresponding calculated Debye response for the basic unit to determine a simulated glassy indomethacin response, which was compared with the original observed data. Each optimized solution consisting of a unique basic unit and corresponding core–shell lattice function was ranked according to how well the simulated glassy response matched the observed glassy response. The highest-ranking basic unit was a single molecule extracted from the known crystal structure of the alpha form. However, a basic unit consisting of the $P\bar{1}$ dimer extracted from the crystal structure of the gamma form also gave a good description of the observed data. Inspection of the derived core–shell lattice functions indicated that, for indomethacin, the dimer solution was not physically realistic. The effective lattice function corresponding to the highest-ranking single-molecule solution along with the 'best fit' core–shell model is shown in Fig. 5.6.41. The resulting core–shell lattice exhibits a well defined exclusion boundary at about 3.2 Å with an associated nearest-neighbour closest approach shell. The closest approach shell has an increased probability (number density) with a coordination number of about 1.2.

The fully normalized glassy indomethacin data are displayed in Fig. 5.6.42 along with simulated data sets derived from the single-molecule and $P\bar{1}$ dimer basic units. Both models provide an adequate fit to the observed data. This highlights a frequently encountered scenario when modelling non-crystalline materials, where a number of different models of local molecular order can describe the observed data. In practice, non-crystalline total diffraction data typically have lower information content than that observed for crystalline materials. As such, modelling non-crystalline materials requires strict limits with respect to the numbers of degrees of freedom used during any minimization procedure. The information content for non-crystalline diffraction data is encoded in the subtle changes in slope observed across the full diffuse continuous profile. To reveal the subtle changes in the diffuse halos requires a comprehensive data pre-

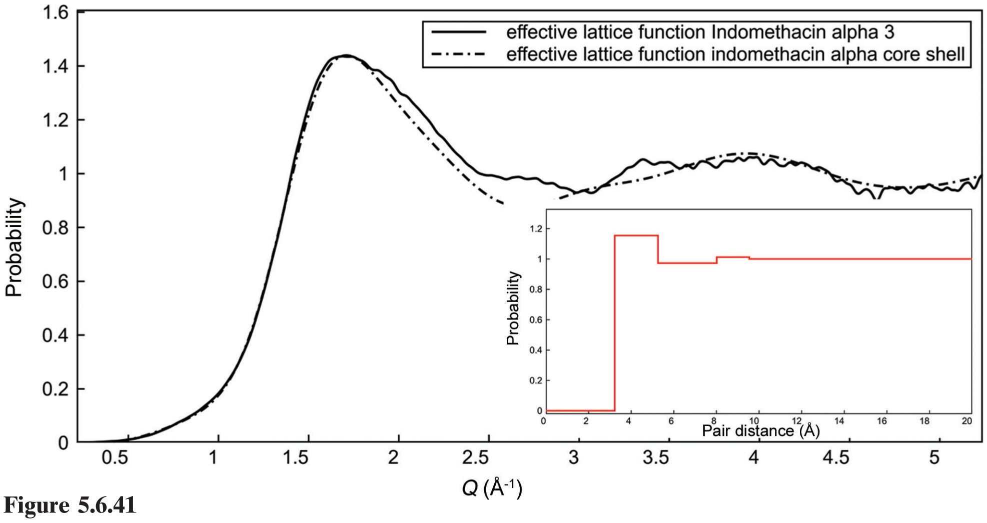

Figure 5.6.41
Effective lattice function for a single indomethacin molecule compared with the 'best fit' core–shell model (three-shell model) (inset).

treatment and normalization to remove as much of the instrument-driven variance as possible. The full Debye normalization procedure provides a robust and reproducible approach to the required data pre-treatment; however, to limit the degrees of freedom during modelling, the full Debye normalization should be performed prior to the modelling exercise and the resulting input data file taken as a fixed target. Furthermore, the choice of potential basic units should also be performed prior to the modelling procedure. Basic units are either selected from known crystal structures or built within molecular modelling/packing programs. For each selected basic unit, the only allowed variables during minimization are the radius of the spherical exclusion zone plus the weight and width of the subsequent concentric shells that define the packing model. For the 'best fit' indomethacin lattice function associated with a single-molecule basic unit, three concentric shells were used. The $P\overline{1}$ dimer basic unit required five concentric shells to achieve the same degree of fit to the observed data.

A comparison between the calculated Debye–Menke response for a single indomethacin molecule and the subsequent simulated data incorporating the core–shell lattice function, see Fig. 5.6.43, is instructive. As expected, both the Debye–Menke response and simulated data describe the observed high-angle diffraction features (above about 30° 2θ for Cu $K\alpha$ X-rays). The appearance of the primary halo at about 22° 2θ is driven by the exclusion zone around each molecule and the corresponding low-angle intensity damping. As observed with the mannitol random-packing models, the exclusion zone is related to nearest-neighbour electron-density closest approach distances and not explicitly related to intermolecular distances. As a consequence, for most linear or planar organic molecules, a common exclusion zone distance will be about 3.0 Å independent of molecular weight. This is in part the origin of the common primary halo positions for a wide range of organic molecular glassy materials. For the single-molecule basic unit, the exclusion-zone core radius was determined to be about 3.2 Å, which is consistent with single-molecule nearest-neighbour electron-density closest approach distances. For the $P\overline{1}$ dimer model, the required exclusion zone had a radius of about 3.1 Å, which was less consistent with closest approach distances for the larger basic unit. Molecular-dynamics simulation of glassy indomethacin (Xiang & Anderson, 2013) has indicated that, although the hydrogen-bonded dimers observed in the alpha and gamma crystalline polymorphs are present to a limited extent in the simulated glass, the molecular relationships are more complex with the appearance of extended hydrogen-bond chains. The extracted core–shell model is consistent with a complex local molecular environment which on average across a bulk glass reduces to an exclusion zone with weak nearest-neighbour correlation.

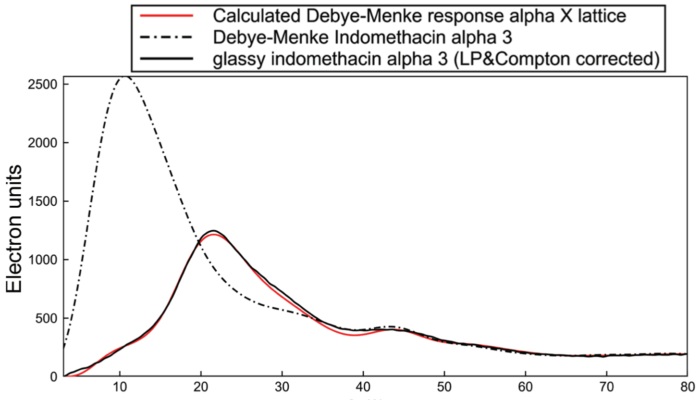

Figure 5.6.43
Fully normalized glassy indomethacin data (measured on the melt–quench alpha form) displayed with a simulated data set derived from a single-molecule basic unit and the corresponding Debye–Menke response.

An interesting example of effective lattice modelling that will be briefly discussed is that of simvastatin. Fig. 5.6.26 shows the two powder patterns collected on non-crystalline simvastatin prepared by melt–quench and cryo-grinding. These two non-crystalline forms of the same molecule exhibit significantly different physical stability with different glass transition and re-crystallization temperatures. After normalization, the two powder patterns are also observed to be significantly different in appearance. The powder pattern collected on the melt–quench data shows a shifting in the overall diffraction intensity towards higher angles while more closely following the calculated Debye–Menke curve at higher angles. As discussed previously, non-crystalline materials that generate powder patterns that closely follow the Debye–Menke curve have little in the way of local intermolecular order and approach the ideal non-crystalline symmetry state.

A relative shifting in diffraction intensity towards higher angles was also observed for simulated powder patterns generated from 100 randomly packed mannitol molecules. As the packing density is increased, the low-angle diffraction intensity is damped, and the primary halo intensity distribution is consequently shifted to higher angles. This is because of a reduction in the volume occupied by a single molecule and hence a reduction in the extent of the physical exclusion zone. Core–shell lattice

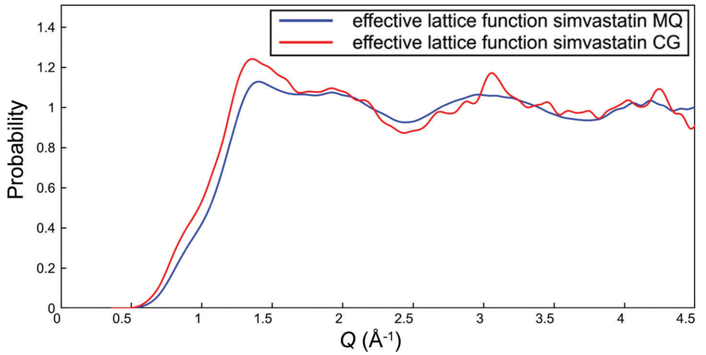

Figure 5.6.44
Effective lattice functions extracted from non-crystalline powder patterns measured on melt–quench (MQ) and cryo-ground (CG) simvastatin.

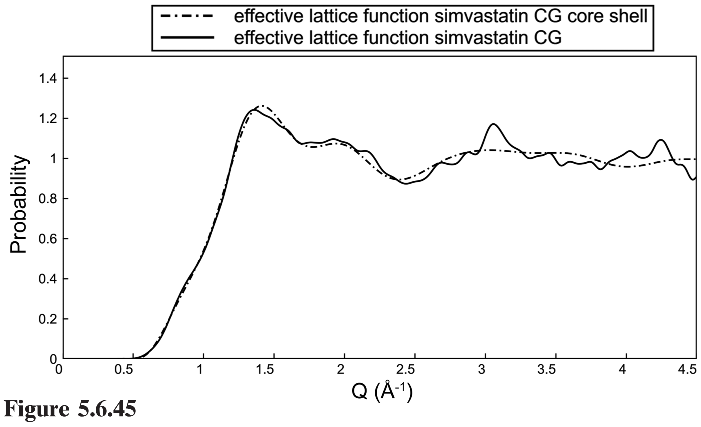

Figure 5.6.45
Core–shell lattice function fit to the effective lattice function for cryo-ground simvastatin.

function modelling can be performed on the simvastatin data to determine the difference in the exclusion zones for the melt–quench and cryo-ground materials. The extracted effective lattice functions are displayed in Fig. 5.6.44. The effective lattice function for the cryo-ground material exhibits significant noise due to the rapid data collection required to avoid re-crystallization.

The core–shell modelling was able to adequately describe both of the extracted lattice functions using a single-molecule basic unit and a core plus five concentric shells. The resulting fit to the effective lattice function extracted from non-crystalline cryo-ground data is shown along with the core–shell model data in Fig. 5.6.45.

The individual core–shell lattice models for the cryo-ground and melt–quench materials are displayed in Fig. 5.6.46. The general shape of the exclusion zone for the simvastatin materials exhibits a fuzzy boundary rather than the abrupt, well defined boundary observed for indomethacin. Outside the fuzzy exclusion zone, neither of the core–shell models exhibits a preferred molecular closest approach distance. The absence of significant intramolecular order except for an exclusion zone suggests that glassy simvastatin is close to an 'ideal' glassy system. The melt–quench simvastatin material exhibits a more restrictive exclusion zone than the cryo-ground material, as expected from the observed high-angle shift in the diffraction intensity. The resulting simulated data provide a good description of the observed data, describing all observed features of the non-crystalline profile for both cryo-ground and melt–quench materials.

While the change in the exclusion-zone profile between the cryo-ground and melt–quench materials is significant, the relationship between the exclusion zone and the packing density is more difficult to extract. As observed with the mannitol random-packing example, the extent of the exclusion zone is related to closest approach distances rather than the actual volume occupied by a single molecule. For the simvastatin example, the largest extent of the exclusion appears to increase from about 3.8 Å for the melt–quench material to about 4.0 Å for the cryo-ground material. This might be driven by a change in the average molecular conformation that forces the closest approach distance to change, or it might be related to an actual change in packing volume. Typically, changes in exclusion-zone profiles do not allow a direct modelling of molecular-packing differences but, as demonstrated for the simvastatin example, they can provide a measure of the change in physical stability between glassy forms of the same molecular entity.

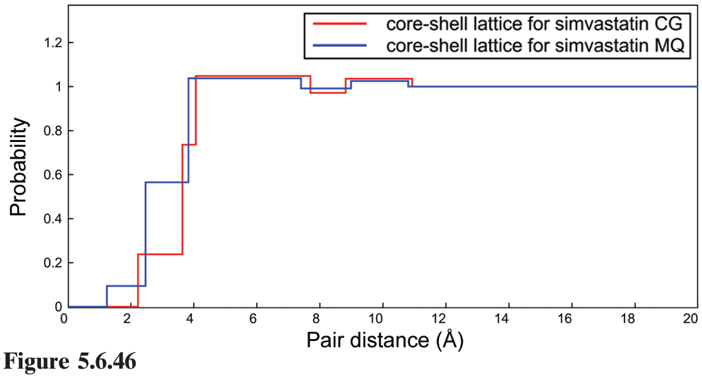

Figure 5.6.46
Core–shell lattice functions for cryo-ground and melt–quench simvastatin.

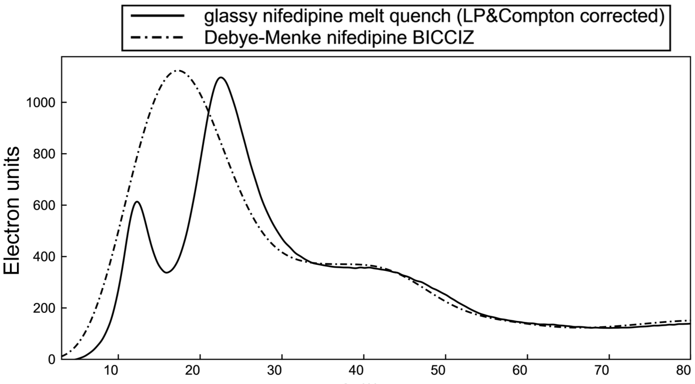

Figure 5.6.47
Fully normalized glassy nifedipine data (measured on a melt–quench glassy form) displayed with a single-molecule Debye–Menke response.

The previous examples (indomethacin and simvastatin) all exhibited weak low-angle halos in the corresponding non-crystalline diffraction patterns. In each case, the halo position was related to features within the individual molecular Debye diffraction profile rather than a specific intermolecular packing distance; see for example Fig. 5.6.43. The observed intensity of the smaller halo was, however, controlled by the specific molecular packing function. Nifedipine has been chosen as the last example in this section, as the glassy form exhibits two well defined diffraction halos within the total diffraction measurement that do not correspond to features in the individual molecular Debye response; see Fig. 5.6.47. The nifedipine molecule used for the Debye calculation was taken from the published crystal structure of the monoclinic polymorph (CCDC refcode BICCIZ; Triggle *et al.*, 1980). A molecular drawing is presented in Fig. 5.6.48.

The extracted effective lattice function and 'best fit' core–shell results are displayed in Fig. 5.6.49, and the corresponding simulated powder pattern is displayed in Fig. 5.6.50. The results clearly show that a five-shell spherical lattice model is able to fully describe both of the observed halos for glassy nifedipine. In addition to a well defined exclusion zone with a closest approach distance of about 3.15 Å, the derived lattice function is periodic in appearance, extending out to almost 20 Å. The overall periodic character of the core–shell lattice model suggests that a more

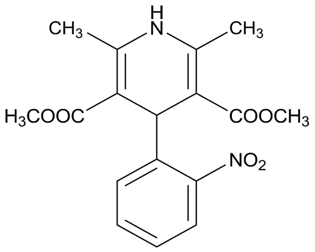

Figure 5.6.48

extensive local molecular order is driven by the characteristic shape of nifedipine and the associated preferred closest approach distances.

Although only a limited number of examples are presented in this section, the modelling results indicate that the total diffraction patterns from molecular non-crystalline systems can be adequately described using a single-molecule basic unit combined with a simple core–shell spherical lattice that describes the molecular exclusion zone and nearest-neighbour closest approach distances. However, the nifedipine core–shell results indicate that more extensive local order may be present within the glassy systems. The final section in this chapter explores modelling approaches for more extensive local order.

5.6.14. Debye diffraction models for larger molecular ensembles

The investigation of more extensive local ordering beyond what can be described by a spherical core–shell model will often require the simulation of total diffraction patterns from larger-scale molecular models. As with all total diffraction modelling using the Debye equation, the size and shape of the molecular cluster will be folded into the total diffraction response and may generate spurious results. As an example, in Fig. 5.6.17, the Debye total diffraction response calculated for a 3 nm silicon nanocrystal exhibited a series of weaker oscillations in addition to the expected diffraction peaks. The oscillations were generated by the sharp crystal surfaces of the nanocrystal atomic model. In previous sections, the spherically symmetric Menke correction has been used to remove molecular-shape effects from the Debye diffraction model. However, the Menke correction is a spherical approximation (similar to the Guinier small-angle scattering approximation) and will not fully compensate for molecular dimensionality and strong asymmetry in molecular shape. This was observed for the silicon nanocrystal example where the Menke correction did not remove the crystal-surface interference effects.

For larger-scale molecular models, an alternative Debye calculation procedure has been developed to avoid cluster size effects and to ensure representative sampling of the molecular model.

This approach is based upon the use of multiple spherical subsets (bubbles) extracted from the large-scale molecular model. As illustrated with the forced mannitol packing example, the shape effects from spherical molecular models can be fully removed by applying the Menke correction. To ensure a close-to-spherical electron-density distribution, each spherical subset must be wholly contained within the boundaries of the large-scale model. The radius of the spherical subset defines the effective coherence length of the Debye calculation. To explore different coherence lengths, a series of spherical radii can be used. Typically, spherical radii of 3.0 to 15.0 Å give sufficient coverage for non-crystalline materials. The number of spherical subsets selected and their location will be defined by the unique atomic environments that exist within the large-scale molecular model. If the molecular model is based upon a crystal structure, then each atom within the central asymmetric unit can be selected as a unique bubble centre. For large-scale randomly packed models, a reasonable approach is to select all atoms as unique bubble centres provided they are at least the spherical radius from the model boundary. A schematic representation of the bubble approach using multiple spherical subsets is shown in Fig. 5.6.51.

The core–shell lattice models for non-crystalline nifedipine indicated the presence of more extensive periodic local order

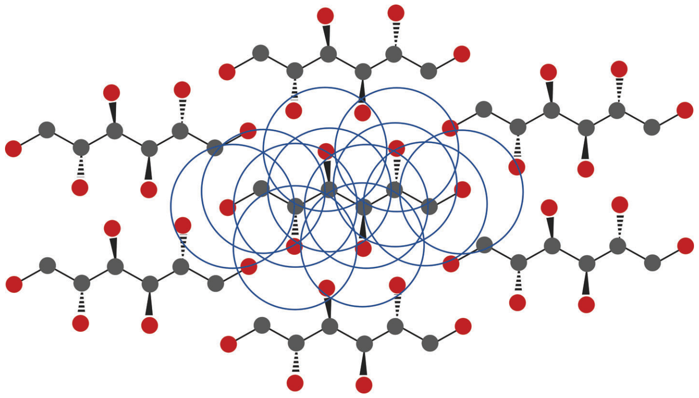

Figure 5.6.51

than could be fully captured using a single-molecule packing model. To investigate the nature of the observed local order, the bubble Debye calculation approach was applied to large-scale crystalline models of nifedipine. The crystalline models were generated from the two known polymorphs of nifedipine (CCDC refcodes BICCIZ and BICCIZ01; Bortolotti *et al.*, 2011). Each model consisted of 5 × 5 × 5 unit cells; the smallest dimension was about 50 Å. For each molecular model, the atoms within the central asymmetric unit were taken as unique bubble centres. A series of Debye–Menke calculations was performed centred on the unique atoms and the total diffraction response was taken to be the sum of the individual Debye–Menke responses. The summation over multiple spherical subsets of the same radii gives a cluster-size response that can be removed by the Menke correction, giving a total diffraction response representative of the local molecular structure. To normalize the calculated total diffraction response from the bubble calculation, the high-angle diffraction response was scaled to match the single-molecule Debye–Menke response. The total diffraction results for the two nifedipine crystal structures are shown in Figs. 5.6.52 and 5.6.53 for bubble radii of 3, 5, 8, 10 and 12 Å (as indicated by _3 to _12 in the figure legends). For the small bubble radii, both crystal structures give a similar total diffraction response to the single-molecule Debye–Menke response. For larger bubble radii, both crystal structures develop a well defined low-angle halo similar in appearance to the experimentally observed data for non-crystalline nifedipine. The larger bubble radii as applied to the BICCIZ01 crystal structure also begin to develop the characteristic second higher-angle halo observed for non-crystalline nifedipine. The crystal structure BICCIZ gives a broader doublet in place of the higher-angle second halo and does not describe the observed data. For non-crystalline nifedipine, the core–shell lattice model indicated the presence of periodic local order and the Debye bubble calculation suggests that the periodic order might be related to the local molecular packing of the BICCIZ01 crystal structure.

The observation for nifedipine that the local order from a crystal structure is able to give a calculated total diffraction response that reproduces characteristic features observed in measured data from the non-crystalline material is not unusual. For many organic molecular non-crystalline systems, one of the associated crystalline polymorphs can be used as an initial model of non-crystalline local order. The relationships between crystalline and non-crystalline local order are beyond the scope of this introductory chapter and will be investigated in a subsequent publication.

5.6.15. Conclusions

The purpose of this chapter was to explore and introduce, at a basic level, X-ray diffraction from non-crystalline systems and to investigate the utility of the Debye diffraction approach as a tool for helping to characterize the measured diffraction data. Non-crystalline systems were defined to be high-density liquid or solid molecular systems that can be considered to be essentially isotropic and random with no long-range intermolecular order. Ideal non-crystalline systems represent the ‘high-symmetry’ ideal, where the only average interatomic order present will be due to rigid and irreducible fragments of individual molecules. X-ray powder diffraction measurements made on these types of systems give essentially continuous diffraction patterns characterized by a series of diffuse halos and an absence of any discrete diffraction peaks. Because of the continuous nature of non-crystalline diffraction, specific data-normalization and data-processing steps are required to transform the observed data into a suitable form for modelling.

For close-to-ideal non-crystalline systems, it was shown that total diffraction patterns calculated from a single molecule using the Debye theory should be representative of the measured high-angle diffraction response and can be used as an asymptote for data scaling. For systems where the molecular structure is unknown, the asymptote can be approximated by the independent coherent intensity, which is only dependent on the elemental makeup of the sample. For mixed or single-phase samples where the elemental makeup is similar (like organic systems) then the high-angle asymptote will be similar for all samples and data can be scaled to a common high-angle response. In practice, this Debye normalization step should only be applied when the measured background levels are similar from sample to sample or after suitable background modelling. The use of Debye normalization was illustrated using a model lyophile system where the sample masses and measurement conditions were carefully controlled to ensure a consistent background response. The Debye normalization was applied directly to the observed data, giving a self-consistent set of data that can be analysed using chemometric variance methods. Chemometric methods are often the method of choice for the characterization of non-crystalline systems and are particularly well suited to the quantitative analysis of multicomponent systems.

For more extensive total diffraction modelling, the measured data should be transformed into an instrument-free form that allows direct comparison with calculated Debye responses. The most critical data-processing step in this transformation was shown to be the modelling of instrumental background including sample-related contributions such as *Bremsstrahlung* and Compton scattering. After application of an appropriate background model, the background-free data were corrected to remove a calibrated instrument intensity response (*i.e.* a Lorentz–polarization correction was applied). Because of the nature of the Debye diffraction equation, the Lorentz correction as applied to non-crystalline data was shown to be different from the Lorentz corrections traditionally applied to single-crystal or powder diffraction data. With the measured total diffraction data transformed into an instrument-free form, calculated Debye diffraction patterns can be directly compared with the measured data to elucidate the nature of local molecular order present in the sample.

Within the spirit of Debye diffraction modelling, a suitable molecular model representing the sample of interest must first be generated. The Debye diffraction equation should then be applied iteratively to every atom–atom pair within the molecular model. However, for non-crystalline systems, the generation of a suitable molecular model that reflects the isotropic and random nature of the material can be challenging. As an alternative approach, the use of a single representative molecule and a spherically symmetric packing function or exclusion zone was explored. This modelling approach was based upon the observation that for ideal non-crystalline molecular systems, the only local atomic order would be due to the rigid sections of the molecular structure. For the majority of the examples presented in this chapter, the Debye diffraction response calculated for a single molecule when combined with the spherical core–shell-like packing function was able to describe the observed total diffraction data. This simplified approach to Debye diffraction modelling of non-crystalline systems is straightforward to employ for real-world modelling problems.

While examples of close-to-ideal non-crystalline systems can be found for larger flexible molecules (for example simvastatin), small-molecule systems with a well defined shape or strong directional bonding tend to exhibit more extensive local intermolecular order and require extended molecular models. For these larger-scale molecular models, the Debye bubble approach was introduced. The bubble algorithm was used to split the model into a series of spherical subsets. The total diffraction response from the individual subsets was then summed to give the total diffraction response of the system. The bubble approach allowed representative sampling of large-scale molecular models while limiting the effective diffraction coherence length and in addition gave a shape contribution that could be removed from the total diffraction calculation using the Menke correction. For systems exhibiting more extensive local order than can be described by the core–shell model, the Debye bubble approach applied to large-scale molecular models can be a practical approach to generating artifact-free total diffraction responses.

The motivation behind this work as applied to organic molecular solid forms was the investigation of relationships between local molecular order and long-term chemical/physical stability, in particular how changes in production conditions affect local order and long-term stability. These studies are continuing and will be the subject of a future publication.

I would like to thank Ting Xu, Harsh Shah and Rusha Sardhara from Long Island University, Arnold and Marie Schwartz College of Pharmacy, and Jeffrey Stewart from Triclinic Labs for X-ray diffraction data and constructive discussions during the preparation of this manuscript.

5.7. Nanometre-scale structure from powder diffraction: total scattering and atomic pair distribution function analysis

S. J. L. Billinge

5.7.1. Introduction

In this chapter we develop the theory and describe the methodology for studying nanometre-scale structure in materials from 'powder diffraction' data. These methods are often referred to as 'total scattering' or atomic pair distribution function (PDF) analysis. In contrast to the case of crystals, it is not valid to use as a starting point the presumption of periodicity, leading as it does to the Bragg (Bragg, 1912) and Laue (Friedrich *et al.*, 1913) equations. Rather, as laid out in the introductory Chapter 1.1 of this volume, nanostructure results in diffraction intensities that are broad and diffuse rather than the sharp delta-function Bragg peaks of a well ordered crystal, and form part of what was traditionally thought of as the 'background' signal. The theoretical basis for calculating the scattering in this case is the Debye equation (Debye, 1915), which is derived herein. The formalism of correlation functions is also introduced; this comes from the atomic density of the material in real space. The Debye equation is related to the real-space pair correlation function through a Fourier transform, as shown first by Zernike & Prins (1927). Representing the data in real space can be highly intuitive, as well as being an appropriate representation for very diffuse signals which may be more sharply peaked in real space than in reciprocal space. The information content in the data is the same in reciprocal and real space, but how it is studied and what is learned from it can vary. Both approaches can be very valuable (Egami & Billinge, 2003, 2012). Enormous progress has been made in experimental techniques for studying nanomaterials from powders such that a revolution is taking place in this regard with high-throughput, time-resolved, spatially resolved and *in situ* studies now possible because of the high data acquisition rates that are made possible with new sources and methods. Advanced computation is also making data analysis quicker and modelling more powerful. This chapter aims to present the background theory in a rigorous but intuitive way. Some aspects of the experimentation are described to help understand issues and the current state of the art, but this is changing rapidly. Different approaches to modelling the data are then described.

5.7.1.1. *Types of nanostructure*

Any material that has structure whose coherence extends only on nanometre length scales can be thought of as nanostructured. The most obvious case is that of a discrete nanoparticle, which in the simplest case is a tiny nano-scale chunk of crystal. But this ignores an abundance of other possibilities. Nanoporous materials have been studied for some time, and are often referred to as mesoporous materials. These are bulk materials that have nano-sized holes in them. These holes may be empty, or may be themselves filled with confined liquids, molecules or nanoparticles. One of the most interesting emerging classes of material is that of bulk crystals that have an additional aperiodic component with nano-scale order (Billinge & Kanatzidis, 2004; Billinge, 2008; Young & Goodwin, 2011). These types of nanostructure are illustrated in Fig. 5.7.1.

Many of these materials have long been studied crystallographically, but have only revealed their nanostructure when studied using the total-scattering methods that are described in this chapter, or looked at in detail with nanometre-resolution spatially resolved probes such as atomic force (AFM), scanning tunnelling (STM) microscopies and electron and X-ray nanoprobes. In some of the most important cases the nanostructure is an important factor in determining the material properties, and only with its study can these material properties be understood.

According to the official US definition of nanotechnology (http://www.nano.gov/), structural dimensions should be between 1 and 100 nm to be considered a nanomaterial. According to this definition, particles with diameters of 100 nm are considered nanoparticles. At this size nanoparticles still scatter with Bragg peaks, albeit broadened because of finite size effects, and a total-scattering analysis is not really warranted. However, in many applications such as catalysis, it is the nanoparticles on the smaller end of the spectrum that have the most interesting properties. Total-scattering methods are the most powerful and widely used for such nanoparticles in the domain below 10 nm. The lower size boundary of 1 nm or 10 Å excludes small molecules and short-range structural correlations in most glasses and amorphous materials. These classes of materials are of great interest, but their study is not generally classified as nanotechnology, excepting the case of nanoparticles of short-range-ordered molecules. Folded proteins can definitely be considered as nanoparticles, with highly complex and interesting properties, but are too soft and of too low symmetry to be studied using total-scattering methods, at least at the time of writing.

Amorphous materials, although not considered as nanomaterials, are studied using total-scattering methods. In fact, the application of total-scattering methods to nanomaterials grew out of years of work on liquids and amorphous materials (Warren, 1934; Warren *et al.*, 1936; Franklin, 1950; Wright, 1998; Barnes *et al.*, 2003). It is probably fair to say that there now exists a synergy such that developments in the nano arena are feeding back again into work on the the structure of liquid and amorphous materials.

5.7.2. Scattering from nanostructures

5.7.2.1. *The Debye equation*

A number of textbooks describe the total-scattering and PDF technique (Warren, 1990; Klug & Alexander, 1974; Nield & Keen, 2001; Egami & Billinge, 2003; Dinnebier & Billinge, 2008; Egami & Billinge, 2012), but, except for the last one, the full derivation of the PDF equations is not reproduced clearly. It is worth following the derivation to gain a more complete understanding of the origin of features in the PDF. (The symbols and abbreviations used in this chapter are listed in Table 5.7.1.)

We start from the scattering amplitude from a set of i atoms at points $\mathbf{r}_i$. In the limit of kinematical scattering

$$\begin{aligned}\psi(\mathbf{Q}) &= \sum_i f_i(Q)\exp(i\mathbf{Q}\cdot\mathbf{r}_i)\\ &= \sum_i \psi_i. \qquad (5.7.1)\end{aligned}$$

This equation was justified in Chapter 1.1. In this equation the sum runs over every atom in the solid, $\mathbf{Q}$ is the scattering vector, $\mathbf{r}_i$ is the vector from the origin to the ith atom and $f_i(Q)$ is the atomic form factor of the ith atom; this equation serves to define ψ_i.

If the scattering from these atoms were totally incoherent, the total scattered intensity would be the sum of the intensities from each atom,

$$\begin{aligned}I_{\rm inc} &= \sum_i \psi_i^*\psi_i\\ &= \sum_i f_i^*(Q)f_i(Q)\\ &= \sum_\alpha N_\alpha f_\alpha^*(Q)f_\alpha(Q) \qquad (5.7.2)\\ &= N\sum_\alpha c_\alpha f_\alpha^*(Q)f_\alpha(Q)\\ &= N\langle f^2\rangle.\end{aligned}$$

In the lower versions of the equation we have changed the sum to be over α, which is now a sum over the different *species* of atoms in the sample with N being the total number of atoms and N_α being the number of atoms of type α; thus the concentration of species α is $c_\alpha = N_\alpha/N$. The asterisk indicates the complex conjugate and the angle brackets indicate a sample average, which is defined in detail in the equation.

Similarly, we can define the sample-averaged scattering power, $\langle f\rangle = \sum_\alpha c_\alpha f_\alpha$, and

$$\begin{aligned}\langle f\rangle^2 &= \frac{1}{N^2}\sum_{ij} f_j^* f_i\\ &= \sum_{\alpha\beta} c_\alpha c_\beta f_\alpha^* f_\beta. \qquad (5.7.3)\end{aligned}$$

Here we have dropped the Q dependence of the atomic scattering factors to simplify the notation, but the f's are understood to retain their Q dependence.

The full coherent scattering intensity, I_c, which contains the structural information, is given by $\psi^*\psi$,

$$\begin{aligned}I_c &= \sum_i\sum_j f_j^* f_i \exp[i\mathbf{Q}\cdot(\mathbf{r}_i-\mathbf{r}_j)]\\ &= \sum_{i,j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}), \qquad (5.7.4)\end{aligned}$$

which serves to define $\mathbf{r}_{ij}$. We can separate out the self-scattering, $i = j$, for which $\mathbf{r}_{ij} = 0$, which gives

Table 5.7.1
List of symbols and abbreviations used in this chapter

Note that there is a wide range of notations used in the literature for the same, or similar, functions, so it is important to check the precise definition of functions used in any given article. In particular, there is little overlap between nomenclature used in the community using PDF/RDF to study glasses and that used by those studying nanomaterials. Please see the article by Keen (2001) for more details on this.

Symbol	Definition
c_α	Concentration of atomic species α, or N_α/N
F_{hkl}	Crystallographic structure factor
$F(Q)$	Reduced total-scattering structure function
$f_i(Q)$	X-ray atomic form factor or scattering length of atom i in a sample; b_i for neutrons
$\mathscr{F}(r)$	Atomic pair distribution function, the inverse Fourier transform of the reduced total-scattering structure function
$G(r)$	Reduced atomic pair distribution function. Obtained from a sample when the SAS data is excluded: observed $G_{\rm obs}$ or calculated $G_{\rm calc}$
$I(Q)$	Scattering intensity diffracted by a sample: coherent I_c, incoherent $I_{\rm inc}$, distinct I_d, and small-angle $I^{\rm SAS}$ scattering intensity
N	Total number of atoms or scatterers in a sample, or of a specific type
N_α	Total number of atoms of element α in a sample
$\mathbf{Q}$	The diffraction vector: magnitude and direction of the momentum transfer in a scattering event
Q	Magnitude of the diffraction vector
$Q_{\rm min}$	Minimum value of Q in a measurement
$Q_{\rm max}$	Maximum value of Q in a measurement
r	Distance
$\mathbf{r}_{ij}$	The vector joining the ith and jth atoms
r_{ij}	The distance between the ith and jth atoms
$r_{\rm max}$	The maximum range the PDF is calculated over
r_{nn}	The distance between nearest neighbours in the material
$R(r)$, RDF	Radial distribution function
R_w	Residuals function used as a measure of 'goodness-of-fit' in PDF modelling
$S(Q)$	Total-scattering structure function, normalized scattering intensity of a sample
$S_{\alpha\beta}(Q)$	Partial structure function between atoms of atomic species α and β
$w(r_i)$	Statistical weighting factor for the ith point in r, *e.g.*, used in calculating R_w
Z	Atomic number for a sample species
$\gamma_0(r)$	Characteristic function of a nanoparticle. The auto-correlation function of the particle shape
$\rho(r)$	The atom-pair density, related to the PDF. Has units of inverse volume
ρ_0	Average number density of the material
$\rho_{\rm bulk}(r)$	The atomic pair density for an infinite solid
σ_{ij}^2	Correlated broadening term for pair of atoms i and j
$\psi(\mathbf{Q})$	Scattering amplitude

Abbreviation	Definition
ADP	Atomic displacement parameter. ADPs quantify the atomic distributions around their mean positions
AFM	Atomic force microscopy
CCD	Charge-coupled device
ePDF	Pair distribution function from electron diffraction data
EPSR	Empirical potential structure refinement
EXAFS	Extended X-ray absorption fine structure
PDF	Pair distribution function
RAPDF	Rapid acquisition pair distribution function
RMC	Reverse Monte Carlo
SAS	Small-angle scattering
STM	Scanning tunnelling microscopy
TEM	Transmission electron microscopy

$$\begin{aligned} I_c &= \sum_i f_i^* f_i + \sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}) \\ &= N\langle f^2\rangle + \sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}), \end{aligned} \qquad (5.7.5)$$

where we have used equation (5.7.2). This allows us to define a *distinct scattering intensity* for $i \neq j$ as

$$\begin{aligned} I_d &= I_c - N\langle f^2\rangle \\ &= \sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}). \end{aligned} \qquad (5.7.6)$$

We want an expression for the total-scattering structure function, $S(\mathbf{Q})$, which in the Faber–Ziman formalism (Faber & Ziman, 1965) is defined as $(I_c/N\langle f\rangle^2) - [\langle (f-\langle f\rangle)^2\rangle/\langle f\rangle^2]$. The second term in this definition is the Laue monotonic diffuse scattering that comes about because of the imperfect cancelation of intensity at the destructive interference condition when atomic sites are occupied by atoms of different scattering strength. It results in a monotonically decreasing background even in the case of perfectly coherent scattering, although of course it is absent in elemental materials.

To get $S(\mathbf{Q})$ from equation (5.7.4) we normalize by the total number of scatterers, N,

$$\frac{I_c}{N} = \langle f^2\rangle + \frac{1}{N}\sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}), \qquad (5.7.7)$$

and subtract the normalized self-scattering term to get

$$\frac{I_c}{N} - \langle f^2\rangle = \frac{1}{N}\sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}). \qquad (5.7.8)$$

Finally, we normalize by $\langle f\rangle^2$ to obtain

$$\frac{I_c}{N\langle f\rangle^2} - \frac{\langle f^2\rangle}{\langle f\rangle^2} = \frac{1}{N\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}). \qquad (5.7.9)$$

Thus,

$$\begin{aligned} S(\mathbf{Q}) - 1 &= \frac{I_c}{N\langle f\rangle^2} - \frac{\langle f^2\rangle}{\langle f\rangle^2} \\ &= \frac{I_d}{N\langle f\rangle^2} \\ &= \frac{1}{N\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}). \end{aligned} \qquad (5.7.10)$$

This expression yields precisely $S(\mathbf{Q}) - 1$ in terms of scattering from atoms in our sample and from measurable intensities.

For an isotropic sample, *e.g.* a powder of crystals or nanoparticles, we assume there to be a crystallite with every orientation with equal probability and we can take an orientational average. To do this we define the z axis as the direction of the $\mathbf{Q}$ vector, in which case, without loss of generality, we can express the dot product of $\mathbf{Q}$ with $\mathbf{r}_{ij}$, the vector separating atom i and atom j, as

$$\mathbf{Q}\cdot\mathbf{r}_{ij} = Qr_{ij}\cos\theta. \qquad (5.7.11)$$

The orientational averaging means that θ takes all values with equal probability. The measured intensity will therefore be proportional to the uniform average of the intensity over all orientations of the interatomic vector. To evaluate this we take the spherical integral of $\exp(i\mathbf{Q}\cdot\mathbf{r}_{ij})$,

$$\begin{aligned} \overline{\exp(i\mathbf{Q}\cdot\mathbf{r}_{ij})} &= \frac{\int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta \exp(iQr_{ij}\cos\theta) r_{ij}^2 \sin\theta}{\int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta\, r_{ij}^2 \sin\theta} \\ &= \frac{-2\pi r_{ij}^2 \left[\exp(iQr_{ij}\cos\theta)\right]_0^{\pi}}{4\pi r_{ij}^2 iQr_{ij}} \\ &= \frac{\left[\exp(iQr_{ij}) - \exp(-iQr_{ij})\right]}{2iQr_{ij}} \\ &= \frac{\sin(Qr_{ij})}{Qr_{ij}}. \end{aligned} \qquad (5.7.12)$$

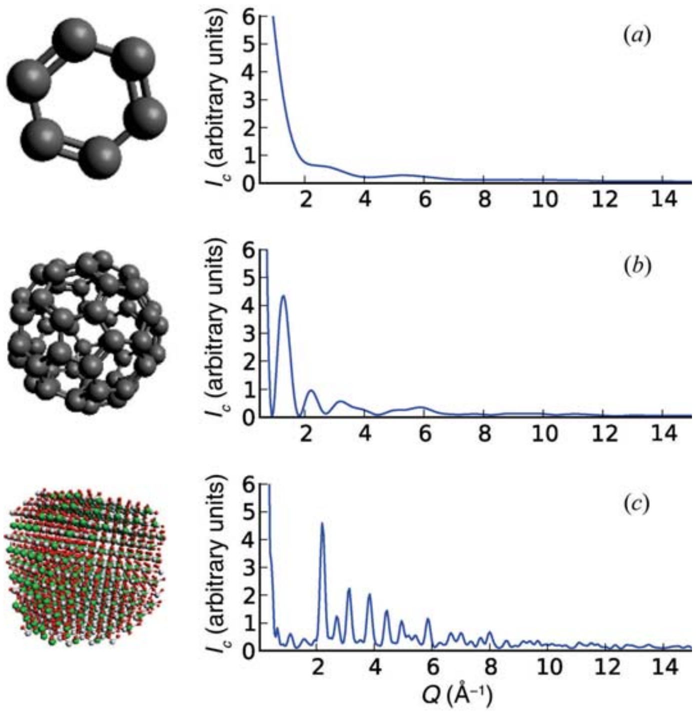

Figure 5.7.2
Scattering intensity calculated using the Debye function [equation (5.7.13)] for a number of discrete particles: (*a*) benzene, (*b*) fullerene C_{60} and (*c*) a $BaTiO_3$ nanoparticle. The intensities in part (*b*) are about ten times those in part (*a*) and the intensities in part (*c*) are about 10 000 times those in part (*a*).

Using this in equation (5.7.4) gives the average coherent scattering intensity, as expressed originally by the Debye (1915) equation,

$$I_c = \sum_{ij} f_j^* f_i \frac{\sin(Qr_{ij})}{Qr_{ij}}. \qquad (5.7.13)$$

Examples of the Debye function curves from some representative small clusters are shown in Fig. 5.7.2.

Bear in mind that the sum is over all atoms in the sample. This is quick to evaluate for molecules and small clusters, but computation is slow when the number of atoms becomes large. As discussed in Chapter 1.1, for the case of a crystal we can define a unit cell. In real space the full structure is the convolution of the unit-cell contents with the periodic lattice and the scattering is the product of the scattering from the unit cell and the lattice. The scattering from the unit-cell contents is just the Debye equation with the sum taken only over the atoms in the unit cell, none other than the crystallographic structure factor, F_{hkl}. The scattering from the lattice is simply a set of delta functions at the positions of the reciprocal-lattice points, so the observed scattering is a set of sharp Bragg peaks at the reciprocal-lattice points whose intensity is given by equation (5.7.4) taken over the contents of the unit cell. For noncrystalline (or far from crystalline) samples, this approximation is no longer a good one and the scattering is a continuous function given quantitatively by taking the sum over all the atoms in the sample, as done in equation (5.7.13).

5.7.2.2. *Correlation functions*

In 1927, Zernike & Prins (1927) first wrote down the scattering in terms of correlation functions of the density. At the atomic scale, the density is given by a set of delta functions at the positions of the atomic nuclei. The Fourier transform of the scattered X-ray intensity does not give the density directly but the autocorrelation function of the density, or the convolution of the density with itself. It still appears as delta functions but there are many more of them, at positions determined by taking the vectors joining every pair of atoms in the sample and moving them so their tails lie at the origin. This density–density autocorrelation function is therefore often referred to as the pair correlation function. In the case of powder diffraction the directions of the vectors are lost and the autocorrelation function becomes a distribution of delta functions on the distance axis at positions given by the separations of each atom. This is like taking all the pair vectors, with their tails at the origin, and rotating them to lie on top of each other, then placing a delta function at their tips. This is shown schematically in Fig. 5.7.3.

This is a histogram of interatomic distances, and this is where the name 'pair distribution function' comes from. Depending on the exact definition of the correlation function used, it may also have the dimensions of inverse volume, in which case it is referred to as the pair density function, although these terms are often applied somewhat loosely and non-rigorously. Some of the confusion that might result from the use in the literature of different correlation functions can be avoided by referring to the paper by Keen (2001), which defines rigorous transformations between some of the more commonly used variants.

We would like to find the precise relationship between the Debye equation and the correlation functions of Zernike & Prins (1927). If we normalize equation (5.7.13) by the number of scatterers and the mean scattering per atom and compare with equation (5.7.10) we get

$$S(Q) - 1 = \frac{1}{N\langle f\rangle^2} \sum_{i\neq j} f_j^* f_i \frac{\sin(Qr_{ij})}{Qr_{ij}}. \qquad (5.7.14)$$

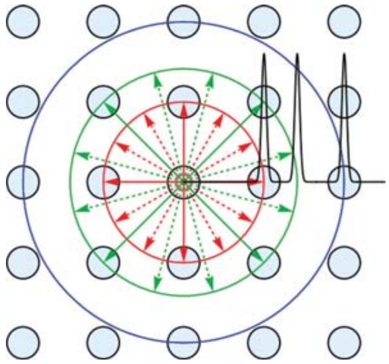

Figure 5.7.3

Schematic showing how the PDF is calculated. The origin is on a randomly selected atom in the sample. Spheres are then drawn (shown as circles in this 2D schematic) with all radii, and the number of atom centres in a differential annulus at that radius are counted and plotted as a histogram. If the structure were well ordered and the atoms stationary, the peaks would be sharp delta functions, but disorder and thermal motion broaden them into Gaussian-like peaks of finite width. In the plot the interatomic vectors are shown as solid arrows. The arrows drawn with dashed lines are the same length as the pair vectors and define the circle. The resulting partial RDF (referenced to the origin atom) is shown as the black line. The total PDF is the sum of the PDFs when each atom is taken in turn as the origin.

The quantity in the kernel of the Fourier transform that connects the scattering with the correlation functions is the reduced total-scattering structure function, $F(Q) = Q[S(Q) - 1]$, which is, using equation (5.7.14),

$$F(Q) = \frac{Q}{N\langle f\rangle^2} \sum_{i\neq j} f_j^* f_i \frac{\sin(Qr_{ij})}{r_{ij}}. \qquad (5.7.15)$$

The Q dependence of the X-ray form factors is problematic in the Fourier transform when there is more than one atomic species, since we do not know, *a priori*, the different Q dependencies of the different contributions to the scattering. It is convenient to remove the Q dependence of f by an approximate method. The form factors are assumed to be isotropic so depend only on Q and not $\mathbf{Q}$, which is a good approximation for scattering from core electrons in particular. We write $f(Q) = f(0)\tilde{f}(Q)$, where $\tilde{f}(Q)$ has the value 1 at $Q = 0$ and contains the Q dependence of the form factor, and $f(0)$ is given by the number of scattering electrons, which is generally taken to be the atomic number, Z, although for scattering from ions it is more appropriate to use the number of electrons on the ion rather than Z. The Morningstar–Warren approximation (Warren *et al.*, 1936) assumes that the Q-dependent part of the form factors can be well approximated by an average Q dependence, $\tilde{f}(Q) = (1/N_{\rm species}) \sum_\alpha c_\alpha \tilde{f}_\alpha(Q)$, where $N_{\rm species}$ is the number of different atomic species in the sample. In this case, the Q dependence, $\tilde{f}(Q)$, comes out of the double sums in equation (5.7.15) on the top and the bottom and cancels out. The f's that remain are Q-independent, and are normally replaced by the atomic number (modified by any anomalous scattering factors). Fig. 5.7.4 shows the form factors for Cd and Se. In the lower panel they are normalized and plotted on top of each other, with the average Q-dependent form factor plotted on top for comparison.

The same result holds for neutron scattering, where the f's are replaced by coherent neutron scattering lengths, b. These have no Q dependence and therefore the approximate method for removing the Q dependence is not needed. Errors introduced due to the Morningstar–Warren approximation will create aberrations in the PDF that mimic the effect of thermal factors (Billinge & Farrow, 2013) and in fits to the data will appear as a temperature-independent contribution to the refined atomic displacement factors.

A more precise determination of the X-ray PDF, at the possible cost of computational complexity, can be obtained by calculating the scattering intensity from a model using the Debye equation and Fourier transforming the result to obtain the PDF without approximation. Another approach, which combines the speed of real-space calculation but with increased accuracy, is to convolute the PDF obtained from the model, rather than deconvolute the data, with the atomic form factors. In this approach the PDF is calculated in real space, then each partial PDF is Fourier transformed individually to reciprocal space. These partial PDFs may then be multiplied by the product of the Q-dependent form factors in the pair, $f_\alpha(Q)f_\beta(Q)$, then properly weighted and recombined to yield the total $S(Q)$. This may then be fitted to the un-deconvoluted measured $S(Q)$ directly in reciprocal space, or, if preferred, these may both be Fourier

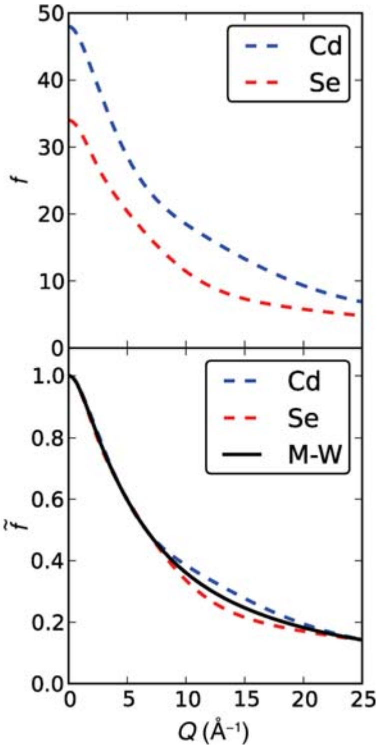

Figure 5.7.4
Atomic form factors and the Morningstar–Warren approximation for CdSe. The full form factors, $f(Q)$, for Cd and Se are shown in the top panel, and the form factors normalized to their value at $Q = 0$, comparing the Q dependence, are displayed in the bottom panel. The bottom panel also displays the Morningstar–Warren approximation for CdSe, labelled as 'M-W'.

transformed back to real space for fitting or visualization. In this case, the PDF will appear visually significantly broadened, since the peak width contains information about the size of the atom as well as the distribution of locations of the atomic centre. However, the information content is the same and the same result should be obtained through modelling, but without the uncertainty of the effects of the Morningstar–Warren approximation. More recently, a expansion to higher order allows a more accurate treatment of the approximation (Masson & Thomas, 2013), although in many cases the Morningstar–Warren approximation is rather good and is not the factor limiting the accuracy of models.

Now we want to consider the (inverse) Fourier transform of $F(Q)$. Because $F(Q)$ is an odd function, we use the sine-Fourier transform,

$$\mathscr{F}(r) = (2/\pi)\int_0^\infty F(Q)\sin(Qr)\,\mathrm{d}Q. \tag{5.7.16}$$

We choose the $2/\pi$ prefactor so that the direct sine transform has a prefactor of 1. Substituting equation (5.7.15) we get

$$\begin{aligned}\mathscr{F}(r) &= \frac{2}{\pi}\int_0^\infty \frac{1}{N\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i \frac{\sin(Qr_{ij})}{r_{ij}}\sin(Qr)\,\mathrm{d}Q\\ &= \frac{2}{\pi N\langle f\rangle^2}\sum_{i\neq j}\frac{f_j^* f_i}{r_{ij}}\int_0^\infty \sin(Qr_{ij})\sin(Qr)\,\mathrm{d}Q\\ &= \frac{1}{N\langle f\rangle^2}\sum_{i\neq j}\frac{f_j^* f_i}{r_{ij}}[\delta(r-r_{ij})-\delta(r+r_{ij})]\\ &= \frac{1}{rN\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i[\delta(r-r_{ij})-\delta(r+r_{ij})],\end{aligned} \tag{5.7.17}$$

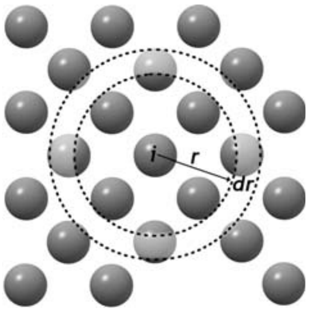

Figure 5.7.5
An illustration of the annulus used to calculate the coordination number. This is a 2D slice of a 3D spherical shell of thickness dr at distance r from an arbitrary origin atom.

which, if we confine ourselves to the positive axis only, is

$$\mathscr{F}(r) = \frac{1}{rN\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i \delta(r-r_{ij}). \tag{5.7.18}$$

We can interpret $\mathscr{F}(r)$ in terms of the radial distribution function (RDF). The RDF, denoted $R(r)$, is defined for an elemental system such that for an arbitrary atom i at the origin $R_i(r)\,\mathrm{d}r$ gives the number of atoms in a shell of thickness dr at a distance r from that atom. This is illustrated in Fig. 5.7.5.

The total RDF is the scattering-length-weighted average of the partial RDFs over each atom taken at the origin. Thus, the integral of the RDF between two bounds, a and b, gives the number of atomic pairs per atom with separation within those bounds, N_{ab}. By inspection we see that equation (5.7.18) yields this behaviour if we multiply $\mathscr{F}(r)$ by r. For a solid with atomic species α we get

$$\begin{aligned}\int_a^b \mathscr{F}(r) r\,\mathrm{d}r &= \int_a^b \frac{1}{N\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i \delta(r-r_{ij})\,\mathrm{d}r\\ &= \frac{1}{N\langle f\rangle^2}\sum_i\sum_{j\in S} f_j^* f_i\\ &= \frac{1}{\langle f\rangle^2}\sum_\alpha c_\alpha f_\alpha \sum_{j\in S} f_j^*,\end{aligned} \tag{5.7.19}$$

where S is the set of atoms with distance from atom i greater than a and less than b. In the case of just one atomic species, this reduces to

$$\begin{aligned}\int_a^b \mathscr{F}(r) r\,\mathrm{d}r &= (f^2/f^2)\sum_{j\in S} 1\\ &= N_{ab},\end{aligned} \tag{5.7.20}$$

as required. Thus,

$$\begin{aligned}\mathscr{F}(r) &= \frac{R(r)}{r}\\ &= 4\pi r\rho(r),\end{aligned} \tag{5.7.21}$$

where $\rho(r)$ is the atom-pair density. The second expression in equation (5.7.21) comes from the relationship between the RDF and the pair density. The pair density is defined such that $\int \mathrm{d}r\,\mathrm{d}\phi\,\mathrm{d}\theta\, r^2\sin(\theta)\rho(r) = \int R(r)\,\mathrm{d}r$, so that $4\pi r^2\rho(r) = R(r)$.[1]

---

[1] Historical note: The re-derivation of the PDF equations reproduced here was presented first in Farrow & Billinge (2009). Prior to that, in many papers the right-hand side of equation (5.7.16) was often incorrectly equated to the function $G(r)$, which is formally defined in equation (5.7.23), *i.e.* it was incorrectly written as $G(r) = (2/\pi)\int_0^\infty F(Q)\sin(Qr)\,\mathrm{d}Q$ (Egami & Billinge, 2003) but we see here that $(2/\pi)\int_0^\infty F(Q)\sin(Qr)\,\mathrm{d}Q = R(r)/r \neq G(r)$.

Rearranging equation (5.7.21) gives

$$\begin{aligned}\rho(r) &= \frac{\mathcal{F}(r)}{4\pi r}\\ &= \frac{1}{4\pi r^2 N\langle f\rangle^2}\sum_{i\neq j} f_j^* f_i \delta(r - r_{ij}).\end{aligned}\tag{5.7.22}$$

In reality, the scattering intensity in a PDF experiment, $I_c(Q)$ [equation (5.7.4)] is not measured to $Q = 0$ but to a minimum Q value because of the direct beam and the experimental setup. This means that in general the forward-scattering contributions are lost. We will consider the impact of this on the measured real-space function $\mathcal{F}(r)$. We rewrite the expression for the experimental $\mathcal{F}(r)$ as

$$\begin{aligned}\mathcal{F}(r; Q_{\min}) &= (2/\pi)\int\limits_{Q_{\min}}^{\infty} F(Q)\sin(Qr)\,\mathrm{d}Q\\ &= 4\pi r\rho(r) - (2/\pi)\int\limits_{0}^{Q_{\min}} F(Q)\sin(Qr)\,\mathrm{d}Q.\end{aligned}\tag{5.7.23}$$

Of course, we have a finite $Q_{\max}$ as well, but this will be disregarded during the following discussion, as the effects are well understood (Toby & Egami, 1992).

5.7.2.3. *Low-angle scattering intensity*

We will now consider a number of explicit examples to understand how the missing forward scattering affects the measured $\mathcal{F}(r; Q_{\min})$. This development makes explicit the connection between the equations of small-angle scattering and those of PDF analysis. We begin by considering the scattering from a large, uniform scatterer and gradually move to more realistic cases in steps.

First consider the RDF of an infinite scatterer of *uniform* density, ρ_0. Because the density is uniform the only scattering is in the forward direction (all the finite-Q scattering cancels) as a delta function at $Q = 0$: there is only small-angle scattering. In this case the scattering is infinite at $Q = 0$ and $F(0)$ is not well defined. We must therefore use a more rigorous description of the scattered intensity in this case. Since the scattering length is defined per atom, the scattering amplitude of a three-dimensional volume element $\mathrm{d}\mathbf{r}$ at position $\mathbf{r}$ is $\psi = \rho_0\langle f\rangle \exp(i\mathbf{Q}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r}$. Then, for an infinite uniform scatterer, the intensity is given by

$$I_c(\mathbf{Q}) = \rho_0^2\langle f\rangle^2 \int\int \exp[i\mathbf{Q}\cdot(\mathbf{r}-\mathbf{r}')]\,\mathrm{d}\mathbf{r}\,\mathrm{d}\mathbf{r}',\tag{5.7.24}$$

where the integrals are over all space. Using this in equation (5.7.10) and integrating over Q first in equation (5.7.16) gives $\mathcal{F}(r) = 4\pi r\rho_0$, as expected. As a side note, using $I_c(Q) = 2\pi^2 N\langle f\rangle^2\rho_0\delta(Q)/Q$ gives the correct result, but we forgo this derivation for the one below, where we consider in detail the general case of an arbitrary scatterer.

To evaluate the scattered intensity for an arbitrary scatterer of uniform density we define a shape function $s(\mathbf{r})$ such that inside the shape $s = 1$ and outside the shape $s = 0$. For such a material,

$$I_c(\mathbf{Q}) = \rho_0^2\langle f\rangle^2 \int\int s(\mathbf{r})s(\mathbf{r}')\exp[i\mathbf{Q}\cdot(\mathbf{r}-\mathbf{r}')]\,\mathrm{d}\mathbf{r}\,\mathrm{d}\mathbf{r}'.\tag{5.7.25}$$

We redefine variables so that $\mathbf{r}'' = \mathbf{r} - \mathbf{r}'$ and $\mathrm{d}\mathbf{r}'' = \mathrm{d}\mathbf{r}$, in which case we have

$$\begin{aligned}I_c(\mathbf{Q}) &= \rho_0^2\langle f\rangle^2 \int\int s(\mathbf{r}')s(\mathbf{r}'+\mathbf{r}'')\exp(i\mathbf{Q}\cdot\mathbf{r}'')\,\mathrm{d}\mathbf{r}'\,\mathrm{d}\mathbf{r}''\\ &= \rho_0^2\langle f\rangle^2 \int \mathrm{d}\mathbf{r}''\exp(i\mathbf{Q}\cdot\mathbf{r}'')\int s(\mathbf{r}')s(\mathbf{r}'+\mathbf{r}'')\,\mathrm{d}\mathbf{r}'.\end{aligned}\tag{5.7.26}$$

The second integral is a self convolution, or autocorrelation, of the shape function. Let us define

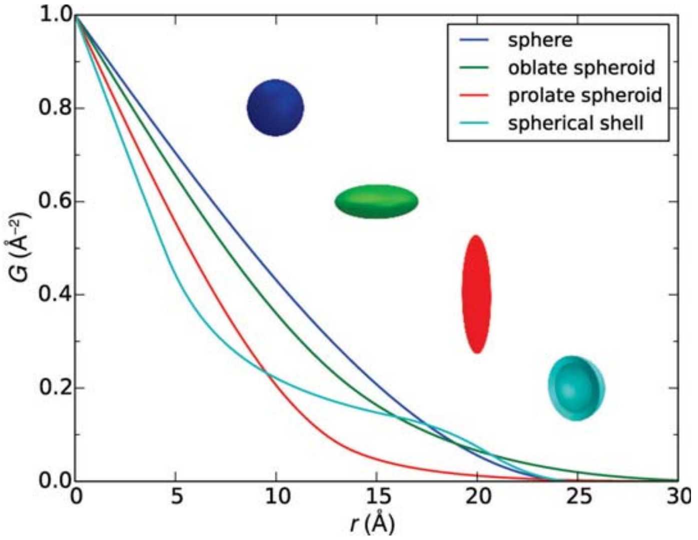

Figure 5.7.6
The nanoparticle form factors for a range of particle shapes.

$$\gamma_0(\mathbf{r}) = (1/V)\int s(\mathbf{r}')s(\mathbf{r}'+\mathbf{r})\,\mathrm{d}\mathbf{r}',\tag{5.7.27}$$

where $V = \int s(\mathbf{r})\,\mathrm{d}\mathbf{r}$ is the volume defined by the shape function. This $\gamma_0(\mathbf{r})$ is the characteristic function of the shape (Guinier *et al.*, 1955), and has been called the nanoparticle form factor in the PDF literature (Qiu *et al.*, 2005; Kodama *et al.*, 2006; Masadeh *et al.*, 2007). Defined as such, $\gamma_0(\mathbf{r})$ has the following properties:

$$\begin{aligned}\gamma_0(0) &= 1\\ \int\gamma_0(\mathbf{r})\,\mathrm{d}\mathbf{r} &= V.\end{aligned}\tag{5.7.28}$$

For reference, the nanoparticle form factor for a number of different particle shapes is shown in Fig. 5.7.6.

This definition and a convenient dropping of the double primes gives

$$I_c(\mathbf{Q}) = \rho_0^2\langle f\rangle^2 V\int\gamma_0(\mathbf{r})\exp(i\mathbf{Q}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r}.\tag{5.7.29}$$

In analogy with the discrete case we want to convert this to equation (5.7.10), $S(\mathbf{Q}) - 1 = (I_c/N\langle f\rangle^2) - (\langle f^2\rangle/\langle f\rangle^2)$, and using the fact that $N = \rho_0 V$ we get

$$\begin{aligned}S(\mathbf{Q}) - 1 &= \frac{1}{N\langle f\rangle^2}\rho_0^2\langle f\rangle^2 V\int\gamma_0(\mathbf{r})\exp(i\mathbf{Q}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r} - \frac{\langle f^2\rangle}{\langle f\rangle^2}\\ &= \rho_0\int\gamma_0(\mathbf{r})\exp(i\mathbf{Q}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r} - \frac{\langle f^2\rangle}{\langle f\rangle^2}.\end{aligned}\tag{5.7.30}$$

The second term, $\langle f^2\rangle/\langle f\rangle^2$, is very small compared to the first term. It is of the order of unity, where the first term scales as $N = \rho_0 V$, and can safely be ignored in most cases.

Now we want to take the orientational average. This must be done with care as, in general, the orientation of the nanoparticle shape and the underlying structure are correlated. For example, the morphology of the particles (plates or needles) depends on easy growth directions of the underlying structure. As discussed by Gilbert (2008), this means that the shape function and the internal structure of the particle are not, in general, separable and it is not correct to get the scattered intensity by convoluting the reciprocal-space intensity with the Fourier transform of the characteristic function. Things are greatly simplified in the case where the underlying structure, or the nanoparticle shape, or both, are isotropic, or approximately so. Then we can denote the angle-averaged characteristic function as

$$\overline{\gamma_0(\mathbf{r})} = \gamma_0(r) = \frac{\int \mathrm{d}\phi \int \mathrm{d}\theta \sin(\theta) r^2 \gamma_0(\mathbf{r})}{\int \mathrm{d}\phi \int \mathrm{d}\theta\, r^2 \sin(\theta)}. \tag{5.7.31}$$

Using this and equation (5.7.12) we get

$$\begin{aligned} S(Q) - 1 &= \rho_0 \int\limits_0^\infty \mathrm{d}r \int\limits_0^{2\pi} \mathrm{d}\phi \int\limits_0^{\pi} \mathrm{d}\theta\, \overline{\gamma_0(\mathbf{r}) \exp(i\mathbf{Q}\cdot\mathbf{r})} r^2 \sin\theta \\ &= \rho_0 \int_0^\infty \mathrm{d}r \int\limits_0^{2\pi} \mathrm{d}\phi \int\limits_0^{\pi} \mathrm{d}\theta\, \overline{\gamma_0(\mathbf{r})}\overline{\exp(i\mathbf{Q}\cdot\mathbf{r})} r^2 \sin\theta \\ &= \rho_0 \int_0^\infty \mathrm{d}r \int\limits_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta\, \gamma_0(r) \frac{\sin(Qr)}{Qr} r^2 \sin\theta \\ &= \rho_0 \int_0^\infty \gamma_0(r) \frac{\sin(Qr)}{Qr} 4\pi r^2\, \mathrm{d}r. \end{aligned} \tag{5.7.32}$$

Since the particles have no preferred orientation in space, we have broken the average of the product in the first line into the product of the averages. This gives

$$F(Q) = \int\limits_0^\infty 4\pi\rho_0 r \gamma_0(r) \sin(Qr)\, \mathrm{d}r. \tag{5.7.33}$$

Noting that this is the direct sine-Fourier transform, we take the inverse transform to get

$$\begin{aligned} \mathscr{F}_u(r) &= (2/\pi) \int\limits_0^\infty F(Q) \sin(Qr)\, \mathrm{d}Q \\ &= 4\pi\rho_0 r \gamma_0(r), \end{aligned} \tag{5.7.34}$$

where the subscript u indicates that this result is for a solid of uniform density distribution, ρ_0.

Next we consider a macroscopic crystal. The difference in $F(Q)$ is at higher Q where, instead of complete cancellation of all the discrete intensity it appears at distinct reciprocal-lattice points as sharp Bragg peaks. Importantly, in the region of Q below the first Bragg peak, the distinct scattering is zero except at very low Q where small-angle-scattering region is reached. The *small-angle-scattering intensity*, $I^{\rm SAS} = I^{\rm SAS}_{\rm crystal}$ from the crystal is identical to that from the solid with uniform density, $I^{\rm SAS}_u$, *i.e.*, $I^{\rm SAS}_u = I^{\rm SAS}_{\rm crystal}$. In general the small- and wide-angle-scattering regions are well separated in Q and $I^{\rm SAS}$ decays to zero before $Q_{\rm min}$ is reached in the measurement. Thus,

$$\begin{aligned} \mathscr{F}^{\rm SAS}(r) &= (2/\pi) \int\limits_0^{Q_{\rm min}} F(Q) \sin(Qr)\, \mathrm{d}Q \\ &= \mathscr{F}_u(r) \end{aligned} \tag{5.7.35}$$

and therefore

$$(2/\pi) \int\limits_0^{Q_{\rm min}} F(Q) \sin(Qr)\, \mathrm{d}Q = 4\pi\rho_0 r \gamma_0(r). \tag{5.7.36}$$

We are now in a position to understand in detail the nature of the measured PDF $\mathscr{F}(r; Q_{\rm min})$. Substituting equation (5.7.36) into equation (5.7.23) we get

$$\mathscr{F}(r; Q_{\rm min}) = 4\pi r \rho(r) - 4\pi r \rho_0 \gamma_0(r). \tag{5.7.37}$$

This is similar to the definition of the PDF from equation (5.7.21), except that $\gamma_0(r)$ appears in an additional smoothly varying sloping baseline term.

Finally, we can express the important radial distribution function, $R(r) = 4\pi r^2 \rho(r)$, explicitly in terms of the experimentally accessible $G(r)$ as

$$\begin{aligned} G(r) &= \mathscr{F}(r; Q_{\rm min}) \\ &= \frac{R(r)}{r} - 4\pi r \rho_0 \gamma_0(r), \end{aligned} \tag{5.7.38}$$

and for completeness,

$$R(r) = r\big[G(r) + 4\pi r \rho_0 \gamma_0(r)\big]. \tag{5.7.39}$$

5.7.2.4. *Calculating $\mathscr{F}(r; Q_{\rm min})$ from models*

We can now consider the calculation of measured PDFs using equation (5.7.37) in a number of interesting limits.

5.7.2.4.1. *Calculating in real space for bulk crystals*

In the case of bulk crystals, the region of interest in the PDF is usually $r \ll D$, D being the smallest dimension across the crystal. In this region $\gamma_0(r) \approx 1$. Thus,

$$\begin{aligned} \mathscr{F}(r; Q_{\rm min}) &= G(r) \\ &= 4\pi r(\rho_{\rm bulk}(r) - \rho_0), \end{aligned} \tag{5.7.40}$$

which is the familiar definition of $G(r)$ in equation (5.7.37). The pair density function, $\rho_{\rm bulk}(r)$, is calculated from a model with periodic boundary conditions (Billinge, 1998; Proffen & Billinge, 1999; Farrow *et al.*, 2007) or from a box of atoms that is much larger in extent than the range of r of interest (McGreevy & Pusztai, 1988; Tucker *et al.*, 2007), using equation (5.7.22). The average number density ρ_0 is given by the number of atoms per unit volume, which in the case of crystals is the number of atoms in the unit cell divided by the unit-cell volume.

Equation (5.7.22) can be modified to account for peak broadening due to atomic vibrations and finite maximum Q. These modifications are discussed elsewhere (Proffen & Billinge, 1999; Egami & Billinge, 2012). The Debye–Waller approximation (Warren, 1990) for atomic motion holds rather well in most cases and the delta function is replaced by a Gaussian whose width is given by widths of the atomic displacement factors (ADPs) of each atom in the pair added in quadrature. If the atomic motion of near neighbours is correlated, the peak will be sharper as a result of motional correlations (Jeong *et al.*, 1999, 2003). If there are a large number of atoms in the model, such as in the big-box modelling approaches we describe below, the finite PDF peak widths are generally obtained by averaging over the atomic configuration in the box (or multiple configurations for better statistics) and no convolution is carried out. To account for termination effects in the Fourier transform of the data, the peak obtained by convoluting a Gaussian or sampling the configuration is convoluted with the Fourier transform of the termination function. If that is a simple cutoff the function convoluted is a sinc function.

5.7.2.4.2. *Calculating in real space for nanoparticles modelled as attenuated bulk crystals*

In this case $\rho_{\rm bulk}(r)$ is determined using a model of a bulk structure as described in Section 5.7.2.4.1. The pair density $\rho(r)$ in equation (5.7.37) is the function for the nanoparticle, which is approximated as $\gamma_0(r)\rho_{\rm bulk}(r)$ (Guinier, 1963). Thus,

$$\mathscr{F}(r; Q_{\rm min}) = 4\pi r \gamma_0(r)[\rho_{\rm bulk}(r) - \rho_0]. \tag{5.7.41}$$

This approach has been implemented in the *PDFgui* modelling program (Farrow *et al.*, 2007), for example, and used successfully on rather well ordered CdSe nanocrystals (Masadeh *et al.*, 2007; Yang *et al.*, 2013). The main shortcoming is that effects that cannot be incorporated in the average structure, such as surface relaxations or core–shell inhomogeneities, cannot be modelled this way.

If there is a distribution of nanoparticle sizes and shapes, the characteristic function $\gamma_0(r)$ can be replaced with an appropriately averaged characteristic function

$$\gamma(r) = \textstyle\int \gamma_0(r; R_1, R_2, \ldots) p(R_1, R_2, \ldots) \, \mathrm{d}R_1 \, \mathrm{d}R_2 \ldots . \qquad (5.7.42)$$

Here, $p(R_1, R_2, \ldots)$ is the normalized distribution of nanoparticle shapes parameterized by $R_1, \ R_2, \ldots$. For example, for spherical nanoparticles of radius R, $p(R_1, R_2, \ldots) = p(R)$, the distribution of nanoparticle radii. Finally, we replace equation (5.7.41) with

$$\mathscr{F}(r; Q_{\min}) = 4\pi r \gamma(r)[\rho_{\text{bulk}}(r) - \rho_0]. \qquad (5.7.43)$$

Great care should be taken to ensure that the result is unique when refining a number of nanoparticle morphology parameters beyond one or two.

5.7.2.4.3. *Calculating as the Fourier transform of the properly normalized Debye function*

This approach has been successfully used by a number of authors (Zhang *et al.*, 2003; Cervellino *et al.*, 2006; Farrow *et al.*, 2010). The $F(Q)$ function is evaluated using equation (5.7.15) and then Fourier transformed to obtain the desired real-space function. To account for thermal and zero-point motion in reciprocal-space calculations, equation (5.7.15) is replaced with a version that includes Debye–Waller effects,

$$F(Q) = \frac{1}{N\langle f\rangle^2} \sum_{i \neq j} f_j^* f_i \big[\exp(-\tfrac{1}{2}\sigma_{ij}^2 Q^2)\big] \frac{\sin(Qr_{ij})}{r_{ij}}. \qquad (5.7.44)$$

Here, σ_{ij}^2 is the correlated broadening factor for the atom pair (Proffen & Billinge, 1999; Thorpe *et al.*, 2002; Jeong *et al.*, 2003).

As we show here, for a quantitative comparison with measured data care must be taken with the Fourier transform so that it is carried out over the same range of Q as the experiment. The main drawback of the reciprocal-space approach is that it can be very slow compared to direct real-space calculation because of the long-range extent of the signal from each pair. It is generally preferred for smaller systems such as molecules or small clusters. However, as a result of recent algorithmic advances, the calculation of the Debye equation for larger systems can be greatly accelerated under certain circumstances (Cervellino *et al.*, 2006), although in these cases a real-space calculation of $G(r)$ is still often preferred.

Using this method, the termination effects coming from the finite Q range are implicity included provided that the Fourier transforms to obtain the model and data PDFs are terminated with the same $Q_{\min}$ and $Q_{\max}$ values. Note that it is important to select the right $Q_{\min}$ because of the effects of the small-angle scattering. This is not included in our definition of $G(r)$, and is not measured, but *is* included in the $G(r)$ obtained by Fourier tranforming the Debye equation unless it is explicitly excluded.

5.7.2.4.4. *Calculating in real space from discrete nanoparticle models*

In this case, equation (5.7.37) is used directly, where $\rho(r)$ is calculated from a finite model of the discrete nanoparticle using equation (5.7.22). The difficulty arises in determining a correct form for the baseline $-4\pi r\rho_0\gamma_0(r)$. Up until now, the shape of the baseline has been approximated using expansions of *ad hoc* mathematical functions (Korsunskiy & Neder, 2005; Neder & Korsunskiy, 2005; Korsunskiy *et al.*, 2007; Neder *et al.*, 2007). This is successful at approximating the behaviour of the baseline. As we showed here, the explicit form of the baseline may be calculated self-consistently from the characteristic function of the model or a measurement of the SAS. This is discussed in greater detail below.

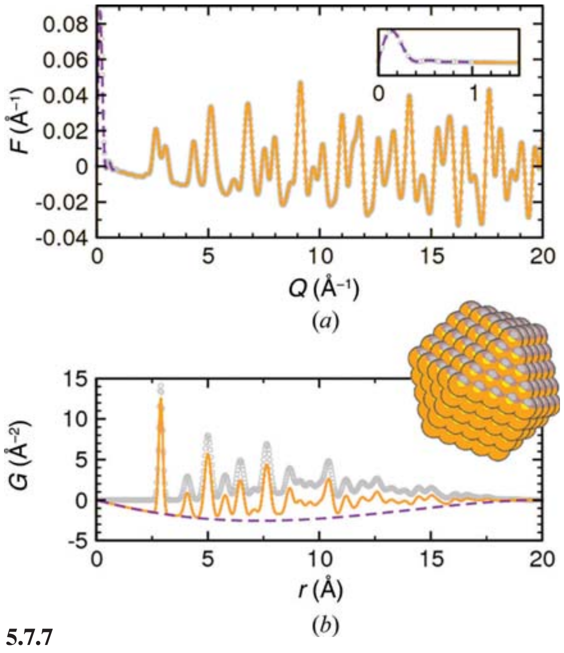

Figure 5.7.7

(*a*) The calculated diffraction pattern from a faceted 2 nm gold nanoparticle. The wide-angle X-ray scattering (WAXS) intensity is shown in gold and the small-angle X-ray scattering (SAXS) intensity is in purple. (*b*) Gold: the PDF of the gold nanoparticle obtained by Fourier transforming only the WAXS intensity shown in gold in (*a*). Purple: the PDF baseline that results from Fourier transforming the SAXS data shown in purple in (*a*). Grey: the RDF that is obtained if both the SAXS and the WAXS scattering are both Fourier transformed. Inset is the gold nanoparticle itself. All data are simulated.

If we have accurate small-angle-scattering data from the samples, from equation (5.7.37) we see that we can compute the PDF baseline from the measured SAS *via* a Fourier transform. This is illustrated in Fig. 5.7.7 for the case of a gold nanoparticle, which is shown in the inset. The simulated scattering signal calculated with the Debye equation is shown in the top panel, where the small-angle scattering is shown in purple and the wide-angle part in gold. In the lower panel, the gold curve is the Fourier transform of the gold data in the top panel (*i.e.*, the wide-angle data only). The dashed purple line that appears as a 'baseline' is the Fourier transform of the purple small-angle-scattering signal. Also plotted in grey is the function $R(r)/r$, which is the Fourier transform of the complete curve including small-angle and wide-angle data.

However, care must be exercised as the derivation assumes that the sample is made up of discrete nanoparticles. In general, clusters and aggregates of nanoparticles will form and small-angle-scattering signals from these structures on different length scales will be present and must be separated. Also, scattering-density fluctuations of any sort in the sample will affect the SAS signal, as discussed elsewhere (Cargill, 1971). None of these effects need be explicitly considered if the SAS signal is not used in the PDF definition, as in equation (5.7.37), although an alternative method is then required to determine the baseline.

The inclusion of SAS data has the potential to add significant value to any refinement of nanoparticle models from the PDF. Both small- and large-angle scattering contain information about the shape and size of nanoparticles, but this information is decoupled from the internal nanoparticle structure in the small-angle scattering. This same information is in the PDF, but it can be obscured by structural features, such as when the PDF prematurely attenuates because of a complex or amorphous surface structure. In this case the nanoparticle size obtained from SAS will be larger than the apparent nanoparticle size obtained from the PDF that reflects the size of the coherent core structure, which is sometimes called the crystallite size. Even without the inclusion of SAS data into PDF refinements, we can learn much from SAS analysis techniques. PDF nanoparticle refinements usually start with a simple model that includes atomic positions restricted by a shape. Therefore, PDF analysis can benefit from the various *ab initio* methods (Svergun & Stuhrmann, 1991; Chacón *et al.*, 1998) for determining the shape of a scatterer from the SAS.

Without the use of the small-angle intensity for determining $\gamma_0(r)$, we can consider approaches to determine it self-consistently from the model since it is the autocorrelation of the particle shape, which is directly available from the model itself by determining a 'shrink-wrapping' of the atomistic model. On the contrary, when the internal structure is well known, but the size and shape distribution of nanoparticles is not, then the characteristic function can be parameterized and refined to obtain the approximate nanoparticle dimensions, as was done by Masadeh *et al.* (2007).

5.7.2.5. *The extent of small-angle scattering*

We have considered the two asymptotic situations here of including or excluding all the SAS. If the SAS is retained in the intensity that is Fourier transformed, the resulting real-space function obtained is $4\pi r\rho(r) = R(r)/r$ [equation (5.7.18)]. Excluding it all results in $G(r)$ [equation (5.7.37)]. We now consider the possibility that some, but not all, of the small-angle scattering is included in the Fourier transform. This might occur in the case of very small nanoparticles, for example, when the SAS extends to wider angles. Here we estimate the circumstances under which a significant amount of small-angle intensity will appear in a wide-angle PDF experiment for the case of a sphere of uniform density. The scattered intensity is given by (Rayleigh, 1914)

$$I(Q) \propto \frac{9}{(QR)^6}[\sin(QR) - QR\cos(QR)]^2, \qquad (5.7.45)$$

where R is the radius of the sphere. By integrating this equation from 0 to $Q_{\min}$ and dividing by the total integrated intensity, we get an expression for the proportion of small-angle intensity above $Q_{\min}$ for a given nanoparticle diameter (Rayleigh, 1914):

$$\begin{aligned} i(x) = 1 - \frac{1}{2\pi r^5}\big[&(2x^4 - x^2 + 3)\cos(2x) \\ &+ x(x^2+6)\sin(2x) + 4x^5\mathrm{Si}(2x) - (5x^2+3)\big]. \end{aligned} \qquad (5.7.46)$$

Here, $x = Q_{\min}R$ and $\mathrm{Si}(x)$ represents the sine integral, $\mathrm{Si}(x) = \int_0^x \sin(x')/x'\,\mathrm{d}x'$. For a very small nanoparticle of radius 5 Å, we see that $i(5) < 0.01$, corresponding to $Q_{\min} \simeq 1$ Å^{-1}, which is typical for a rapid-acquisition PDF (RAPDF) (Chupas *et al.*, 2003) experiment, as very commonly carried out at synchrotron X-ray sources. Thus, for even quite small nanoparticles, practically all small-angle intensity is below $Q_{\min} = 1$ Å^{-1} and equation (5.7.37) is appropriate. However, care should be taken not to extend $Q_{\min}$ too low in Q in a measurement of a nanoparticulate system.

In the few-atom limit, such as the case of discrete small molecules, the small- and wide-angle scattering are not cleanly separated. To produce a complete real-space signal, one can approximate the small-angle scattering from a candidate structure model. This approach is commonly used in the study of small molecules in the gas phase (Hargittai & Hargittai, 1988). The Fourier transform of the estimated scattering approximates to $R(r)/r$, the nominal 'experimental' or 'modified' RDF. An equivalent method for obtaining the modified RDF from wide-angle scattering alone is to add a baseline estimated from a model structure to $\mathcal{F}(r, Q_{\min})$ (Ruan *et al.*, 2007). This approach has been successful for calculating $R(r)/r$ for many-atom nanoparticles.

5.7.2.6. *PDFs from structures with multiple elements*

The equations defined so far in Section 5.7.2 are given as double sums over all the atoms in the sample. It is often useful to separate these sums into partial sums over different atomic species in the material. The reason is that the prefactor for each term in the sum is $f_i^* f_j / \langle f \rangle^2$, which is the same for all pairs involving atoms of the same elements, allowing the prefactor to be pulled out of the partial sum over only those pairs. Thus, if we reconsider equation (5.7.14), for a compound,

$$\begin{aligned} S(Q) &= \frac{1}{\langle f \rangle^2}\left[\frac{1}{N}\sum_{i,j(i\neq j)} f_j^* f_i \frac{\sin(Qr_{ij})}{r_{ij}} + \langle f \rangle^2\right] \\ &= \frac{1}{\langle f \rangle^2}\left[\sum_{\alpha,\beta}\ \sum_{i\in\{\alpha\},j\in\{\beta\}(i\neq j)} \frac{f_\alpha^* f_\beta}{N}\frac{\sin(Qr_{ij})}{r_{ij}} + \langle f \rangle^2\right] \\ &= \frac{1}{\langle f \rangle^2}\left[\sum_{\alpha,\beta}\sum_{a,b}\frac{f_\alpha^* f_\beta}{N}\frac{\sin(Qr_{ij})}{r_{ij}} + \sum_{\alpha,\beta} c_\alpha c_\beta f_\alpha^* f_\beta\right] \\ &= \sum_{\alpha,\beta}\frac{c_\alpha c_\beta f_\alpha^* f_\beta}{\langle f \rangle^2}\left(\sum_{a,b}\frac{1}{N c_\alpha c_\beta}\frac{\sin(Qr_{ij})}{r_{ij}} + 1\right) \\ &= \sum_{\alpha,\beta}\frac{c_\alpha c_\beta f_\alpha^* f_\beta}{\langle f \rangle^2} S_{\alpha\beta}. \end{aligned} \qquad (5.7.47)$$

Here we have taken the double sum over all the atoms in the sample, and split it into partial sums over atom pairs between particular atom types. α denotes the set of atom types in the material, for example, if the material is an alloy of composition A_xB_{1-x}, then $\alpha = \beta = \{A, B\}$, and there are three partial sums over pairs of atom types, $\sum_{A,A}$, $\sum_{A,B}$ and $\sum_{B,B}$. Finally, we introduce the notation $\sum_{a,b}$ for brevity, defined in equation (5.7.47). The expression for $\langle f \rangle^2$ is taken from equation (5.7.3). This serves both to define the 'partial structure function',

$$S_{\alpha\beta} = \sum_{a,b}\frac{1}{N c_\alpha c_\beta}\frac{\sin(Qr_{ij})}{r_{ij}} + 1, \qquad (5.7.48)$$

and to show how the partial structure functions are combined to make the total. This definition is not unique, and is due to Faber & Ziman (1965). It has the nice feature that the partial structure functions have the same high-Q asymptotic behaviour as the total $S(Q)$, *i.e.*, they tend to unity, which means that it is straightforward to define their real-space equivalents, $\mathcal{F}_{\alpha\beta}(r; Q_{\min})$, by analogy with equation (5.7.23),

$$\mathcal{F}_{\alpha\beta}(r; Q_{\min}) = (2/\pi)\int\limits_{Q_{\min}}^{\infty} Q\big[S_{\alpha\beta} - 1\big]\sin(Qr)\,\mathrm{d}Q, \qquad (5.7.49)$$

which, following equation (5.7.23) and the discussion in Section 5.7.2.4, is simply

$$G_{\alpha\beta}(r) = (2/\pi) \int\limits_{Q_{\min}}^{\infty} Q\big[S_{\alpha\beta} - 1\big] \sin(Qr)\,\mathrm{d}Q. \qquad (5.7.50)$$

Here we can refer to $G_{\alpha\beta}(r)$ as the partial reduced pair distribution function. However, as discussed later in Section 5.7.5.1, when calculating pair distribution functions from models we need to know the relationship to the 'partial radial distribution function', $R_{\alpha\beta}(r)$, of the material. The full derivation requires use of equation (5.7.63), which allows partial sums to be taken in the real-space $R(r)$ function just as the case of the $S_{\alpha\beta}$ definition above. The full derivation is reproduced in Section 5.7.5.2, but for completeness we present the result here without derivation:

$$R(r) = \sum_{\alpha\beta} \frac{c_\alpha c_\beta f_\alpha f_\beta}{\langle f\rangle^2} R_{\alpha\beta}(r). \qquad (5.7.51)$$

5.7.2.7. *Differential structure functions*

Experimentally, $S_{\alpha\beta}$ is not accessible directly. However, it is possible to determine it using differential methods (Fuoss *et al.*, 1981; Waseda, 1984; Price & Saboungi, 1998). The approach of measuring close to an edge to get chemical information was first suggested by Shevchik (1977), with the first experimental demonstration making use of the newly available synchrotron radiation a few years later (Fuoss *et al.*, 1981). We rederive the equations here. Consider a situation where the distinct scattering intensity [equation (5.7.6)] is measured in two experiments which differ only in the sense that the scattering factor of one of the atom types changes from experiment 1 to experiment 2, *i.e.* we have $f_A(1) \neq f_A(2)$ and $\Delta f_A = f_A(2) - f_A(1)$. Now,

$$\begin{aligned}
\frac{I_d}{N} &= \langle f\rangle^2[S(Q) - 1] \\
&= \sum_{\alpha,\beta} c_\alpha c_\beta f^*_\alpha f_\beta S_{\alpha\beta} - \langle f\rangle^2 \\
&= c_A f^*_A \sum_\beta c_\beta f_\beta S_{A\beta} + \text{c.c.} + \sum_{(\alpha,\beta)\neq A} c_\alpha c_\beta f^*_\alpha f_\beta S_{\alpha\beta} \\
&\quad - c_A f^*_A \sum_\beta c_\beta f_\beta - \text{c.c.} - \sum_{(\alpha,\beta)\neq A} c_\alpha c_\beta f^*_\alpha f_\beta \\
&= c_A f^*_A \sum_\beta c_\beta f_\beta (S_{A\beta} - 1) + \text{c.c.} \\
&\quad + \sum_{(\alpha,\beta)\neq A} c_\alpha c_\beta f^*_\alpha f_\beta (S_{\alpha\beta} - 1), \qquad (5.7.52)
\end{aligned}$$

where c.c. denotes the complex conjugate. This form for I_d splits it into two sums; one involves A atoms and one does not. When we take the difference between the two measurements (1) and (2) the terms that do not involve A atoms cancel and we get

$$\begin{aligned}
\frac{\Delta I_d}{N} &= \frac{I_d(2) - I_d(1)}{N} \\
&= c_A^2[f^*_A(2) f_A(2) - f^*_A(1) f_A(1)](S_{AA} - 1) \\
&\quad + \left[c_A\big[f^*_A(2) - f^*_A(1)\big] \sum_{\beta\neq A} c_\beta f_\beta (S_{A\beta} - 1) + \text{c.c.}\right] \\
&= c_A^2 \Delta|f_A^2|(S_{AA} - 1) + \left[c_A \Delta f^*_A \sum_{\beta\neq A} c_\beta f_\beta (S_{A\beta} - 1) + \text{c.c.}\right].
\end{aligned} \qquad (5.7.53)$$

For neutrons, $f = b$ is real. For X-rays

$$f(Q, E) = f_0(Q) + f'(E) + if''(E), \qquad (5.7.54)$$

where $f_0(Q)$ is the non-resonant form factor and f' and f'' are the so-called anomalous scattering factors which have an effect at all wavelengths but which are only significant in the vicinity of an absorption edge. f' and f'' are connected by a Kramers–Kronig transform (Kronig, 1926; Kramers, 1927) and so are not independent. Values for f' and f'' may be calculated, at some computational expense, from relativistic quantum-mechanical calculations of atoms. They may also be measured directly by measuring X-ray absorption to find f'' over a sufficiently wide range of energies from below to above the absorption edge, and computing f' from the Kramers-Kronig transformation. If we assume that the difference between measurement (1) and measurement (2) is the incident X-ray energy, which is changed in the vicinity of an absorption edge for atom type A, we can define

$$\begin{aligned}
\Delta f &= [f_0 + f'(E_2)] - [f_0 + f'(E_1)] + i[f''(E_2) - f''(E_1)] \\
&= \Delta f' + i\Delta f'',
\end{aligned} \qquad (5.7.55)$$

and

$$\begin{aligned}
\Delta|f^2| &= [f_0 + f'(E_2)]^2 + f''^2(E_2) - [f_0 + f'(E_1)]^2 + f''^2(E_1) \\
&= [f'^2(E_2) - f'^2(E_1)] + 2f_0[f'(E_2) - f'(E_1)] \\
&\quad + [f''^2(E_2) - f''^2(E_1)] \\
&= \Delta f'^2 + 2\Delta f' f_0 + \Delta f''^2 \\
&\sim 2\Delta f' f_0,
\end{aligned} \qquad (5.7.56)$$

where for the last line it is assumed that $\Delta f'$ and $\Delta f''$ are small compared to f_0 and we can neglect terms of higher than linear order in the delta values. Below the absorption edge it is also true that $\Delta f'' \ll \Delta f'$ and it is a reasonable approximation to neglect $\Delta f''$. Finally, far from the absorption edges, true for the non-A-type atoms, f' and f'' themselves are small. Equation (5.7.53) can then be rewritten as

$$\begin{aligned}
\frac{\Delta I_d}{N} &= 2c_A^2 \Delta f'_A f_0^A (S_{AA} - 1) \\
&\quad + \left[c_A \Delta f'_A \sum_{\beta\neq A} c_\beta f_0^\beta (S_{A\beta} - 1) + \text{c.c.}\right] \\
&= 2c_A \Delta f'_A \sum_\beta c_\beta f_0^\beta (S_{A\beta} - 1)
\end{aligned} \qquad (5.7.57)$$

where now the sum over β includes atom-type A. This is now in a form where we can express it as a type of 'differential $S(Q)$' that is not a 'partial' that encodes correlations between atoms of two specified types, or a 'total' between all atom types, but an intermediate function that is between atom-type A and all the other atom types. We would like to define this 'differential structure function', $\Delta S = S_A$, such that it has the same asymptotic properties as all the Faber–Ziman structure functions already defined. Now, since $\langle f\rangle = \sum_\beta c_\beta f_0^\beta$,

$$\frac{\Delta I_d}{N} = 2c_A \Delta f'_A \left[\sum_\beta c_\beta f_0^\beta S_{A\beta} - \langle f\rangle\right], \qquad (5.7.58)$$

which, in analogy with equation (5.7.10) allows us readily to define S_A as

$$S_A = \frac{\Delta I_d}{N 2 c_A \Delta f'_A \langle f\rangle} + 1 \qquad (5.7.59)$$

and

$$S_A = \sum_\beta \frac{c_\beta f_\beta}{\langle f\rangle} S_{A\beta}. \qquad (5.7.60)$$

Equation (5.7.59) allows us to determine S_A experimentally, and equation (5.7.60) to express it in terms of partials, which can be calculated from models.

The differential structure function S_A is an experimentally accessible structure function that has chemical specificity. Explicitly, it contains the information about the positions of all the atoms surrounding atoms of type A. Since we defined it to have the same properties as all our other Faber–Ziman structure functions, we can use the same Fourier transform to obtain a corresponding real-space differential reduced pair distribution function $G_A(r)$,

$$G_A(r) = (2/\pi) \int\limits_{Q_{\min}}^{\infty} Q\big[S_A - 1\big] \sin(Qr)\,\mathrm{d}Q, \qquad (5.7.61)$$

which is the correlation function that yields the positions of all atoms around every atom of type A and is given by

$$G_A = \sum_{\beta} \frac{c_\beta f_\beta}{\langle f \rangle} G_{A\beta}. \qquad (5.7.62)$$

The desired differential may then be obtained by taking two measurements from the same sample but with two different incident energies, one close to (but just below) the absorption edge, and the other further below the edge (typically around 200 eV lower in energy).

For neutrons, the form factor (more commonly called the coherent scattering length and designated by b rather than f) depends on the isotopic composition of the element and may be varied for the A atoms in a sample by synthesising two samples with different isotopic compositions. The equations (5.7.59) and (5.7.60) are readily extended to the case of neutrons simply by replacing the f's with b's. The approach using isotopic substitution works very well, but synthesizing large quantities (preferred for neutron measurements) of isotopically enriched samples can be very expensive.

Finally, the poor person's way of doing the isotopically enriched experiment is to carry out two experiments on chemically similar compounds, where the assumption is made that the two samples have the same structure. We also note that non-diffraction-based methods can also provide valuable information here, such as extended X-ray absorption fine structure (EXAFS) (Teo, 1986; Lytle *et al.*, 1975) measurements.

5.7.3. Collecting data for total-scattering and PDF measurements

5.7.3.1. *Neutrons*

Neutrons for scientific studies are produced either at research reactors or at pulsed spallation neutron sources. The latter are generally the most useful for PDF analysis because of the presence of many short-wavelength epithermal neutrons in the spectrum and the vast majority of PDF studies to study disorder on crystalline materials are carried out at spallation sources. However, reactor neutrons also yield high-quality PDFs, especially from diffractometers that look at a hot moderator, such as D4 at the Institut Laue Langevin (ILL) in Grenoble, France.

Neutron powder diffractometers for PDF work are similar to those used for regular powder diffraction, and indeed early PDF work was done on regular powder diffractometers. Some special characteristics of the total-scattering measurement mean that now diffractometers optimized for this measurement are appearing. The time-of-flight diffractometer itself consists of a sample holder surrounded by fixed detectors.

In total-scattering measurements from crystals, a balance must be struck between Q-space resolution and intensity. Samples are generally held in cylindrical containers made of incoherently scattering materials such as vanadium. Other sample geometries are also used, for example, wide flat samples are used on SANDALS and NIMROD at the ISIS neutron source at Rutherford Appleton Laboratory in the UK, since most of the detectors on these instruments are in the forward-scattering direction. The secondary flight path is usually in the vicinity of 1–2 m. Low-angle detectors can be located further from the sample to help compensate for the inferior resolution in the forward-scattering direction. The vicinity of the sample is usually evacuated to reduce air scattering and to facilitate the use of sample environments such as cryostats and furnaces. Data consist of the histogram of neutrons that arrived at various time intervals after the generation of the incident pulse. The time-of-flight t over the path L translates into the neutron velocity, $v = L/t$, which gives the momentum $\hbar k = mv$. Thus t is inversely related to Q. To increase detected flux, as much solid angle as possible is filled with detectors. The modern trend is to use pixelated detectors to produce a three-dimensional data set: two dimensions for Q and the third dimension for t. At the time of writing some of the best instruments for PDF measurements are NPDF (Proffen *et al.*, 2002) at the Lujan Center at Los Alamos, NOMAD (Neuefeind *et al.*, 2012) at the spallation neutron source (SNS) at Oak Ridge National Laboratory, GEM (Williams *et al.*, 1997; Hannon, 2005), NIMROD (Bowron *et al.*, 2010) and the upgraded POLARIS (http://www.isis.stfc.ac.uk/instruments/polaris/) at the ISIS neutron source at the Rutherford Appleton Laboratory in the UK, and the NOVA, iMATERIA (Ishigaki *et al.*, 2009) and SPICA instruments at J-PARC/MLF in Japan (http://j-parc.jp/researcher/MatLife/en/instrumentation/ns.html). NIMROD has many detectors in the forward-scattering direction and is particularly suitable for studying complex liquids such as organics. It is especially designed for handling hydrogenated materials, although it has a low resolution. It also yields data over a wide range of Q, including the low-angle region, which may make it ideally suited to studying nanoparticles as discussed above in the theory section. Finally, as well as combining SAS and PDF into a single instrument, very good PDFs have been obtained from an inelastic neutron scattering spectrometer, ARCS (Bozin *et al.*, 2009) at SNS, meaning that PDF and inelastic neutron scattering from powders may be readily studied using a single instrument.
